6. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations.

EAU	European Association of Urology
EMDA	transdermal electromotive drug administration or electromotive drug administration
SWL	shock wave lithotripsy
GR	grade of recommendation
IIEF	international index of erectile function
LE	level of evidence
MeSH	Medical Subject Headings
PDE5i	Phosphodiesterase type 5 inhibitors

Conflict of interest

All members of the Penile Curvature guidelines writing panel have provided disclosure statements of all relationships they have that may be perceived as a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on Male Infertility

TABLE OF CONTENTS PAGE

1. METHODOLOGY

1.1 Introduction

The European Association of Urology (EAU) Guideline Panel on Male Infertility has prepared these guidelines to assist urologists and healthcare professionals from related specialities in the treatment of male infertility.

Urologists are usually the specialists who are initially responsible for assessing the male partner when male infertility is suspected. However, infertility can be a multifactorial condition requiring multidisciplinary involvement. The Male Infertility Guidelines Panel consists of urologists and endocrinologists with special training in andrology and experience in the diagnosis and treatment of male infertility.

1.2 Data identification

The recommendations provided in the current guidelines are based on a systemic literature search performed by the panel members. MedLine, Embase, and Cochrane databases were searched to identify original and review articles. The controlled vocabulary of the Medical Subject Headings (MeSH) database was used alongside a 'free-text' protocol, combining 'male infertility' with the terms 'diagnosis', 'epidemiology', 'investigations', 'treatment', 'spermatogenic failure', 'genetic abnormalities', 'obstruction', 'hypogonadism', 'varicocele', 'cryptorchidism', 'testicular cancer', 'male accessory gland infection', 'idiopathic', 'contraception', 'ejaculatory dysfunction' and 'cryopreservation' .

All articles published between January 2010 (previous update) and November 2011 were considered for review. The expert panel reviewed these records and selected articles with the highest evidence.

1.3 Level of evidence and grade of recommendation

References in the text have been assessed according to their level of scientific evidence (Table 1), and guideline recommendations have been graded (Table 2) according to the Oxford Centre for Evidence-based Medicine Levels of Evidence (1). Grading aims to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence (LE)*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

**Modified from Sackett et al. (1).*

When recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of RCTs may not translate into a grade A recommendation when there are methodological limitations or disparity in published results.

Absence of high-level evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. There may be exceptions where corroborating studies cannot be performed, perhaps for ethical or other reasons, and unequivocal recommendations are considered helpful. Whenever this occurs, it is indicated in the text as "upgraded based on panel consensus". The quality of the underlying scientific evidence must be balanced against benefits and burdens, values and preferences and cost when a grade is assigned (2-4).

The EAU Guidelines Office does not perform cost assessments, nor can it address local/national preferences systematically. The expert panels include this information whenever it is available.

Table 2: Grade of recommendation (GR)*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett et al. (1).*

1.4 Publication history

The EAU Male infertility Guidelines were first published in 2001, followed by full text updates in 2004, 2007 and 2010. For this 2012 publication all sections have been revised and limited changes were implemented. Starting in 2012, the expert panel instigate start a new updating cycle. A quick reference guide presenting the main findings of the Male Infertility Guidelines is also available as well as a number of scientific publications in the EAU journal European Urology. All texts can be viewed and downloaded for personal use at the society website: http://www.uroweb.org/guidelines/online-guidelines/.

This document was peer-reviewed prior to publication.

1.5 Definition

'Infertility is the inability of a sexually active, non-contracepting couple to achieve spontaneous pregnancy in one year' World Health Organization (WHO) (5).

1.6 Epidemiology and aetiology

About 15% of couples do not achieve pregnancy within 1 year and seek medical treatment for infertility. Eventually, 5% remain unwillingly childless. Infertility affects both men and women. In 50% of involuntarily childless couples, a male infertility associated factor is found together with abnormal semen parameters. A fertile partner may compensate for the fertility problem of the man and thus infertility usually becomes manifest if both partners have reduced fertility (5). Male fertility can be reduced as a result of (5):

- congenital or acquired urogenital abnormalities;
- urogenital tract infections;
- increased scrotal temperature (e.g. as a consequence of varicocele);
- endocrine disturbances;
- genetic abnormalities;
- immunological factors.

In 30-40% of cases, no male infertility associated factor is found (idiopathic male infertility). These men present with no previous history of fertility problems and have normal findings on physical examination and endocrine laboratory testing. However, semen analysis reveals a decreased number of spermatozoa (oligozoospermia), decreased sperm motility (asthenozoospermia), and many abnormal forms of sperm (teratozoospermia). These sperm abnormalities usually occur together and are called oligo-astheno-teratozoospermia (OAT) syndrome. Table 3 summarises the main male infertility-associated factors. Idiopathic male infertility may be explained by several factors, including endocrine disruption as a result of environmental pollution, reactive oxygen species, or genetic abnormalities.

Table 3: Male infertility associated factors and percentage of distribution in10,469 patients

Male infertility associated factor	Distribution %
Idiopathic male infertility	31
Maldescended testes	7.8
Urogenital infection	8.0
Disturbances of semen deposition and sexual factors	5.9
General and systemic disease	3.1
Varicocele	15.6
(Endocrine) Hypogonadism	8.9
Immunological factors	4.5
Obstructions	1.7
Other abnormalities	5.5

1.7 Prognostic factors

Prognostic factors for male infertility are:

- duration of infertility;
- primary or secondary infertility;
- results of semen analysis;
- age and fertility status of female partner.

The cumulative pregnancy rate in infertile couples with 2 years of follow-up and oligozoospermia as the primary cause of infertility is 27% (7). Female age is the most important single variable influencing outcome in assisted reproduction (8). Compared to a woman aged 25 years, the fertility potential of a woman aged 35 years is reduced to 50%, to 25% at 38 years, and less than 5% at over 40 years. In many Western countries, women postpone their first pregnancy until after their education and starting a career.

1.8 Recommendations on epidemiology and aetiology

Recommendations	GR
To categorise infertility, both partners should be investigated simultaneously.	C
In the diagnosis and management of male subfertility, the fertility status of the female partner must also be considered, as this might determine the final outcome (8).	B
The urologist/andrologist should examine any male with fertility problems for urogenital abnormalities. This applies to all males diagnosed with reduced sperm quality. A diagnosis is mandatory to start appropriate therapy (drugs, surgery, assisted reproduction) (5).	C

2. INVESTIGATIONS

2.1 Semen analysis

A medical history and physical examination are standard assessments in all men, including semen analysis. A comprehensive andrological examination is indicated if semen analysis shows abnormalities compared with reference values (Table 4). As important treatment decisions are based on the results of semen analysis, it is essential that the complete laboratory work-up is standardised. Ejaculate analysis has been standardised by the WHO and disseminated by publication of the *WHO Laboratory Manual for the Examination and Processing of Human Semen* (5th edn.) (1). It is the consensus that modern spermatology must follow these guidelines.

Table 4: Lower reference limits (5th centiles and their 95% confidence intervals) for semen characteristics

Parameter	Lower reference limit (range)
Semen volume (mL)	1.5 (1.4-1.7)
Total sperm number (10^6 per ejaculate)	39 (33-46)
Sperm concentration (10^6 per mL)	15 (12-16)
Total motility (PR + NP)	40 (38-42)
Progressive motility (PR, %)	32 (31-34)
Vitality (live spermatozoa, %)	58 (55-63)
Sperm morphology (normal forms, %)	4 (3.0-4.0)
Other consensus threshold values	
pH	> 7.2
Peroxidase-positive leukocytes (10^6 per mL)	< 1.0
MAR test (motile spermatozoa with bound particles, %)	< 50
Immunobead test (motile spermatozoa with bound beads, %)	< 50
Seminal zinc (µmol/ejaculate)	≥ 2.4
Seminal fructose (µmol/ejaculate)	≥ 13
Seminal neutral glucosidase (mU/ejaculate)	≥ 20

PR = progressive; NP = non-progressive; MAR = Mixed antiglobulin reaction.

*2.1.1 **Frequency of semen analysis***

If the results of semen analysis are normal according to WHO criteria, one test should be sufficient. If the results are abnormal in at least two tests, further andrological investigation is indicated. It is important to differentiate between the following:

- oligozoospermia: < 15 million spermatozoa/mL
- asthenozoospermia: < 32% motile spermatozoa
- teratozoospermia: < 4% normal forms.

Quite often, all three anomalies occur simultaneously which is defined as OligoAsthenoTeratozoospermia (OAT). As in azoospermia, in extreme cases of oligozoospermia (< 1 million spermatozoa/mL), there is an increased incidence of obstruction of the male genital tract and genetic abnormalities.

2.2 Recommendations for investigations in male infertility

Recommendations	GR
According to WHO criteria, andrological investigations are indicated if semen analysis is abnormal in at least two tests.	C
Assessment of andrological status must consider the suggestions made by WHO for the standardised investigation, diagnosis, and management of the infertile couple; this will result in implementation of evidence-based medicine in this interdisciplinary field of reproductive medicine (2).	C
Semen analysis must follow the guidelines of the *WHO Laboratory Manual for the Examination and Processing* (5th edn) (1).	B

1. World Health Organization. WHO Laboratory Manual for the Examination and Processing of Human Semen. 5th edn. WHO, 2010. http://www.who.int/reproductivehealth/publications/infertility/9789241547789/en/index.html
2. World Health Organization. WHO Manual for the Standardised Investigation and Diagnosis of the Infertile Couple. Cambridge: Cambridge University Press, 2000.

3. TESTICULAR DEFICIENCY (SPERMATOGENIC FAILURE)

3.1 Definition

Testicular deficiency as a consequence of spermatogenic failure is caused by conditions other than hypothalamic-pituitary disease and obstructions of the male genital tract. It is the commonest form of reduced male fertility. Testicular deficiency may have different aetiologies and present clinically as severe OAT or non-obstructive azoospermia (NOA) (1).

3.2 Aetiology

The causes of testicular deficiency are summarised in Table 5.

Table 5: Causes of testicular deficiency

Factors	Causes
Congenital	Anorchia
	Testicular dysgenesis/cryptorchidism
	Genetic abnormalities (karyotype, Y chromosome deletions)
	Germ cell aplasia, resulting in Sertoli cell only syndrome
	Spermatogenic arrest (maturation arrest)
Acquired	Trauma
	Testicular torsion
	Post-inflammatory forms, particularly mumps orchitis
	Exogenous factors (medications, cytotoxic drugs, irradiation, heat)
	Systemic diseases (liver cirrhosis, renal failure)
	Testicular tumour
	Varicocele
	Surgery that may compromise vascularisation of the testes and subsequently testicular atrophy
Idiopathic	Unknown aetiology
	Unknown pathogenesis

3.3 Medical history and physical examination

Typical findings from the history and physical examination of a patient with testicular deficiency are:

- cryptorchidism;
- testicular torsion;
- genitourinary infection;
- testicular trauma;
- exposure to environmental toxin(s);
- gonadotoxic medication;
- exposure to radiation or chemical(s);
- testicular cancer;
- absence of testes;
- abnormal secondary sexual characteristics;
- gynaecomastia;
- abnormal testicular volume and/or consistency;
- varicocele.

3.4 Investigations

Routine investigations include semen analysis and hormonal determinations. Other investigations may be required depending on the individual situation.

3.4.1 ***Semen analysis***

In NOA, semen analysis shows normal ejaculate volume and azoospermia after centrifugation. A recommended method is semen centrifugation at 3000 g for 15 minutes and a thorough microscopic examination by phase contrast optics at x200 magnification of the pellet. All samples can be stained and re-examined microscopically (2).

3.4.2 ***Hormonal determinations***

In men with testicular deficiency hypergonadotrophic hypogonadism is usually present, with high levels of follicle stimulating hormone [FSH] and luteinising hormone [LH], and sometimes low levels of testosterone. Generally, the levels of FSH correlate with the number of spermatogonia:

- When spermatogonia are absent or markedly diminished, FSH values are usually elevated.
- When the number of spermatogonia is normal, but spermatocyte or spermatid blockage is complete. FSH values are within normal range.

However, for an individual patient, FSH levels do not accurately predict the spermatogenesis status (3-5). Preliminary data indicate a stronger correlation between low inhibin B level and spermatogenic damage (6).

3.4.3 ***Testicular biopsy***

Testicular biopsy can be part of an intracytoplasmic sperm injection (ICSI) treatment in patients with clinical evidence of NOA. Testicular sperm extraction (TESE) is the technique of choice and shows excellent repeatability (7-9). Spermatogenesis may be focal, which means that in about 50-60% of men with NOA, spermatozoa can be found and used for ICSI. Most authors therefore recommend taking several testicular samples (10,11). There is a good correlation between the histology found upon diagnostic biopsy and the likelihood of finding mature sperm cells during testicular sperm retrieval and ICSI (12,13). However, no clear relationship has been found between FSH, inhibin B or testicular volume and successful sperm harvesting. When there are complete AZFa and AZFb microdeletions, the likelihood of sperm retrieval is virtually zero.

Microsurgical testicular sperm extraction may increase retrieval rates, even though comparative studies are not yet available (14-16). After opening the testis, tubules exhibiting larger diameter are excised using micro-scissors or forceps. Then, tubules are minced using mechanical or enzymatic digestion to facilitate sperm search (17). Positive retrievals are reported even in conditions, such as Sertoli cell only syndrome type II (14). Percutaneous Epididymal Sperm Aspiration (PESA) results in lower retrieval rates and does not allow histological examination to detect for instance carcinoma in situ (CIS) and testicular malignancies (18,19). PESA may also result in more tubular and vascular damage than TESE (20).

The results of ICSI are worse when using sperm retrieved from men with NOA compared to sperm from ejaculated semen and from men with obstructive azoospermia (OA) (21-24):

- Birth rates are lower in NOA versus OA (19% vs 28%) (25).
- Fertilisation and implantation rates are significantly lower (26).
- Miscarriage rates are higher in NOA versus OA (11.5% vs 2.5%) (27).

In OA, there were no significant differences in ICSI results between testicular and epididymal sperm (24). Also,

no significant differences have been reported in ICSI results between the use of fresh and frozen-thawed sperm (22,26-28).

3.5 Conclusions and recommendations for testicular deficiency

Conclusions
Impaired spermatogenesis is often associated with elevated FSH concentration.
Testicular biopsy is the best procedure to define the histological diagnosis and the possibility of finding sperm. Spermatozoa should be cryopreserved for use in ICSI.
Spermatozoa are found in about 60% of patients with non-obstructive azoospermia (NOA).
Men who are candidates for sperm retrieval must receive appropriate genetic advice.
For patients with NOA, who have spermatozoa in their testicular biopsy, ICSI with fresh or cryopreserved spermatozoa is the only therapeutic option.
Pregnancies and live births are achieved in 30-50% of couples with NOA, when spermatozoa has been found in the testicular biopsy.

Recommendations	GR
Men with non-obstructive azoospermia (NOA) can be offered a testicular sperm extraction with cryopreservation of the spermatozoa to be used for intracytoplasmic sperm injection (28).	B
To increase the chances of positive sperm retrievals in men with NOA, testicular sperm extraction (single, multiple or microsurgical) should be used rather than PESA.	B

4. GENETIC DISORDERS IN INFERTILITY

4.1 Introduction

All urologists working in andrology must have an understanding of genetic abnormalities in infertility, so that they can provide correct advice to couples seeking fertility treatment. Men with very low sperm counts can be given a reasonable chance of paternity, using in vitro fertilisation (IVF), ICSI and sperm harvesting from the epididymis or the testis in case of azoospermia. However, the sperm of infertile men show an increase in aneuploidy, other genetic abnormalities and DNA damage and carry the risk of passing genetic abnormalities to the next generation. Although there are prospects for screening of sperm (1,2), current routine clinical practice is based on screening peripheral blood samples.

4.2 Chromosomal abnormalities

Chromosome abnormalities can be numerical (e.g. trisomy) or structural (e.g. inversions or translocations) (3,4). In a survey of pooled data from 11 publications, including 9,766 infertile men, the incidence of chromosomal abnormalities was 5.8% (3). Of these, sex chromosome abnormalities accounted for 4.2% and autosomal abnormalities for 1.5%. For comparison, the incidence of abnormalities was 0.38% in pooled data from three series, with a total of 94,465 newborn male infants, of which 131 (0.14%) were sex chromosome abnormalities and 232 (0.25%) autosomal abnormalities (4). The frequency of chromosomal abnormalities increases as the testicular deficiency becomes more severe. Patients with < 5 million spermatozoa/mL already show a 10-fold higher incidence (4%) of mainly autosomal structural abnormalities compared with the general population (5). At highest risk are secretory azoospermic men.

Based on the frequencies of chromosomal aberrations in patients with different sperm concentration, karyotype analysis is indicated in azoospermic men and in oligozoospermic men with < 5 million spermatozoa/mL (5). If there is a family history of recurrent abortions, malformations or mental retardation, karyotype analysis should be requested, regardless of the sperm concentration.

*4.2.1 **Sperm chromosomal abnormalities***

Sperm can be examined for chromosomal normality using multicolour fluorescent *in situ* hybridisation (FISH). Aneuploidy in sperm, particularly sex chromosome aneuploidy, is associated with severe damage to spermatogenesis (3,6-10) and is also seen in men with translocations (11).

FISH analysis of spermatozoa is a research investigation. It should be used to assess spermatozoa from men with defined andrological conditions (6). Techniques are needed to separate populations of genetically abnormal sperm from normal sperm or to safely screen individual spermatozoa before IVF and ICSI.

*4.2.2 **Sex chromosome abnormalities (Klinefelter's syndrome and variants [47,XXY; 46,XY/47, XXY mosaicism])***

Klinefelter's syndrome is the most common sex chromosome abnormality (3,12). Adult men with Klinefelter's syndrome have small firm testicles devoid of germ cells. The phenotype varies from a normally virilised man to a man with the stigmata of androgen deficiency, including female hair distribution, scant body hair, and long arms and legs due to late epiphyseal closure. Leydig cell function is commonly impaired in men with Klinefelter's syndrome (13). Testosterone levels may be normal or low, oestradiol levels normal or elevated, and FSH levels increased. Libido is often normal despite low testosterone levels, but androgen replacement may be needed as the patient ages.

Germ cell presence and sperm production are variable in men with Klinefelter's mosaicism, 46,XY/47,XXY. There is one case report of declining spermatogenesis in a man with Klinefelter's syndrome, with the recommendation that early sperm retrieval sperm should be considered (14). Based on sperm FISH studies showing an increased frequency of sex chromosomal abnormalities and increased incidence of autosomal aneuploidies (disomy for chromosomes 13, 18 and 21), concerns have been raised about the chromosomal normality of the embryos generated through ICSI (15).

The production of 24,XY sperm has been reported in 0.9% and 7.0% of men with Klinefelter's mosaicism (16-18) and in 1.36-25% of men with somatic karyotype 47,XXY (19-22). In azoospermic patients, TESE or (MicroTESE) can be proposed as a therapeutic option since spermatozoa can be recovered in about 30% of cases. To date, 49 healthy children have been born using ICSI without preimplantation genetic diagnosis (PDG) and the conception of one 47,XXY fetus has been reported (12). However, a study of ICSI combined with PDG in 113 embryos reported a significant fall in the rate of normal embryos for couples with Klinefelter's syndrome in respect to controls (54% vs 77.2%) (15). Due to the significant increase of sex chromosomal and autosomal abnormalities in the embryos of Klinefelter's patients, pre-implantation diagnosis or amniocentesis and karyotype analysis should be strongly advised.

Follow-up (possibly every year) of men with Klinefelter's syndrome is required and androgen replacement therapy should be started when testosterone level is in the range of hypoandrogenism. All men

with Klinefelter's syndrome who undergo testicular biopsy procedures for sperm retrieval need long-term endocrine follow-up.

*4.2.3 **Autosomal abnormalities***

Genetic counselling should be offered to all couples seeking fertility treatment (including IVF/ICSI) when the male partner is known or found to have an autosomal karyotype abnormality.

The most common autosomal karyotype abnormalities are Robertsonian translocations, reciprocal translocations, paracentric inversions and marker chromosomes. It is important to look for these structural chromosomal anomalies because there is an increased associated risk of aneuploidy or unbalanced chromosomal complements in the fetus. As with Klinefelter's syndrome, sperm FISH analysis provides a more accurate risk estimation of affected offspring.

When IVF/ICSI is carried out for men with translocations, preimplantation genetic diagnosis or amniocentesis and karyotype analysis should be used. Embryos with known unbalanced translocation should probably not be implanted.

4.3 Genetic defects

*4.3.1 **X-linked genetic disorders and male fertility***

Each man has only one X chromosome. An X-linked recessive disorder manifests in males. The defect will be transmitted to daughters, but not to sons.

*4.3.2 **Kallmann syndrome***

The most common X-linked disorder in infertility practice is Kallmann syndrome. The predominant form is an X-linked recessive disorder caused by a mutation in the KALIG-1 gene on Xp22.3 (23). A number of newly identified autosomal gene mutations can also cause Kallmann syndrome (24). Patients with Kallmann syndrome have hypogonadotrophic hypogonadism and anosmia, but may also have other clinical features, including facial asymmetry, cleft palate, colour blindness, deafness, maldescended testes, and renal abnormalities.

Since spermatogenesis can be relatively easily induced by hormonal treatment (25), genetic screening prior to therapy is strongly adviced. Treatment with gonadotrophins allows natural conception in most cases, even in men with a relatively low sperm count. Thus, identification of the involved gene (X-linked, autosomal dominant or recessive) can help to provide more accurate genetic counselling i.e. risk estimation for transmission to the offspring.

*4.3.3 **Mild androgen insensitivity syndrome***

The AR gene is located on the long arm of the X chromosome. Mutations in the AR gene may result in mild to complete androgen insensitivity (26).The phenotypic features of complete androgen insensitivity syndrome (CAIS) are female external genitalia and absence of pubic hair (Morris syndrome). In partial androgen insensitivity syndrome, several different phenotypes are evident, ranging from predominantly female phenotype through ambiguous genitalia, to predominantly male phenotype with micropenis, perineal hypospadias, and cryptorchidism. The later phenotype is also termed Reifenstein syndrome. In the above mentioned severe forms of androgen resistances there is no risk of transmission since affected men cannot generate their own biological children using the current technologies. Patients with mild AIS have male infertility as their primary or even sole symptom. Disorders of the androgen receptor causing infertility in the absence of any genital abnormality are rare, only a few mutations have been reported in infertile men (26-30).

*4.3.4 **Other X-disorders***

An unexpectedly high number of genes with a testis-specific or enriched expression pattern have been identified on the X chromosome and especially pre-meiotic genes are over-represented on the X chromosome compared with autosomal chromosomes (31,32). Nevertheless, up to now only two genes, USP26 and TAF7L, have been screened in relatively small study populations and neither of them appear relevant for male infertility (33,34).

4.4 Y chromosome and male infertility

*4.4.1 **Introduction***

The first association between azoospermia and microscopically detectable deletions of the long arm of the Y chromosome was demonstrated by Tiepolo and Zuffardi in 1976 (35). The first cases of Y microdeletions and male infertility were reported in 1992 (36), and many case series have subsequently been published. Microdeletions have been found in three non-overlapping regions, AZFa+b+c, of the Y chromosome (37). Several years after the discovery of the three AZF regions and with knowledge of the precise structure of the Y chromosome in Yq11, it was realised that the AZFb and AZFc regions overlap and that there was no AZFd region (38). Clinically relevant deletions remove partially, or in most cases completely, one or more of the AZF

regions, and are the most frequent molecular genetic cause of severe oligozoospermia and azoospermia (39). In each AFZ region, there are a number of candidate genes, but their function in spermatogenesis remains largely unknown (40).

Since deletions occur in block (i.e. removing more than one gene), it is not possible to determine the role of a single AZF gene from the AZF deletion phenotype and thus it is unclear if they are all participating in spermatogenesis. Gene-specific deletions, which remove a single gene, have been reported only in the AZFa region. These studies suggested that the USP9Y gene is not essential for spermatogenesis and is most likely to be a 'fine tuner' of sperm production (41).

A new type of Yq deletions, known as 'gr/gr deletion' has been described in the AZFc region (42). This deletion removes half of the AZFc region gene content and affects the dosage of multicopy genes mapping inside this region (e.g. DAZ, CDY1, BPY2).

*4.4.2 **Clinical implications of Y microdeletions***

The clinical significance of Yq deletions have been debated for a long time because of the large variability found in deletion frequencies and reports of Yq deletions in 'fertile' men. More than 10 years of clinical research has found the following about Y deletions:

- They are not found in normospermic men, proving there is clearly a cause-and-effect relationship between Y deletions and spermatogenic failure (43).
- The highest frequency of Y deletions is found in azoospermic men (8-12%), followed by oligozoospermic (3-7%) men.
- Deletions are extremely rare with a sperm concentration > 5 million of spermatozoa/mL (approximately 0.7%).
- AZFc deletions are most common (approximately 65-70%), followed by deletions of the AZFb and AZFb+c or AZFa+b+c regions (25-30%). AZFa region deletions are extremely rare (5%).
- Complete removal of the AZFa region is associated with severe testicular phenotype (Sertoli cell only syndrome), while complete removal of the AZFb region is associated with spermatogenic arrest. Complete removal of the AZFc region causes a variable phenotype ranging from azoospermia to oligozoospermia.
- Classical AZF deletions do not confer a risk for cryptorchidism or testicular cancer (39).

The specificity and genotype/phenotype correlation reported above means that Y deletion analysis has both a diagnostic and prognostic value for testicular sperm retrieval (39). In the case of gr/gr deletion, there is no such strict genotype/phenotype correlation. This type of partial AZFc deletion can also be found in normozoospermic men, although at a significantly lower frequency (0.5-1%) than in men with abnormal spermatogenesis (3-5%). In the largest Caucasian study population (> 1000 men), gr/gr deletion carriers were 7-fold more likely to develop oligozoospermia (44). The phenotypic expression may vary in different ethnic groups, depending on the Y chromosome background (45,46). An overall risk of 2.4-fold for reduced sperm production in gr/gr deletion carriers has recently been reported by a meta-analysis that included only studies free from methodological and selection bias (47). There has also been a report of gr/gr deletion as a potential risk factor for testicular germ cell tumours (48). However, this data needs further confirmation in an ethnically and geographically matched case-control study setting.

After conception, any Y deletions are transmitted automatically to a male offspring, and genetic counselling is therefore mandatory. In most cases, father and son have the same microdeletion (49-52), but occasionally the son has a larger microdeletion (53). It has been proposed that partial AZFc deletions (gr/gr and b2/b3) may predispose to complete AZFc deletion in the next generation (54). There is a substantial variation in the son's phenotype and the extent of spermatogenic failure (still in the range of azoo/oligozoospermia) cannot be predicted entirely, due to the different genetic background and the presence or absence of environmental factors with potential toxicity for reproductive function. A significant proportion of spermatozoa from men with complete AZFc deletion are nullisomic for sex chromosome (55,56), indicating a potential risk for any offspring to develop 45,X0 Turner's syndrome and other phenotypic anomalies associated with sex chromosome mosaicism, including ambiguous genitalia.

The screening for Y chromosome microdeletions in patients bearing a mosaic 46,XY/45,X0 karyotype with sexual ambiguity and/or Turner stigmata has shown a relatively high incidence of AZFc deletions (33%) (57). There is data to support the association of Yq microdeletions with an overall Y chromosomal instability, which leads to the formation of 45,X0 cell lines (58,59). Despite this theoretical risk, babies born from fathers affected by Yq microdeletions are phenotypically normal (39,60). This could be due to the reduced implantation rate and a likely higher risk of spontaneous abortions of embryos bearing a 45,X0 karyotype.

When ICSI is used in the presence of a Y microdeletion, long-term follow up of any male children is needed with respect to their fertility status and cryoconservation of spermatozoa at a young age can be considered. However, there has only been a single report (48) of an enhanced risk for testicular germ cell

tumours in carriers of gr/gr deletion. Thus, it is only necessary to consider introducing preventive measures (e.g. testis ultrasound) in the sons of gr/gr deletion carriers if confirmatory studies are published.

4.4.2.1 Testing for Y microdeletions

Indications for AZF deletions screening are based on sperm count and include azoospermia and severe oligozoospermia (< 5 million spermatozoa/mL). Thanks to the European Academy of Andrology (EAA) guidelines (60) and EAA/EMQN (European Molecular Genetics Quality Network) external quality control programme (http://www.emqn.org/emqn/), Yq testing has become more homogeneous and reliable in different routine genetic laboratories. The EAA guidelines provide a set of primers capable of detecting > 95% of clinically relevant deletions (60). The primers consist of two markers for each region and control markers from the Yp and X chromosome. The initial reports of large variability of deletion frequencies are more likely to have been caused by technical problems and unreliable markers rather than be an expression of true ethnic differences.

4.4.2.2 Y chromosome: 'gr/gr' deletion

A new type of Yq deletions, known as the gr/gr deletion, has been described in the AZFc region (42). This deletion removes half of the gene content of the AZFc region, affecting the dosage of multicopy genes mapping inside this region. There is an almost 8-fold higher risk of developing oligozoospermia (OR = 7.9, 95% CI: 1.8-33.8; $p < 0.001$) in gr/gr deletion carriers in the largest Caucasian study population published to date (43). The frequency of gr/gr deletion in oligozoospermic patients is about 4%. According to four meta-analyses, gr/gr deletion is a significant risk factor for impaired sperm production (61,62).

However, both the frequency of gr/gr deletion and its phenotypic expression vary between different ethnic groups, depending on the Y chromosome background. For example, in some Y haplogroups, the deletion is fixed and appears to have no negative effect on spermatogenesis). The routine screening for gr/gr deletion is a still a debated issue, especially in those laboratories serving diverse ethnic and geographic populations.

4.4.2.3 Conclusions

Testing for microdeletions is not necessary in men with obstructive azoospermia when ICSI is used because spermatogenesis should be normal.
Men with severely damaged spermatogenesis (with < 5 million spermatozoa/mL) should be advised to undergo Yq microdeletion testing for both diagnostic and prognostic purposes. Yq microdeletion also has important implications for genetic counselling (*see below*).
If complete AZFa or AZFb microdeletions are detected, microtesticular sperm extraction is not worth doing because it is extremely unlikely that any sperm will be found.
gr/gr deletion has been confirmed as a significant risk factor for impaired sperm production, whereas further evidence of the prognostic significance of gr/gr and development of TCGTs is needed.
If a man with microdeletion and his partner wish to proceed with ICSI, they should be advised that microdeletions will be passed to sons, but not to daughters.
A son who inherits a microdeletion will have abnormal spermatogenesis because complete AZF deletions are not reported in normozoospermic men.

4.4.3 ***Autosomal defects with severe phenotypic abnormalities and infertility***

Several inherited disorders are associated with severe or considerable generalised abnormalities and infertility (Table 6). Patients with these defects will be well known to doctors, often from childhood. A fertility problem must be managed in the context of the care of the man as a whole and considering the couple's ability to care for a child.

Table 6: Less common inherited disorders associated with infertility and other alterations to phenotype

Disorder	Phenotype	Genetic basis
Prader-Willi syndrome	Obesity, mental retardation	Deletion of 15q12 on paternally inherited chromosome
Bardet-Biedle syndrome	Obesity, mental retardation, retinitis pigmentosa, polydactyly	Autosomal recessive 16q21
Cerebellar ataxia and hyogonadotrophic hypogonadism	Eunuchoidism, disturbances of gait and speech	Autosomal recessive
Noonan's syndrome	Short stature, webbed neck, cardiac and pulmonary abnormalities, cryptorchidism	Autosomal dominant
Myotonic dystrophy	Muscle wasting, cataract, testicular atrophy	Autosomal dominant 19q13.3
Dominant polycystic kidney disease	Renal cysts, obstruction from epididymal cysts	Autosomal dominant 16p13.3 and 4q
5-alpha reductase deficiency	Perineal or scrotal hypospadias, vaginal pouch, immature female phenotype	Autosomal recessive

4.5 Cystic fibrosis mutations and male infertility

Cystic fibrosis is a fatal autosomal-recessive disorder. It is the most common genetic disease of Caucasians; 4% are carriers of gene mutations involving the CF transmembrane conductance regulator (CFTR) gene. This gene is located on the short arm of chromosome 7. It encodes a membrane protein that functions as an ion channel and influences the formation of the ejaculatory duct, seminal vesicle, vas deferens and distal two thirds of the epididymis.

Congenital bilateral absence of the vas deferens (CBAVD) is associated with CFTR gene mutations and was found in approximately 2% of men with OA attending a clinic in Edinburgh (63). The incidence in men with OA varies between different countries. The clinical diagnosis of absent vasa is easy to miss and all men with azoospermia should be very carefully examined to exclude CBAVD, particularly those with a semen volume of < 1.5 mL and pH less than 7.0.

Approximately 1,500 mutations are listed on the CFTR database (http://www.genet.sickkids.on.ca/cftr/). Many series of men with CBAVD tested for varying numbers of mutations have been published. In general, the more mutations tested for, the higher the percentage of men found to have them. In a review of published series of 449 men with CBAVD, the Delta F508 mutation was detected in 244 men, the R117H mutation in 54 men and the W1282X mutation in 37; 63 other mutations were found in 1 to 9 men, but not all mutations were tested for in all case series (64).

As more mutations are defined and tested for, almost all men with CBAVD will probably be found to have mutations. It is not practical to test for all known mutations, as many have a very low prevalence in a particular population. Testing is usually restricted to the most common mutations in a particular community.

Mutations may be found in both copies of the CFTR gene; however, in most men with CBAVD, mutation is found in only one copy. In some of these supposedly heterozygous cases, there may be an unknown second mutation, but there is also another mechanism. In two-thirds of men with CBAVD, a DNA variant (the fifth allele) can be detected in a non-coding region of CFTR (65). Consequently, since the 5T-tract variant is now considered a mild CFTR mutation rather than a polymorphism, it should be analysed in each CAVD patient.

Men with CBAVD often have mild clinical stigmata of CF (e.g. history of chest infections). Children born after ICSI, where the father has CBAVD and is either hetero- or homozygous, must be followed up.

When a man has CBAVD, it is important to test him and his partner for CF mutations. If the female partner is found to be a carrier of CFTR, the couple must consider very carefully whether to proceed with ICSI using the husband's sperm, as the risk of a having a baby with CF will be 25% if the man is heterozygous and 50% if the man is homozygous. If the female partner is negative for known mutations, the risk of being a carrier of unknown mutations is about 0.4%.

4.6 Unilateral or bilateral absence/abnormality of the vas and renal anomalies

Unilateral absence of the vas deferens is usually associated with ipsilateral absence of the kidney (66) and probably has a different genetic causation. Men with unilateral absence of the vas deferens are usually

fertile, and the condition is most commonly encountered as an incidental finding in the vasectomy clinic. Nevertheless, men with unilateral absence of the vas deferens and CF mutations may have the same underlying genetic diseases as men with true CBAVD. Men with bilateral absence of vas deferens and renal abnormalities do not have CFTR gene abnormalities (67).

Men who have unilateral absence of the vas and normal kidneys or bilateral absence or bilateral abnormality, should be tested for CF mutations. If the results are negative and renal anatomy has not been defined, an abdominal ultrasound should be undertaken. Findings may range from unilateral absence of the vas with ipsilateral absence of the kidney, to bilateral vessel abnormalities and renal abnormalities, such as pelvic kidney.

4.7 Unknown genetic disorders

Considering the high predicted number of genes involved in male gametogenesis, it is likely that most 'idiopathic' forms of spermatogenic disturbances are caused by mutations or polymorphisms in spermatogenesis candidate genes (34). However, despite an intensive search for new genetic factors, no clinically relevant gene mutations or polymorphisms (except those related to the Y chromosome) have so far been identified (34, 68, 69, and references therein). The introduction of new analytical approaches is likely to provide major advancement in this field (70,71).

ICSI is used to enable men with severely damaged spermatogenesis to father children in situations formerly considered hopeless and where very few spermatozoa can be obtained. This has led to concern that children may be born with a fetal abnormality, because ICSI may enable defective sperm to bypass the selective processes of the female genital tract and egg covering. Alternatively, eggs may be fertilised that would otherwise not be fertilised. However, fetal abnormality statistics from ICSI centres do not indicate any increase in congenital malformations compared with the general population.

On the other hand, ICSI babies have a higher risk of *de novo* sex chromosomal aberrations (about a 3-fold increase compared with natural conceptions) and paternally inherited structural abnormalities (72-74).

Indications for ICSI are constantly being extended to include fertilisation with immature sperm forms, and it is therefore particularly important to continue to monitor fetal abnormality rates, using detailed subgroup analysis according to the father's clinical and molecular diagnosis.

4.8 DNA fragmentation in spermatozoa

There is increased DNA damage in spermatozoa from men with oligozoospermia. This increase is associated with reduced chances of natural conception and, to a lesser extent, conception after IVF/ICSI, and with an increase in early pregnancy loss (75,76). DNA damage may improve after varicocele ligation (77,78).

4.9 Genetic counselling and ICSI

The best management is to agree treatment with the couple and provide them with full information on the genetic risks. Initially, the couple should be given full information about the risks to the child to help them decide whether to proceed with ICSI. Where there is conflict between the wishes of the couple and the interests of the future child, it may be ethically correct to withhold therapy.

When both partners are known to carry defects (e.g. CF mutations), there is up to a 50% chance of the child developing a clinical condition and dying early after a number of years of morbidity. Many clinicians and infertility clinic personnel may consider it is unethical to proceed because their duty of care to the future child and the interests of society outweigh the wishes of the individual couple. If there is a conflict that cannot be resolved by agreement, the interests of a future child probably take precedence over the interests of a couple. The couple also need to give consideration to preimplantation diagnosis and replacement only of normal embryos.

4.10 Conclusions and recommendations for genetic disorders in male infertility

Conclusions
New insights into the genetic basis of infertility and the advent of ICSI require a good understanding of genetics by clinicians and the general public.
Diagnostic advances will allow us to identify the genetic basis of more disorders and diagnose known disorders at a lower cost. For some of these disorders, gene therapy might be practical.

Recommendations	GR
Standard karyotype analysis should be offered to all men with damaged spermatogenesis (< 10 million spermatozoa/mL) who are seeking fertility treatment by in vitro fertilisation/intracytoplasmic sperm injection (ICSI) (2).	B
Men with Klinefelter's syndrome might require androgen replacement therapy as they get older.	B
All men with Klinefelter's syndrome who undergo testicular biopsy procedures for sperm retrieval need long-term endocrine follow-up.	B
For men with severely damaged spermatogenesis (< 5 million spermatozoa/mL), testing for Yq microdeletions is strongly advised (39,60).	B
When a man has structural abnormalities of the vas deferens (bilateral absence of vas deferens, unilateral absence of the vas), it is important to test him and his partner for CF gene mutations (64).	A
Genetic counselling is mandatory in couples with a genetic abnormality found in clinical or genetic investigation and in patients who carry a (potential) inheritable disease (1).	A

5. OBSTRUCTIVE AZOOSPERMIA

5.1 Definition

Obstructive azoospermia (OA) is the inability to detect both spermatozoa and spermatogenetic cells in semen and post-ejaculate urine due to bilateral obstruction of the seminal ducts. OA is less common than NOA and occurs in 15-20% of men with azoospermia. Common causes of OA are summarised in Table 7.

Men with OA present with normal FSH, normal size testes and epididymal enlargement. Sometimes, the vas deferens is absent due to congenital factors or previous inguinal or scrotal surgery. Obstruction in primary infertile men is often present at the epididymal level; other sites of obstruction are the ejaculatory ducts and the vas deferens. In 25% of men with a suspected obstruction, no spermatozoa are found in the epididymis during scrotal exploration, indicating an intratesticular obstruction.

Table 7: Classification of OA, on the basis of ductal obstruction due to congenital and acquired causes

Conditions	Congenital	Acquired
Epididymal obstruction	Idiopathic epididymal obstruction	Post-infective (epididymitis) Post-surgical (epididymal cysts)
Vas deferens obstruction	Congenital absence of vas deferens	Post-vasectomy Post-surgical (hernia, scrotal surgery)
Ejaculatory duct obstruction	Prostatic cysts (Müllerian cysts)	Post-surgical (bladder neck surgery) Post-infective

5.2 Classification

*5.2.1 **Intratesticular obstruction***

Intratesticular obstruction occurs in 15% of OA (1). Congenital forms (dysjunction between rete testis and efferent ductules) are less common than acquired forms, i.e. post-inflammatory or post-traumatic obstructions. Acquired forms are often associated with an obstruction of epididymis and vas deferens.

*5.2.2 **Epididymal obstruction***

Epididymal obstruction is the most common cause of OA, affecting 30-67% of azoospermic men with a serum FSH less than twice the upper limit of normal (1-4).

Congenital epididymal obstruction usually manifests as CBAVD, which is associated with at least one mutation of the CF gene in 82% of cases (5). This form is often accompanied by absence of the distal part of the epididymis and seminal vesicle agenesis (*see above* Chapter 4: Genetic disorders in infertility). Other congenital forms of obstruction are rare, e.g. disjunction between efferent ductules and the corpus epididymis, agenesis/atresia of a short part of the epididymis.

Congenital forms of epididymal obstruction include chronic sinopulmonary infections (Young's syndrome) (6), in which obstruction results from a mechanical blockage due to debris within the proximal epididymal lumen.

Acquired forms secondary to acute (e.g. gonococcal) and subclinical (e.g. chlamydial) epididymitis are most common (7,8) (*see below* Chapter 11: Male accessory gland infections). Acute or chronic traumas can result in epididymal damage (9).

Azoospermia caused by surgery may occur after epididymal surgery, e.g. cyst removal. Epididymal obstruction secondary to long-lasting distal obstruction must be considered when repairing seminal ducts (10).

*5.2.3 **Vas deferens obstruction***

Vas deferens obstruction is the most common cause of acquired obstruction following vasectomy for sterilisation, with possible subsequent germ cell impairment and fibrosis (11,12). Approximately 2-6% of these men request vasectomy reversal. Of those undergoing vaso-vasostomy, 5-10% have epididymal blockage as a result of tubule rupture, making epididymo-vasostomy mandatory (*see below* Chapter 10: Male contraception). Vasal obstruction may also occur after herniotomy (13). Polypropylene mesh herniorrhaphy appears to be able to induce a fibroblastic response able to entrap or obliterate the vas deferens (14).

The most common congenital vasal obstruction is CBAVD, often accompanied by CF. Unilateral agenesis or a partial defect is associated with contralateral seminal duct anomalies or renal agenesis in 80% and 26% of cases, respectively (15) (*see above* Chapter 4: Genetic disorders in infertility). Distal vas deferens obstruction includes CBAVD and accidental injury to the vas deferens during hernia surgery (16).

*5.2.4 **Ejaculatory duct obstruction***

Ejaculatory duct obstruction is found in about 1-3% of OA (1) and is classified as either cystic or post-inflammatory.

Cystic obstructions are usually congenital (i.e. Müllerian duct cyst or urogenital sinus/ejaculatory duct cysts) and are medially located in the prostate between the ejaculatory ducts. In urogenital sinus abnormalities, one or both ejaculatory ducts empty into the cyst (17), while in Müllerian duct anomalies, ejaculatory ducts are laterally displaced and compressed by the cyst (18).

Paramedian or lateral intraprostatic cysts are Wolffian in origin and rare in clinical practice (19). Post-inflammatory obstructions of the ejaculatory duct are usually secondary to acute, non-acute, or chronic urethro-prostatitis (20).

Congenital or acquired complete obstructions of the ejaculatory ducts are commonly associated with low semen volume, decreased or absent seminal fructose and acid pH. The seminal vesicles are usually dilated (anterior-posterior diameter > 15 mm) (20,21).

*5.2.5 **Functional obstruction of the distal seminal ducts***

Functional obstruction of the distal seminal ducts might be attributed to local neuropathy (22). This abnormality is often associated with urodynamic dysfunction because of the vasographic patterns of ampullo-vesicular atony or of ejaculatory duct hypertony. Functional obstruction of the distal seminal ducts has been reported in juvenile diabetes and polycystic kidney disease (23); however, no relevant pathology has been found in most cases. Results of semen analysis vary between azoospermia, cryptozoospermia and severe OAT syndrome.

5.3 Diagnosis

*5.3.1 **Clinical history***

Clinical history taking should follow the suggestions for investigation of infertile men (*see* Chapter 2: Investigations).

Patients should be asked about:

- haematospermia;
- post-ejaculatory pain;
- previous or present urethritis or prostatitis;
- obstructive or irritative urinary symptoms;
- previous scrotal enlargement or pain or surgery;
- previous inguinal herniorrhaphy or traumas;
- chronic sinopulmonary infections.

5.3.2 ***Clinical examination***

Clinical examination should follow suggestions for investigation of the infertile man. The following findings indicate OA:

- at least one testis with a volume > 15 ml, although a smaller testicular volume may be found in some patients with OA and concomitant partial testicular failure;
- enlarged and hardened epididymis;
- nodules in the epididymis or vas deferens;
- absence or partial atresia of the vas;
- signs of urethritis;
- prostatic abnormalities.

5.3.3 ***Semen analysis***

At least two examinations must be carried out at an interval of 2-3 months, according to the WHO (*see above* Chapter 2: Investigations). Azoospermia means the inability to detect spermatozoa after centrifugation at x400 magnification. Careful repeat observation of several smears after semen liquefaction is needed. If no spermatozoa are found in a wet preparation, then aliquots or the whole semen sample should be centrifuged at 3000 G for 15 minutes. The pellet must be examined for spermatozoa.

Ejaculatory duct obstruction or CBAVD is suggested by a semen volume of less than 1.5 mL, acid pH and a low fructose level. When semen volume is low, a search must be made for spermatozoa in urine after ejaculation, as their presence confirms an ejaculatory disorder. Absence of spermatozoa and immature germ cells in semen smears suggest complete proximal or distal seminal duct obstruction.

5.3.4 ***Hormone levels***

Serum FSH levels may be normal, but do not exclude a testicular cause of azoospermia (e.g. spermatogenic arrest). Follicle-stimulating hormone is normal in 40% of men with primary spermatogenic failure. Inhibin B seems to have a higher predictive value for normal spermatogenesis (4).

5.3.5 ***Ultrasonography***

Scrotal ultrasound is helpful in finding signs of obstruction (e.g. dilatation of rete testis, enlarged epididymis with cystic lesions, absent vas deferens) and may demonstrate signs of testicular dysgenesis (e.g. non-homogenous testicular architecture and microcalcifications) and associated carcinoma *in situ* of the testis. For patients with a low seminal volume and in whom distal obstruction is suspected, transrectal ultrasound (TRUS) is essential. If possible, TRUS should be performed at high resolution and with high frequency (> 7 MHz) biplane transducers. Seminal vesicle enlargement (anterior-posterior diameter 15 mm) (21) and roundish, anechoic areas in the seminal vesicle (24) are TRUS anomalies more often associated with ejaculatory duct obstruction, especially when semen volume is < 1.5 mL. Müllerian duct cysts or urogenital sinus/ejaculatory duct cysts (20) and ejaculatory duct calcifications (25) are other known anomalies in obstructive azoospermia. Transrectal ultrasound may also be used to aspirate seminal vesicle fluid (26).

Invasive diagnosis, including testicular biopsy, scrotal exploration, and distal seminal duct evaluation, are indicated in patients with OA in whom an acquired obstruction of the seminal ducts is suspected. Explorative and recanalisation surgery should be carried out at the same time.

5.3.6 ***Testicular biopsy***

In selected cases, testicular biopsy may be indicated to exclude spermatogenic failure. Testicular biopsy should be combined with extraction of testicular spermatozoa (i.e. TESE) for cryopreservation and subsequent ICSI, when surgical recanalisation cannot be carried out or has failed. A scoring system for testicular biopsies is given in Table 8 (27).

Table 8: Scoring system for testicular biopsies (Johnsen score)*

Score	Histological criteria
10	Full spermatogenesis
9	Slightly impaired spermatogenesis, many late spermatids, disorganised epithelium
8	< 5 spermatozoa per tubule, few late spermatids
7	No spermatozoa, no late spermatids, many early spermatids
6	No spermatozoa, no late spermatids, few early spermatids
5	No spermatozoa or spermatids, many spermatocytes
4	No spermatozoa or spermatids, few spermatocytes
3	Spermatogonia only
2	No germinal cells, Sertoli cells only
1	No seminiferous epithelium

** From Johnsen, 1970 (27).*

5.4 Treatment

*5.4.1 **Intratesticular obstruction***

At this level seminal duct recanalisation is impossible. Both Testicular Sperm Extraction (TESE) or Microsurgical Epididymal Sperm Aspiration (MESA) allow sperm retrieval in nearly all OA patients. TESE and MESA are therefore recommended. The spermatozoa retrieved may be used immediately for ICSI, or may be cryopreserved.

*5.4.2 **Epididymal obstruction***

Microsurgical epididymal sperm aspiration (MESA) (28) is indicated in men with CBAVD. TESA and PESA are also viable options for retrieving epididymal sperm from men with OA (29). Retrieved spermatozoa are used for ICSI. Usually, one MESA procedure provides sufficient material for several ICSI cycles (30) and it produces high pregnancy and fertilisation rates (31). In patients with azoospermia due to acquired epididymal obstruction, end-to-end or end-to-side microsurgical epididymo-vasostomy is recommended, with the preferred technique being microsurgical intussusception epididymo-vasostomy (32).

Reconstruction may be carried out unilaterally or bilaterally; patency and pregnancy rates are usually higher with bilateral reconstruction. Before microsurgery, it is important to check for full patency downstream of the epididymis. Anatomical recanalisation following surgery may require 3-18 months. Before microsurgery (and in all cases where recanalisation is impossible), epididymal spermatozoa should be aspirated and cryopreserved for use in ICSI in case of surgical failure (30).

Patency rates range between 60% and 87% (33-35) and cumulative pregnancy rates between 10% and 43%. Recanalisation success rates may be adversely affected by pre-operative and operative findings (e.g. concomitant abnormal testicular histology, absence of sperm in the spermatic fluid on sectioning the small epididymal tubules, wide fibrosis of the epididymis).

*5.4.3 **Proximal vas obstruction***

Proximal vas obstruction after vasectomy requires microsurgical vasectomy reversal (*see* Chapter 10: Male contraception). Vaso-vasostomy is also required in rare cases of proximal vasal obstructions (iatrogenic, post-traumatic, post-inflammatory). The absence of spermatozoa in the intraoperative vas deferens fluid may suggest the presence of a secondary epididymal obstruction, especially if the seminal fluid of the proximal vas has a thick 'toothpaste' appearance. Microsurgical vaso-epididymostomy is then indicated.

*5.4.4 **Distal vas deferens obstruction***

It is usually impossible to correct large bilateral vas deferens defects, resulting from involuntary excision of the vas deferences during hernia surgery in early childhood or previous orchidopexy (16). In these cases, proximal vas deferens sperm aspiration (37) or TESE/MESA can be used for cryopreservation for future ICSI. In large unilateral vas deferens defects associated with contralateral testicular atrophy, the vas deferens of the atrophic testis can be used for a cross-over vaso-vasostomy or vaso-epididymostomy.

*5.4.5 **Ejaculatory duct obstruction***

The treatment of ejaculatory duct obstruction depends on its aetiology. Transurethral resection of the ejaculatory ducts (TURED) (20,38) can be used in large post-inflammatory obstruction and when one, or both,

ejaculatory ducts empty into an intraprostatic midline cyst. Resection may remove part of the verumontanum. In cases of obstruction due to a midline intraprostatic cyst, incision or unroofing of the cyst is required (20). Intra-operative TRUS makes this procedure safer. If distal seminal tract evaluation is carried out at the time of the procedure, installation of methylene blue dye into the vas deferens can help to document opening of the ducts. The limited success rate of surgical treatment of ejaculatory duct obstruction in terms of spontaneous pregnancies should be weighed against sperm aspiration and ICSI.

Complications following TURED include retrograde ejaculation due to bladder neck injury and urine reflux into ducts, seminal vesicles and vasa (causing poor sperm motility, acid semen pH and epididymitis). The alternatives to TURED are MESA, TESE, proximal vas deferens sperm aspiration, seminal vesicle ultrasonically guided aspiration and direct cyst aspiration.

In cases of functional obstruction of the distal seminal ducts, TURED often fails to improve sperm output. Spermatozoa can then be retrieved by antegrade seminal tract washout (38). Spermatozoa retrieved by any of the aforementioned surgical techniques should always be cryopreserved for assisted reproductive procedures.

5.5 Conclusions and recommendation for obstructive azoospermia

Conclusions
Obstructive lesions of the seminal tract should be suspected in azoospermic or severely oligozoospermic patients with normal-sized testes and normal endocrine parameters.
Results of reconstructive microsurgery depend on the cause and location of the obstruction and the surgeon's expertise. Standardised procedures include vaso-vasostomy and epididymo-vasostomy.
Sperm retrieval techniques, such as MESA, TESE, and PESA can be used additionally. These methods should be used only when cryostorage of the material obtained is available.

Recommendation	GR
In azoospermia caused by epididymal obstruction, a scrotal exploration with microsurgical epididymal sperm aspiration and cryopreservation of the spermatozoa should be carried out, together with a microsurgical reconstruction (35).	B

6. VARICOCELE

6.1 Introduction

Varicocele is a common abnormality (*see* Chapter 2: Investigations) with the following andrological implications:

- failure of ipsilateral testicular growth and development;
- symptoms of pain and discomfort;
- infertility.

6.2 Classification

The following classification of varicocele (1,2) is useful in clinical practice:

- subclinical: not palpable or visible at rest or during valsalva manoeuvre, but can be shown by special tests (Doppler ultrasound studies) (3);
- grade 1: palpable during valsalva manoeuvre, but not otherwise;
- grade 2: palpable at rest, but not visible;
- grade 3: visible and palpable at rest.

6.3 Diagnosis

The diagnosis of varicocele is made by clinical examination and can be confirmed by colour Doppler analysis (2). In centres where treatment is carried out by antegrade or retrograde sclerotherapy or embolisation, diagnosis is additionally confirmed by X-ray.

6.4 Basic considerations

*6.4.1 **Varicocele and fertility***

Varicocele is a physical abnormality present in 11.7% of adult men and in 25.4% of men with abnormal semen analysis (4). The exact association between reduced male fertility and varicocele is unknown, but a recent meta-analysis showed that semen improvement is usually observed after surgical correction (5). Current information fits with the hypothesis that in some men the presence of varicocele is associated with progressive testicular damage from adolescence onwards, and consequent reduction in fertility. Varicocele is associated

with increased sperm DNA damage, and this sperm pathology may be secondary to varicocele-mediated oxidative stress.Varicocelectomy can reverse this sperm DNA damage, as shown in several studies (6).

*6.4.2 **Varicocelectomy***

Varicocele repair has been a subject of debate for decades: controversy exists as to whether varicocele repair results in more spontaneous pregnancies as compared to observation. The 2009 Cochrane Database review concluded that there is no evidence that treatment of the varicocele improves a couples' chance of conception (7). This meta-analysis was criticised for including several heterogenous studies, men with normal semen analysis and men with a subclinical varicocele (8). In 3 randomised controlled studies varicocele repair in men with a subclinical varicocele was found to be ineffective (9-11). Also, studies of men with a varicocele and normal semen analysis showed no clear benefit of treatment over observation (12,13).

The duration of the infertility also seems of importance: in a recent study it was shown that couples with an infertility duration of more than 2 years had a significant higher pregnancy rate compared to couples with an uncorrected varicocele. In couples with a shorter duration of infertility, such a difference was not observed (14).

In a recent meta-analysis of 4 RCTs on varicocelectomy in men with a clinical varicocele, oligospermia and otherwise unexplained infertility a trend in favour of surgical correction was observed (15). The combined odds ratio was 2.23 (95% confidence interval [CI], 0.86-5.78; p=0.091), indicating that varicocelectomy is moderately superior to observation, but the effect was not statistically significant.

There is a need for a large, properly conducted RCT of varicocele treatment in men with abnormal semen from couples with otherwise unexplained subfertility (16). While treatment of varicocele in infertile men may be effective, in adolescents there is a significant risk of overtreatment: most adolescents with a varicocele will have no problem achieving pregnancy later in life (17).

6.5 Treatment

Several treatments are available for varicocele (Table 9). The type of intervention chosen depends mainly on the experience of the therapist. Although laparoscopic varicocelectomy is feasible, it must be justified in terms of cost effectiveness.

Table 9: Recurrence and complication rates associated with treatments for varicocele

Treatment	Ref.	Recurrence/ persistence %	Complication rates
Antegrade sclerotherapy	18	9	Complication rate 0.3-2.2%: testicular atrophy, scrotal haematoma, epididymitis, left-flank erythema
Retrograde sclerotherapy	19	9.8	Adverse reaction to contrast medium, flank pain, persistent thrombophlebitis, vascular perforation
Retrograde embolisation	20,21	3.8-10	Pain due to thrombophlebitis, bleeding haematoma, infection, venous perforation, hydrocele, radiological complication (e.g. reaction to contrast media), misplacement or migration of coils, retroperitoneal haemorrhage, fibrosis, ureteric obstruction
Open operation			
Scrotal operation		-	Testicular atrophy, arterial damage with risk of devascularisation and gangrene of testicle, scrotal haematoma, post-operative hydrocele
Inguinal approach	22	13.3	Possibility of missing out a branch of testicular vein
High ligation	23	29	5-10% incidence of hydrocele (< 1%)
Microsurgical inguinal or subinguinal	24,25	0.8-4	Post-operative hydrocele arterial injury, scrotal haematoma
Laparoscopy	26,27	3-7	Injury to testicular artery and lymph vessels, intestinal, vascular and nerve damage, pulmonary embolism, peritonitis, bleeding, post-operative pain in right shoulder (due to diaphragmatic stretching during pneumoperitoneum), pneumoscrotum, wound infection

6.6 Conclusions and recommendations for varicocele

Conclusions
Current information supports the hypothesis that the presence of varicocele in some men is associated with progressive testicular damage from adolescence onwards and a consequent reduction in fertility.
Although the treatment of varicocele in adolescents may be effective, there is a significant risk of over-treatment.
Varicocele repair may be effective in men with subnormal semen analysis, a clinical varicocele and otherwise unexplained infertility. Further RCTs are needed to confirm that this subgroup of infertile couples will benefit from treatment.

Recommendations	GR
Varicocele treatment is recommended for adolescents with progressive failure of testicular development documented by serial clinical examination (9,10).	B
No evidence indicates benefit from varicocele treatment in infertile men who have normal semen analysis or in men with subclinical varicocele. In this situation, varicocele treatment cannot be recommended (15-17).	A
Varicocele repair should be considered in case of a clinical varicocele, oligospermia, duration of infertility of at least 2 years and otherwise unexplained infertility in the couple.	B

7. HYPOGONADISM

7.1 Introduction

Hypogonadism is characterised by impaired testicular function, which may affect spermatogenesis and/or testosterone synthesis. The symptoms of hypogonadism depend on the degree of androgen deficiency and if the condition develops before or after pubertal development of the secondary sex characteristics. The symptoms and signs of hypoandrogenism presenting before and after completion of puberty are given in Table 10.

Table 10: Symptoms and signs of hypogonadism debuting before and after completion of puberty*

Affected organ/function	Before completed puberty	After completed puberty
Larynx	No voice mutation	No voice mutation
Hair	Horizontal pubic hairline Straight frontal hairline Diminished beard growth	Diminished secondary body hair
Skin	Absent sebum production Lack of acne Pallor Skin wrinkling	Decreased sebum production Lack of acne Pallor Skin wrinkling
Bones	Eunuchoid tall stature Osteoporosis	Osteoporosis
Bone marrow	Mild anaemia	Mild anaemia
Muscles	Underdeveloped	Hypotrophy
Prostate	Underdeveloped	Hypotrophy
Penis	Infantile	No change of size
Testes	Possibly maldescended testes Small volume	Decrease of testicular volume
Spermatogenesis	Not initiated	Involuted
Libido and potency	Not developed	Loss

**Modified from Nieschlag et al. (1998) (1).*

The aetiological and pathogenetic mechanisms of male hypogonadism can be divided into three main categories:

1. Primary (hypergonadotrophic) hypogonadism due to testicular failure.
2. Secondary (hypogonadotrophic) hypogonadism caused by insufficient gonadotrophin-releasing hormone (GnRH) and/or gonadotrophin (FSH, LH) secretion.
3. Androgen insensitivity (end-organ resistance).

The most common conditions within these three categories are given in Table 11 (*see also* Chapter 4: Genetic disorders in infertility).

Table 11: Disorders with male hypogonadism*

Primary (hypergonadotropic) hypogonadism (testicular failure)*
Anorchia
Maldescended testes
Klinefelter's syndrome
Y chromosome microdeletions
Numerical and structural chromosomal anomalies
Trauma, testicular torsion, orchitis
Iatrogenic (surgery, medications, irradiation, cytostatic drugs)
Exogenous factors (toxins, heat, occupational hazards)
Systemic diseases (liver cirrhosis, renal failure)
Testicular tumour
Varicocele
Idiopathic
Secondary (hypogonadotropic) hypogonadism (secondary testicular failure)
Congenital o Idiopathic hypogonadotrophic hypogonadism o Normosmic o Iposmic/anosmic (Kallmann syndrome)

Acquired (tumours in the following regions) o Dyencephalon (craniopharyngiomas, meningiomas) o Hypothalamus or pituitary
Empty sella
Granulomatous illnesses
Fractures of the skull base
Ischaemic or haemorrhagic lesions in hypothalamic area
Hyperprolactinaemia
Drugs/anabolic steroids, radiotherapy
Target organ resistance to androgens
Testicular feminisation
Reifenstein's syndrome

7.2 Hypogonadotrophic hypogonadism: aetiology, diagnosis and therapeutic management

Idiopathic hypogonadotrophic hypogonadism (IHH) is characterised by low levels of gonadotrophins and sex steroid in the absence of anatomical or functional abnormalities of the hypothalamic-pituitary-gonadal axis (2). Idiopathic HH may be an isolated condition or may be associated with anosmia/hyposmia (Kallmann syndrome). Genetic factors causing a deficit of gonadotrophins may act at the hypothalamic or pituitary level. Mutations in candidate genes (X-linked or autosomal) can be found in about 30% of congenital cases (2) and should be screened prior to assisted reproduction (3).

Acquired hypogonadotrophic hypogonadism can be caused by some drugs, hormones, anabolic steroids, and by tumours. A suspected tumour requires imaging (CT or MR) of the sella region and a complete endocrine work-up.

The failure of hormonal regulation can easily be determined (4). Endocrine deficiency leads to a lack of spermatogenesis and testosterone secretion as a result of decreased secretion of FSH and LH. After having excluded secondary forms (drug, hormones, tumours), the therapy of choice depends on whether the goal is to achieve normal androgen levels or to achieve fertility.

Normal androgen levels and subsequent development of secondary sex characteristics (in cases of onset of hypogonadism before puberty) and eugonadal state can be achieved by androgen replacement alone. However, the stimulation of sperm production requires treatment with human chorionic gonadotrophin (hCG) combined with recombinant FSH or urinary FSH or human menopausal gonadotropins (HMG). In the rare cases of 'fertile eunuchs', who have sufficient production of FSH but not LH, treatment with hCG alone may be sufficient to stimulate sperm production and to achieve normal testosterone levels (5).

If hypogonadotrophic hypogonadism is hypothalamic in origin, an alternative to hCG treatment is therapy with pulsatile GnRH (6). In patients who have developed hypogonadism before puberty and have not been treated with gonadotropins or GnRH, 1-2 years of therapy may be needed to achieve sperm production. Once pregnancy has been established, patients can return to testosterone substitution.

7.3 Hypergonadotrophic hypogonadism: aetiology, diagnosis and therapeutic management

Many conditions are associated in men with hypogonadotrophic hypogonadism (Table 11, *see also* Chapter 4: Genetic disorders in infertility). Most conditions listed in Table 11 only affect the reproductive function of the testis so that only the FSH level is elevated. However, it has been reported that men with infertility problems are at higher risk for developing impaired Leydig cell function (7), while men with Klinefelter's syndrome often show high LH values and develop hypoandrogenism with ageing (8). A decrease in testosterone blood concentrations after extensive testicular biopsy in the context of TESE/ICSI has been observed, raising questions about the need for long-term endocrine follow-up of these patients (9).

Hypogonadism affecting both reproductive and endocrine functions of the testis occurs after treatment with GnRH analogues or surgical castration for prostatic cancer (10).

The laboratory diagnosis of hypergonadotrophic hypogonadism is based on a high level of FSH, decreased serum testosterone and increased LH levels (3). Testosterone levels should be evaluated in view of the concentration of the serum concentration of sex hormone binding globulin (SHBG). Based on levels of total testosterone and SHBG, free and bioavailable testosterone can be calculated (http://www.issam.ch/freetesto.htm).

Due to diurnal variation, blood samples for testosterone assessment should be taken before 10.00 am. The existing guidelines for androgen replacement are based on mainly total testosterone levels. There is general agreement that a total testosterone level > 12 nmol / L (350 ng / dL) does not require substitution. Similarly,

based on the data of younger men, there is consensus that patients with serum total testosterone levels < 8 nmol / L (230 ng / dL) will usually benefit from testosterone treatment. If the serum total testosterone level is between 8 and 12 nmol / L, testosterone supplementation is based on the presence of symptoms.

In obese men, decision-making may be helped by measuring total testosterone with SHBG to calculate free testosterone or measurement of free testosterone by equilibrium dialysis (11). Injectable, oral and transdermal testosterone preparations are available for clinical use (3). The best preparation to use is one that maintains serum testosterone levels as near as possible to physiological concentrations (11-13).

7.4 Conclusion and recommendation for hypogonadism

Conclusion
It is generally agreed that patients with primary or secondary hypogonadism associated with hypoandrogenism should receive testosterone substitution therapy.

Recommendation	GR
Effective drug therapy is available to achieve fertility in men with hypogonadotrophic hypogonadism (4).	A

8. CRYPTORCHIDISM

8.1 Introduction

Cryptorchidism is the most common congenital abnormality of the male genitalia and is found in 2-5% of newborn boys, depending on gestational age (cryptorchidism occurs more often in premature boys) and age after birth. At the age of 3 months, the incidence of cryptorchidism falls spontaneously to 1-2%. Approximately 20% of undescended testes are non-palpable and may be located within the abdominal cavity.

The aetiology of cryptorchidism is multifactorial, involving disrupted endocrine regulation and several gene defects. The normal descent of the testes requires a normal hypothalamo-pituitary-gonadal axis. Endocrine disruption in early pregnancy can potentially affect gonadal development and normal descent of the testes; however, most boys with maldescended testes show no endocrine abnormalities after birth. It has been postulated that cryptorchidism may be a part of the so-called testicular dysgenesis syndrome (TDS), which is a developmental disorder of the gonads caused by environmental and/or genetic influences early in pregnancy. Besides cryptorchidism, TDS includes hypospadias, reduced fertility, increased risk of malignancy, and Leydig cell dysfunction (1).

8.2 Incidence of cryptorchidism

The Caucasian population has a three-fold higher incidence of cryptorchidism compared to African-Americans. Even between Caucasians, there are significant differences in the risk of cryptorchidism, e.g. it is significantly more common among Danish than Finnish newborns (2). Premature babies have a much higher incidence of cryptorchidism than full-term babies. In a British study, the incidence of cryptorchidism was 2.7% in more than 3,000 boys weighing > 2500 g and 21% in premature boys weighing < 2500 g. At the age of 3 months, spontaneous descent occurred in most boys, and the incidence of cryptorchidism fell to 0.9% and 1.7%, in the > 2500 g and < 2500 g group, respectively (3).

8.3 Testicular descent and maldescent

The process of testicular descent has two distinct phases: transabdominal and inguinal. During transabdominal descent, development of the gubernaculum and genitoinguinal ligament plays an important role. The anti-Müllerian hormone regulates the transabdominal descent of the testes. Induction of the gubernaculum depends on a functional Insl3 gene in mice (4). This gene is expressed in Leydig cells and its targeted deletion causes bilateral cryptorchidism with free-moving testes and genital ducts (5). Androgens play an important role in both phases of testicular descent, while other gene families, e.g. the homeobox (HOX) and GREAT/RXFP2 genes (G-protein-coupled receptor affecting testis descent), are important in the development of genital organs and may be associated with testicular maldescent (6,7).

8.4 Hormonal control of testicular descent

Maldescent can be caused by two hormonal factors: hypogonadism and androgen insensitivity. The increasing incidence of reproductive abnormalities in male humans can be explained by increased oestrogen exposure during gestation (8). Some pesticides and synthetic chemicals act as hormonal modulators, often possessing oestrogenic activity (xeno-oestrogens) (9). The oestrogenic and anti-androgenic properties of these chemicals may cause hypospadias, cryptorchidism, reduced sperm density, and an increased incidence of testicular tumours in animal models, via receptor-mediated mechanisms or direct toxic effects associated with Leydig cell dysfunction (10).

8.5 Pathophysiological effects in maldescended testes

*8.5.1 **Degeneration of germ cells***

The degeneration of germ cells in maldescended testes is apparent after the first year of life. Degenerative changes vary, depending on the position of the testis (11). During the second year, the number of germ cells declines. In 10-45% of affected patients, the complete loss of germ cells can be detected. Early treatment is therefore recommended to conserve spermatogenesis, especially in bilateral cases. Surgical treatment is the most effective and reliable method of bringing testes into the scrotum. Hormone treatment with hCG has been used widely in the past, but it has now been abolished because of increased germ cell apoptosis after treatment (12).

*8.5.2 **Relationship with fertility***

Semen parameters are often impaired in men with a history of cryptorchidism (13). Surgical treatment during the first or second year of life may have a positive effect on subsequent fertility (14). However, there is no definitive proof of the protective effect of early orchidopexy. In men with a history of unilateral cryptorchidism, paternity is almost equal (89.7%) to that in men without cryptorchidism (93.7%).

In men with unilateral cryptorchidism, paternity is independent of age at orchidopexy and pre-

operative testicular location and testicular size (15). However, a history of unilateral cryptorchidism may result in reduced fertility potential and therefore a longer time to achieve pregnancy.

In men with bilateral cryptorchidism, oligozoospermia can be found in 31% and azoospermia in 42%. In cases of bilateral cryptorchidism, the rate of paternity is only 35-53%. In cases of bilateral cryptorchidism and azoospermia, orchidopexy performed even in adult life might lead to the appearance of spermatozoa in the ejaculate (16).

8.5.3 ***Germ cell tumours***

Cryptorchidism is a risk factor for testicular cancer and is associated with testicular microcalcification and intratubular germ cell neoplasia of unclassified type [ITGCNU] former "CIS" of the testis. In 5-10% of testicular cancers, there is a history of cryptorchidism (17). The risk of a germ cell tumour is 3.6-7.4 times higher than in the general population and 2-6% of men with a history of cryptorchidism will develop a testicular tumour (17). Orchidopexy preformed before the age of puberty has been reported to decrease the risk of testicular cancer (18). However, this and other similar reports are based on retrospective data and does not exclude the possibility that boys undergoing early and late orchidopexy represent different pathogenetic groups of testicular maldescent.

8.6 Treatment of undescended testes

8.6.1 ***Hormonal treatment***

Human chorionic gonadotrophin or GnRH has been used widely in the past to treat cryptorchidism. However, although 15-20% of retained testes descend during hormonal treatment, one-fifth of these re-ascend later. Also, treatment with hCG may be harmful to future spermatogenesis by increasing the apoptosis of germ cells (12), which is why hormonal treatment is no longer recommended.

8.6.2 ***Surgical treatment***

The success rate of surgical treatment for undescended testes is 70-90% (19). If the spermatic cords or the spermatic vessels are too short to allow proper mobilisation of the testis into the scrotum, a staged orchidopexy (Fowler-Stephenson procedure) can be performed, using open surgery, laparoscopy or microsurgery.

The optimal age for performing orchidopexy is still debated. Some retrospective studies have indicated early treatment (during the first 2 years of life) has a beneficial effect on preserving future fertility (20), while a recent randomised study showed that surgery at 9 months resulted in a partial catch-up of testicular growth until at least age 4 years versus surgery at 3 years. The results clearly indicate that early surgery has a beneficial effect on testicular growth. Because testicular volume is an approximate indirect measure of spermatogenic activity, it is possible that orchidopexy at an early age might improve future spermatogenesis.

A biopsy at the time of orchidopexy (*see section* 8.5.3) can reveal intratubular germ cell neoplasia of unclassified type [ITGCNU], which can be removed thereby preventing development of a malignant tumour. If not corrected by adulthood, an undescended testis should not be removed because it still produces testosterone. Furthermore, as indicated above, correction of bilateral cryptorchidism, even in adulthood, can lead to sperm production in previously azoospermic men (16).

Vascular damage is the most severe complication of orchidopexy and can cause testicular atrophy in 1-2% of cases. In males with non-palpable testes, the post-operative atrophy rate was 12% in those cases with long vascular pedicles that enabled scrotal positioning. Post-operative atrophy in staged ochidopexy has been reported in up to 40% of patients (19).

8.7 Conclusions and recommendations for cryptorchidism

Conclusions
Cryptorchidism is multifactorial in origin and can be caused by genetic factors and endocrine disruption early in pregnancy.
Cryptorchidism is often associated with testicular dysgenesis and is a risk factor for infertility and germ cell tumours.
Whether early surgical intervention can prevent germ cell loss is still debatable, but in a randomised study it improved testicular growth in boys treated at the age of 9 months compared to those aged 3 years at the time of orchidopexy.
Paternity in men with unilateral cryptorchidism in almost equal to that in men without cryptorchidism.
Bilateral cryptorchidism significantly reduces the likelihood of paternity.

Recommendations	GR
Hormonal treatment of cryptorchidism should be abolished because of the risk of germ cell apoptosis and subsequent reduction of sperm production.	B
Early orchidopexy (6-12 months of age) might be beneficial for testicular development in adulthood.	B
If undescended testes are corrected in adulthood, testicular biopsy for detection of intratubular germ cell neoplasia of unclassified type [ITGCNU; former “CIS] is recommended at the time of orchidopexy (17).	B

9. IDIOPATHIC MALE INFERTILITY

9.1 Introduction

No demonstrable cause of male infertility, other than idiopathic OAT syndrome, is found in at least 44% of infertile men (1).

9.2 Empirical treatments

A wide variety of empirical drug treatments of idiopathic male infertility have been used; however, there is little scientific evidence for an empirical approach (2). Androgens, hCG/human menopausal gonadotrophin, bromocriptine, alpha-blockers, systemic corticosteroids and magnesium supplementation are not effective in the treatment of OAT syndrome. Follicle-stimulating hormone (3) and anti-oestrogens in combination with testosterone (4) might be beneficial in a selection of patients (3,4). A Cochrane analysis showed that men taking oral antioxidants had an associated statistically significant increase in live birth rate (pooled odds ratio (OR) = 4.85; 95% CI: 1.92-12.24; p = 0.0008; I(2) = 0%) when compared with men taking the control. No studies reported harmful side effects from the antioxidant therapy used. The evidence suggests that antioxidant supplementation in subfertile males may improve the outcomes of live birth and pregnancy rate for subfertile couples undergoing ART cycles. Further head-to-head comparisons are necessary to identify the superiority of one antioxidant over another (5).

Recommendation	GR
Medical treatment of male infertility is recommended only for cases of hypogonadotrophic hypogonadism (1).	A

10. MALE CONTRACEPTION

10.1 Introduction

'Male contribution to contraception' is a more accurate phrase than 'male contraception', as men do not conceive. Development of male contraceptive methods is important because up to 40% of women have an unmet need for family planning, with approximately 80 million women every year having unintended or unwanted pregnancies (1).

Three of the four methods of male contraception have been in use for hundreds of years (i.e. condoms, periodic abstinence and withdrawal). The typical first-year failure rates of traditional male methods are high (withdrawal 19%, periodic abstinence 20%, and condoms 3-14%) compared to the failure rates of 0.1-3% for modern reversible female methods (2). For men to take more responsibility for family planning, male contraceptive methods must be acceptable, cheap, reversible, and effective.

Research is attempting to (3):

- Prevent sperm production by using exogenic androgens, progestogen and GnRH formulations in various combinations).
- Interfere with the ability of sperm to mature and fertilise, by using an epididymal approach to create a hostile environment for sperm.
- Produce better barrier methods, e.g. polyurethane condoms can be used by those with latex allergy, although they have higher breakage rates (4).
- Produce an antisperm contraceptive vaccine (5).
- Inhibit sperm-egg interactions.

These approaches remain experimental. The method nearest to being generally available clinically is hormonal male contraception, which is based on the suppression of gonadotrophins and testosterone substitution to maintain male sexual function and bone mineralisation and to prevent muscle wasting (6). Various contraceptive regimens have been developed and tested, including testosterone monotherapy, androgen/progestin combinations, testosterone with GnRH analogues, and selective androgen- and progestin-receptor modulators. There are racial differences in the response to androgens alone. However, a combination of testosterone with progestin has resulted in complete suppression of spermatogenesis in all races, and provides contraceptive efficacy equivalent to female hormonal methods (7). Phase III clinical trials of depot preparations of androgen/progestin combinations are in progress.

10.2 Vasectomy

Vasectomy is an effective method of permanent male surgical sterilisation (8). Before vasectomy, the couple should be fully informed about the benefits and risks, especially as an Australian telephone survey found that 9.2% of respondents regretted having a vasectomy (9).

10.2.1 ***Surgical techniques***

Various techniques are available for vasectomy. The least invasive approach is the no-scalpel vasectomy (10), which is also associated with a low rate of complications (11). The most effective occlusion technique is cauterisation of the lumen of the vas deferens and fascial interposition (12-14). Most techniques can be carried out safely under local anaesthesia in an outpatient clinic.

10.2.2 ***Complications***

Vasectomy does not significantly alter spermatogenesis and Leydig cell function. The volume of ejaculate remains unchanged. Potential systemic effects of vasectomy, including atherosclerosis, have not been proven, and there is no evidence of a significant increase in any systemic disease after vasectomy. An increased rate of prostate cancer in men who underwent vasectomy has not been detected (17).

Acute local complications associated with vasectomy include haematoma, wound infection, and epididymitis in up to 5% of cases (15). The potential long-term complications (e.g. chronic testicular pain) (16) must be discussed with the patient before the procedure. Epididymal tubal damage is common, and is associated with consequent development of sperm granuloma and time-dependent secondary epididymal obstruction, which limits vasectomy reversal.

10.2.3 ***Vasectomy failure***

If an effective occlusion technique is used, the risk of recanalisation after vasectomy should be < 1% (12). However, patients should be informed pre-operatively that, although rare, long-term re-canalisation might occur (19). No motile spermatozoa should be detected 3 months after vasectomy. Persistent motility is a sign of vasectomy failure, and the procedure will need to be repeated. A 'special clearance' with non-motile spermatozoa < 10,000/mL is still under discussion (18).

10.2.4 ***Counselling***

Counselling with regard to vasectomy must address the following aspects:

- Vasectomy should be considered irreversible.
- Vasectomy is associated with a low complication rate; however, because it is an elective operation, even small risks must be explained, because men (and their partners) might wish to consider these before giving consent.
- Vasectomy can fail, although the failure rate is low.
- Couples should be advised to continue with other effective contraception until clearance is confirmed.
- All available data indicate that vasectomy is not associated with any serious, long-term, side effects (15).
- Vascetomy involving cauterisation and fascial interposition appears to be the most effective technique (12-14).

10.3 Vasectomy reversal

A wide range of surgical success rates has been published for vasectomy reversal (up to 90%), depending on the time between vasectomy and re-fertilisation, type of vasectomy (e.g. open-ended or sealed), type of reversal (vaso-vasostomy or vaso-epididymostomy), and whether reversal was unilateral or bilateral. However, there have been no randomised controlled trials comparing macrosurgery (loops) and microsurgery. Microsurgical techniques with the help of magnification and smaller suture materials should be used (20).

10.3.1 ***Length of time since vasectomy***

Vaso-vasostomy results have shown patency rates up to 90%. The longer the interval is from vasectomy to reversal, the lower is the pregnancy rate. In a study of 1,469 men who had undergone microsurgical vasectomy reversal, patency and pregnancy rates were 97% and 76%, respectively, for an interval up to 3 years after vasectomy, 88% and 53%, respectively, for 3-8 years, 79% and 44%, respectively, for 9-14 years, and 71% and 30%, respectively, for > 15 years (21).

10.3.2 ***Epididymo-vasostomy***

The chance of secondary epididymal obstruction after vasectomy increases with time. After an interval of 10 years, 25% of men appear to have epididymal blockage. If secondary epididymal obstruction occurs, epididymo-vasostomy is needed to reverse the vasectomy (*see above* Chapter 5: Obstructive azoospermia) (22).

10.3.3 ***Microsurgical vasectomy reversal versus epididymal or testicular sperm retrieval and ICSI***

According to the calculations of cost per delivery for vasectomy reversal versus sperm retrieval/ICSI, under a wide variety of initial assumptions, it is clear that vasectomy reversal is associated with a considerably lower cost per delivery and higher delivery rates (23,24). Sperm retrieval and ICSI must yield an 81% pregnancy rate per cycle to achieve equal costs to vasectomy reversal.

10.4 Conclusions and recommendations for male contraception

Conclusions
The most cost-effective approach to treatment of post-vasectomy infertility is microsurgical reversal. This procedure is also associated with the highest chance of pregnancy.
Pregnancy is still achievable after successful vasectomy reversal.
MESA/TESE/PESA (25) and ICSI should be reserved for failed vasectomy reversal surgery.
All available data indicate vasectomy is not associated with any serious, long-term, side effects (15).
Fascial interposition and cauterisation appears to be the most effective vasectomy technique (12-14).

Recommendations	**GR**
Patients seeking consultation about vasectomy must be informed about the surgical method, risk of failure, irreversibility, the need for post-procedure contraception until clearance, and the risk of complications.	C
Methods of male contraception other than vasectomy are associated with high failure rates or are still experimental (e.g. hormonal approach).	B
Microsurgical vasectomy reversal is a low-risk and (cost-) effective method of restoring fertility.	B

For couples wanting to achieve pregnancy, sperm aspiration together with ICSI is a second-line option for selected cases and in those with failed vaso-vasostomy.	B

11. MALE ACCESSORY GLAND INFECTIONS

11.1 Introduction

Infections of the male urogenital tract are potentially curable causes of male infertility (1-3). The WHO considers urethritis, prostatitis, orchitis and epididymitis to be male accessory gland infections (MAGIs) (2). However, specific data are not available to confirm that these diseases have a negative influence on sperm quality and male fertility in general.

11.2 Urethritis

Infectious, sexually acquired urethritis is caused by various pathogens, most often *Chlamydia trachomatis*, *Ureaplasma urealyticum*, and *Neisseria gonorrhoea* (4). Non-infectious causes of urethritis include irritations as a result of allergic reactions, trauma and manipulations. Urethral discharge and bladder voiding problems are the predominant symptoms of acute urethritis.

11.2.1 ***Diagnosis and treatment***

Diagnosis is based on the analysis of urethral smear and first-voided urine (VB1). Pathognomonic evidence is > 4 granulocytes per microscopic high-power field (×1000) in an urethral smear, or 15 granulocytes per microscopic field (×400) in the smear of the sediment of 3 mL VB1, is pathognomonic (4). In urethritis, defined by inflammatory discharge, semen analysis for disorders of male fertility is not possible because the anterior urethra is full of infectious and inflammatory material that hampers any useful analysis (5).

The impact of urethritis on semen quality and fertility has not been proven because the ejaculate is contaminated with inflammatory material from the urethra.

It is still debated whether infection with sexually transmitted micro-organisms has a negative effect on sperm function (1,6,7). Male fertility can be impaired by urethral strictures, ejaculatory disturbances (2), or the development of obstruction (8). Obstruction can develop as either a normal urethral stricture or a lesion in the posterior urethra in the area of the verumontanum, both of which can lead to ejaculatory disturbances and central obstruction of the seminal pathway (2).

The Centers for Disease Control and Prevention in Atlanta, GA, USA have published guidelines to standardise the treatment of sexually transmitted diseases (9). Because the aetiology of acute urethritis is usually unknown at the time of diagnosis, empirical therapy is used against potential pathogens. A single dose of a fluoroquinolone is given, followed by a 2-week regimen of doxycycline. Treatment is effective both for gonococcal and (co-existing) chlamydial/ureaplasmal infections.

11.3 Prostatitis

Prostatitis is the most common urological diagnosis in men < 50 years of age (10). Traditionally, prostatitis has been classified into four clinical entities:

- acute bacterial prostatitis (abp) and prostatic abscess as a sequela/complication of abp;
- chronic bacterial prostatitis (cbp);
- non- or abacterial prostatitis (nbp);
- prostatodynia.

To improve the definition and understanding of prostatitis, a classification system has been proposed by the National Institutes of Health (NIH) and the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) (10) (Table 12).

Table 12: NIH/NIDDK classification of prostatitis syndrome*

New NIH category	Clinical entity	Description
I	ABP	Acute infection of the prostate gland
II	CBP	Recurrent infection of the prostate
III	Chronic abacterial prostatitis/CPPS	No demonstrable infection
IIIA	Inflammatory CPPS	White cells in semen, expressed prostatic secretions or post-prostatic massage urine
IIIB	Non-inflammatory CPPS	No white cells in semen, expressed prostatic secretions or post-prostatic massage urine
IV	Asymptomatic inflammatory prostatitis	No subjective symptoms. Inflammation detected either by prostate biopsy or by the presence of white cells in expressed prostatic secretions or semen during evaluation for other disorders

** Adapted from Wagenlehner et al. (10).*
ABP = acute bacterial prostatitis; CBP = chronic bacterial prostatitis; CPPS = chronic pelvic pain syndrome.

11.3.1 ***Microbiology***

ABP (NIH I), CBP (NIH II) and, more significantly, prostatic abscesses are clinically relevant but uncommon diseases. The most common causes of bacterial prostatitis are Gram-negative bacteria, mainly strains of *Escherichia coli* (11). The role of Gram-positive bacteria in bacterial prostatitis is controversial. Although enterococci can cause bacterial prostatitis and associated recurrent urinary tract infection (UTI), the importance of other Gram-positive bacteria in chronic prostatitis is doubtful (11), as is that of *C. trachomatis* and *Mycoplasma*, particularly *U. urealyticum* (11-15). Hidden bacteria may be aetiologically involved in patients with chronic idiopathic prostatitis after exclusion of typical bacterial infection (16). Detection of bacteria by molecular techniques has not been evaluated definitively.

11.3.2 ***Diagnosis***

Symptoms must be evaluated using standardised scores, especially the NIH symptom score (17). Other investigative procedures include laboratory diagnosis of CBP using the four-specimen test for bacterial localisation (10,11), which measures sequential quantitative bacteriological cultures of the urethra, bladder urine and prostatic secretions, both in expressed prostatic excretion (EPS) and urine after prostatic massage (12).

Simplified techniques compare bacterial and leukocyte counts in the urine before and after prostatic massage (18). Screening of bladder voiding and imaging analysis of the prostate gland must be integrated.

The key to diagnosis is the demonstration of leukocytes in EPS, urine after prostatic massage and/or ejaculate to differentiate between inflammatory and non-inflammatory CPPS.

11.3.3 ***Ejaculate analysis***

An ejaculate analysis (*see* Chapter 2: Investigations) clarifies whether the prostate is involved as part of a generalised MAGI and provides information about sperm quality. In addition, leukocyte analysis allows differentiation between inflammatory and non-inflammatory CPPS (NIH IIa vs NIH IIIb).

11.3.4 ***Microbiological findings***

After exclusion of urethritis and bladder infection, > 10^6 peroxidase-positive white blood cells (WBCs) per millilitre of ejaculate indicate an inflammatory process. In this case, a culture should be made for common urinary tract pathogens, particularly Gram-negative bacteria.

A concentration of > 10^3 cfu/mL urinary tract pathogens in the ejaculate is indicative of significant bacteriospermia. Various micro-organisms are found in the genital tract of men seen in infertility clinics, usually with more than one strain of bacteria present (1). The sampling time can influence the positive rate of micro-organisms in semen and the frequency of isolation of different strains (19). The ideal diagnostic test for *C. trachomatis* in semen has not yet been established (14). In contrast to serological findings in women, antibody tests for *C. trachomatis* in seminal plasma are not indicative if no type-specific methods are used (14).

Ureaplasma urealyticum is pathogenic only in high concentrations (> 10^3 cfu/mL ejaculate). No more than about 10% of samples analysed for ureaplasma exceed this concentration (20). Normal colonisation of the urethra hampers the clarification of mycoplasma-associated urogenital infections, using samples such as the ejaculate (15).

11.3.5 ***White blood cells***

The clinical significance of an increased concentration of leukocytes in the ejaculate is controversial (21). Infection is indicated only by an increased level of leukocytes (particularly polymorphonuclear leukocytes) and their products (e.g. leukocyte elastase) secreted into the seminal fluid. Most leukocytes are neutrophilic granulocytes, as suggested by the specific staining of the peroxidase reaction (2). Although leukocytospermia is a sign of inflammation, it is not necessarily associated with bacterial or viral infections (7). Earlier findings have shown that elevated leukocyte numbers are not a natural cause of male infertility (22).
According to WHO classification, leukocytospermia is defined as > 10^6 WBCs/mL. Only two studies have analysed alterations of WBCs in the ejaculate of patients with proven prostatitis (23,24). Both studies found more leukocytes in men with prostatitis compared to those without inflammation (CPPS, type NIH IIIb).

11.3.6 ***Sperm quality***

The deleterious effects of chronic prostatitis on sperm density, motility and morphology are under debate (1). All investigations have given contradictory results, and have not confirmed that chronic prostatitis has a decisive role in altering conventional semen parameters (25-27).

11.3.7 ***Seminal plasma alterations***

Seminal plasma elastase is a biochemical indicator of polymorphonuclear lymphocyte activity in the ejaculate (1,28,29), with a suggested cut-off level of approximately 600 ng/mL (1). Various cytokines are involved in inflammation and can influence sperm function. Several studies have investigated the association between interleukin (IL) concentration, leukocytes and sperm function (30-32), but no correlations have been found. The prostate is the main site of origin of IL-6 in the seminal plasma. Cytokines, especially IL-6, play an important role in the male accessory gland inflammatory process (33). However, elevated cytokine levels do not depend on the number of leukocytes in EPS (34).

11.3.8 ***Glandular secretory dysfunction***

Infections of the sex glands can impair their excretory function. Decreased quantities of citric acid, phosphatase, fructose, zinc, and α-glutamyl-transferase activity are indicators of disturbed prostatic secretory parameters (1). Reduced fructose concentration indicates impaired vesicular function (20,35).

11.3.9 ***Sperm antibodies***

Serum antibodies to sperm antigens are not useful in the diagnosis of immune infertility. Early studies found an association between increased levels of sperm antibodies in serum and NBP (36,37). However, except for suspected chlamydial infections (38), only a history of vasectomy is predictive of sperm antibody formation (39).

11.3.10 ***Reactive oxygen species***

Reactive oxygen species might be increased in chronic urogenital infections associated with increased leukocyte numbers (40). However, their biological significance in prostatitis remains unclear (1).

11.3.11 ***Therapy***

Treatment of chronic prostatitis is usually targeted at relieving symptoms (10,41). Andrologically, the aims of therapy for altered semen composition in male adnexitis (acute and chronic infections of the male urogenital tract) are:

- reduction or eradication of micro-organisms in prostatic secretions and semen;
- normalisation of inflammatory (e.g. leukocytes) and secretory parameters;
- improvement of sperm parameters to counteract fertility impairment (42).

Treatment includes antibiotics, anti-inflammatory drugs, surgical procedures, normalisation of urine flow, physical therapy and alterations in general and sexual behaviour.

Only antibiotic therapy of CBP (NIH II) has provided symptomatic relief, eradication of microorganisms and a decrease in cellular and humoral inflammatory parameters in urogenital secretions. The use of alpha-blockers for symptom relief is controversial. Although antibiotics might improve sperm quality (42), there is no evidence that treatment of chronic prostatitis increases the probability of conception (1,43).

11.4 Orchitis and epididymo-orchitis

11.4.1 ***Introduction***

Orchitis is an inflammatory lesion of the testis associated with a predominantly WBC exudate inside and outside the seminiferous tubules, which potentially results in tubular sclerosis. The inflammation causes pain and swelling. Chronic inflammatory alterations in the seminiferous tubules disrupt the normal process

of spermatogenesis and alter sperm number and quality (44). Orchitis might also be an important cause of spermatogenetic arrest (45), which might be reversible in most cases. Testicular atrophy can develop as a result of tubular sclerosis (45).

11.4.2 ***Diagnosis***

Epididymo-orchitis usually presents with unilateral scrotal pain (46). Diagnosis is based on past medical history and palpation. Ultrasonography usually indicates a swollen, enlarged testis. The sonographic features of the tissue do not allow any differential diagnosis (47).

11.4.3 ***Ejaculate analysis***

Ejaculate analysis, including leukocyte analysis, indicates persistent inflammatory activity. In many cases, especially in acute epididymo-orchitis, transiently decreased sperm counts and reduced forward motility occur (44,46). Obstructive azoospermia caused by complete obstruction is a rare complication. Mumps orchitis can result in bilateral testicular atrophy (45) and non-obstructive azoospermia. When granulomatous orchitis is suspected, sperm-bound autoantibodies occur.

11.4.4 ***Therapy***

Only therapy of acute bacterial epididymo-orchitis and of specific granulomatous orchitis is standardised (45) (Table 13). Several regimens improve the inflammatory lesion. Unfortunately, corticosteroids and non-steroidal anti-inflammatory agents (e.g. diclofenac, indomethacin, acetylsalicylic acid) have not been evaluated for their andrological outcome (47). In mumps orchitis, systemic therapy with interferon α-2b prevents testicular atrophy and azoospermia (50). In idiopathic granulomatous orchitis, surgical removal of the testis is the therapy of choice.

Table 13: Treatment of epididymo-orchitis

Condition and pathogen	**Treatment**
Acute bacterial epididymo-orchitis	
N. gonorrhoeae	Tetracyclines
C. trachomatis	Tetracyclines
E. coli, Enterobacteriaceae	Fluoroquinolones
Mumps orchitis	Interferon α-2b
Non-specific chronic epididymo-orchitis	Steroidal and non-steroidal inflammatory agents
Granulomatous (idiopathic) orchitis	Semi-castration
Specific orchitis	According to therapy of underlying diseases

11.5 Epididymitis

11.5.1 ***Introduction***

Inflammation of the epididymis causes unilateral pain and swelling, usually with acute onset. Among sexually active men < 35 years of age, epididymitis is most often caused by *C. trachomatis* or *N. gonorrhoea* (51,52). Sexually transmitted epididymitis is usually accompanied by urethritis. Non-sexually transmitted epididymitis is associated with UTI and occurs more often in men aged > 35 years, those who have recently undergone urinary tract instrumentation or surgery, and those who have anatomical abnormalities (52).

11.5.2 ***Diagnosis***

In acute epididymitis, inflammation and swelling usually start in the tail of the epididymis and can spread to involve the rest of the epididymis and testicular tissue (46). Although men with epididymitis caused by sexually transmitted micro-organisms always have a history of sexual activity, exposure could have occurred several months before onset. The microbial aetiology of epididymitis is usually easy to determine by Gram-stained examination of both a urethral smear for urethritis and of a mid-stream urine specimen for Gram-negative bacteriuria (51,52). Intracellular Gram-negative diplococci on the smear indicate the presence of *N. gonorrhoea*. Only WBCs on urethral smear indicate non-gonorrhoeal urethritis; *C. trachomatis* will be isolated in about two-thirds of these patients (53).

11.5.3 ***Ejaculate analysis***

Ejaculate analysis according to WHO criteria, including leukocyte analysis, might indicate persistent inflammatory activity. In many cases, transiently decreased sperm counts and forward motility are observed

(46,48,51). Ipsilateral low-grade orchitis (54,55) might be the cause of this slight impairment in sperm quality (Table 14) (56).

Development of stenosis in the epididymal duct, reduction of sperm count and azoospermia are more important in the follow-up of bilateral epididymitis *(see* Chapter 5: Obstructive azoospermia). The extent of azoospermia after epididymitis is unclear.

Table 14: Acute epididymitis and impact on sperm parameters.

Authors	Negative influence			
	Density	**Motility**	**Morphology**	**Comment**
Ludwig & Haselberger (57)	+	+	+	Pyospermia in 19 of 22 cases
Berger *et al*. (51)		+		
Weidner *et al*. (47)	+	+	+	Azoospermia in 3 of 70 men
Haidl (58)		+		Chronic infections; macrophages elevated
Cooper *et al*. (59)				Decrease in epididymal markers: α-glucosidase, L-carnitine

11.5.4 ***Treatment***

Antibiotic therapy is indicated before culture results are available (Table 13). Treatment of epididymitis results in:

- microbiological cure of infection;
- improvement of clinical signs and symptoms;
- prevention of potential testicular damage;
- prevention of transmission;
- decrease of potential complications (e.g. infertility or chronic pain).

Patients with epididymitis known or suspected to be caused by *N. gonorrhoea* or *C. trachomatis* must be told to refer their sexual partners for evaluation and treatment (60).

11.6 Conclusions and recommendations for male accessory gland infections

Conclusions
Urethritis and prostatitis are not associated clearly with male infertility.
Antibiotic treatment often only eradicates micro-organisms; it has no positive effect on inflammatory alterations, and cannot reverse functional deficits and anatomical dysfunction.

Recommendations	**GR**
In most cases, the aetiology of acute urethritis is unknown at the time of diagnosis; empirical therapy is therefore suggested using a single dose of a fluoroquinolone, followed by a 2-week regimen of doxycycline. Treatment is effective both for gonococcal and (co-existing) chlamydial/ureaplasmal infections (9).	B
Antibiotic therapy of (chronic) bacterial prostatitis has been shown to provide symptomatic relief, eradication of micro-organisms, and a decrease in cellular and humoral inflammatory parameters in urogenital secretions (61-64).	B
Although antibiotic procedures for MAGI might provide improvement in sperm quality, therapy does not necessarily enhance the probability of conception (1,43).	B
Patients with epididymitis that is known or suspected to be caused by *N.* gonorrhoea or *C. trachomatis* must be instructed to refer their sexual partners for evaluation and treatment (60).	B

12. GERM CELL MALIGNANCY AND TESTICULAR MICROCALCIFICATION

12.1 Germ cell malignancy and male infertility

Testicular germ cell tumour (TGCT) is the most common malignancy in Caucasian men aged 15-40 years and affects approximately 1% of subfertile men. The lifetime risk of TGCT varies between ethnic groups and countries. The highest annual incidence of TGCT occurs in Caucasians, and varies from 10/100,000 (e.g. in Denmark and Norway) to 2/100,000 (e.g. in Finland and the Baltic countries). Generally, seminomas and non-seminomas are always preceded by CIS, and untreated germ cell neoplasia of unclassified type ([ITGCNU] former CIS) will eventually progress to invasive cancer (1,2).

The most convincing evidence for a general decline in male reproductive health is the increase in testicular cancer seen in Western countries (3). In almost all countries with reliable cancer registers, the incidence of testicular cancer has increased (4). Cryptorchidism and hypospadias are associated with an increased risk of testicular cancer; men with cryptorchidism and/or hypospadias are over-represented among patients with testicular cancer.

Men with dysgenic testes have an increased risk of developing testicular cancer in adulthood. These cancers arise from premalignant gonocytes or CIS cells (5). Testicular microlithiasis, seen on ultrasound, can be associated with germ cell tumours and CIS of the testis.

12.2 Testicular germ cell cancer and reproductive function

Men with TGCT have decreased semen quality, even before cancer is diagnosed (6). Orchidectomy implies a risk of azoospermia in these men, with sperm found in the ejaculate before the tumour-bearing testis has been removed. Semen cryopreservation before orchidectomy should therefore be considered (*see* Chapter 14: Semen cryopreservation). Treatment of TGCT can result in additional impairment of semen quality (7).

In addition to spermatogenic failure, patients with TGCT have Leydig cell dysfunction, even in the contralateral testis (8). The risk of hypogonadism may therefore be increased in men treated for TGCT. The measurement of pretreatment levels of testosterone, SHBG, LH and oestradiol might help to anticipate post-treatment hypogonadism. Men who have had TGCT and have low normal androgen levels should receive long-term follow-up because they are at risk of developing hypogonadism as a result of an age-related decrease in testosterone production (9).

The risk of hypogonadism is most pronounced in TGCT patients treated with $\geq$ 3 cycles of chemotherapy and in patients who have received irradiation of retroperitoneal lymph nodes. However, this risk is greatest at 6-12 months post-treatment. This suggests there may be some improvement in Leydig cell function, and why it is reasonable to expect initiation of androgen replacement, until the patient shows continuous signs of testosterone deficiency, even at 2 years' follow-up (10). Even the risk of low libido and erectile dysfunction is increased in TGCT patients (11).

12.3 Testicular microlithiasis

Microcalcification inside the testicular parenchyma can be found in 0.6-9% of men referred for testicular ultrasound (12-14). Although the true incidence of microcalcification in the general population is unknown, it is probably rare. However, ultrasound findings of testicular microlithiasis (TM) are common in men with TGCT, cryptorchidism, testicular dysgenesis, infertility, testicular torsion and atrophy, Klinefelter's syndrome,

hypogonadism, male pseudohermaphroditism, varicocele, epididymal cysts, pulmonary microlithiasis and non-Hodgkin's lymphoma. The incidence reported seems to be higher with high-frequency ultrasound machines (16).

The relationship between TM and infertility is unclear, but probably relates to dysgenesis of the testes, with degenerate cells being sloughed inside an obstructed seminiferous tubule and failure of the Sertoli cells to phagocytose the debris. Subsequently, calcification occurs.

Testicular microlithiasis is found in testes at risk of malignant development. The reported incidence of TM in men with TGCT is 6-46% (17-19), and TM should therefore be considered premalignant. Testicular biopsies from men with TM have found a higher prevalence of CIS, especially in those with bilateral microlithiasis (20). However, TM is found most often in men with a benign testicular condition and the microcalcification itself is not malignant.

Further investigation of the association between TM and CIS will require testicular biopsies in large series of men without signs of a TGCT. However, available data indicate that men in whom TM is found by ultrasound, and who have an increased risk of TGCT, should be offered testicular biopsy for detection of CIS. The list of high-risk patients includes men with infertility and bilateral TM, atrophic testes, undescended testes and those with a history of TGCT, and contralateral TM (21).

12.4 Recommendations for germ cell malignancy and testicular microcalcification

Recommendations	GR
It is important to encourage and educate patients with TM about self-examination, as this might result in early detection of TGCT.	B
Testicular biopsy should be offered to men with TM, who belong to one of the following high-risk groups: infertility and bilateral TM, atrophic testes, undescended testes, and men with a history of TGCT and contralateral TM (21).	B
If there are suspicious findings on physical examination or ultrasound in patients with TM and associated lesions, surgical exploration with testicular biopsy or orchidectomy should be considered.	B
Testicular biopsy, follow-up scrotal ultrasound, routine use of biochemical tumour markers, or abdominal or pelvic computed tomography is not justified for men with isolated TM without associated risk factors (e.g. infertility, cryptorchidism, testicular cancer, atrophic testis) (15).	B
Men with TGCT are at increased risk of developing hypogonadism and sexual dysfunction and should therefore be followed up (10,11).	B

TGCT = testicular germ cell tumour; TM = testicular microlithiasis

13. DISORDERS OF EJACULATION

13.1 Definition

Disorders of ejaculation are uncommon, but important, causes of male infertility. This group includes several heterogeneous dysfunctions, which can be either organic or functional.

13.2 Classification and aetiology

*13.2.1 **Anejaculation***

Anejaculation involves complete absence of antegrade or retrograde ejaculation and is caused by failure of emission of semen from the seminal vesicles, the prostate and the ejaculatory ducts into the urethra (1). True anejaculation is usually associated with a normal orgasmic sensation. Occasionally (e.g. in incomplete spinal cord injuries), this sensation is altered or decreased. True anejaculation is always associated with central or

peripheral nervous system dysfunction or with drugs (2) (Table 15).

Table 15: Aetiology of anejaculation

Neurogenic	**Drug-related**
Spinal cord injury	Antihypertensives
Cauda equina lesion	Antipsychotics
Retroperitoneal lymphadenectomy	Antidepressants
Aortoiliac or horseshoe-kidney surgery	Alcohol
Colorectal surgery	
Multiple sclerosis	
Parkinson's disease	
Autonomic neuropathy (diabetes mellitus)	

13.2.2 ***Anorgasmia***

Anorgasmia is the inability to reach orgasm and can give rise to anejaculation. Anorgasmia is often a primary condition and its cause is usually psychological. Some patients report sporadic events of nocturnal emission or of ejaculation occurring during great emotional excitement unrelated to sexual activity (3).

13.2.3 ***Delayed ejaculation***

In delayed ejaculation, abnormal stimulation of the erect penis is needed to achieve orgasm with ejaculation (1). Delayed ejaculation can be considered a mild form of anorgasmia, and both conditions can be found alternately in the same patient. The causes of delayed ejaculation can be psychological or organic, e.g. incomplete spinal cord lesion (3), iatrogenic penile nerve damage (4), or pharmacological, e.g. antidepressants, antihypertensives, antipsychotics (5).

13.2.4 ***Retrograde ejaculation***

Retrograde ejaculation is the total, or sometimes partial, absence of antegrade ejaculation as a result of semen passing backwards through the bladder neck into the bladder. Patients experience a normal or decreased orgasmic sensation, except in paraplegia. Partial antegrade ejaculation must not be confused with the secretion of bulbo-urethral glands. The causes of retrograde ejaculation can be divided into neurogenic, pharmacological, urethral, or bladder neck incompetence (Table 16).

Table 16: Aetiology of retrograde ejaculation

Neurogenic	**Pharmacological**
Spinal cord injury	Antihypertensives
Cauda equina lesions	α1-adrenoceptor antagonists
Multiple sclerosis	Antipsychotics
Autonomic neuropathy (juvenile diabetes)	Antidepressants
Retroperitoneal lymphadenectomy	**Bladder neck incompetence**
Sympathectomy	Congenital defects/dysfunction of hemitrigone
Colorectal and anal surgery	Bladder extrophy
Urethral	Bladder neck resection
Ectopic ureterocele	Prostatectomy
Urethral stricture	
Urethral valves or verumontaneum hyperplasia	
Congenital dopamine β-hydroxylase deficiency	

13.2.5 ***Asthenic ejaculation***

Asthenic ejaculation, also defined as partial ejaculatory incompetence or 'ejaculation baveuse' (5), is characterised by an altered propulsive phase, with a normal emission phase. The orgasmic sensation is reduced and the typically rhythmical contractions associated with ejaculation are missing, whereas in asthenic

ejaculation caused by urethral obstruction, these contractions are present. Asthenic ejaculation generally is caused by the neurogenic or urethral pathologies already listed in Table 16. Asthenic ejaculation does not usually affect semen quality.

13.2.6 ***Premature ejaculation***

Premature ejaculation is the inability to control ejaculation for a sufficient length of time during vaginal penetration. Although a universally accepted definition of sufficient length of time does not exist, some patients are unable to delay ejaculation beyond a few coital thrusts, or even after vaginal penetration. Premature ejaculation may be strictly organic (e.g. prostatitis-related) or psychogenic, primary or acquired, partner-related or non-selective, and can be associated with erectile dysfunction. Premature ejaculation does not impair fertility, provided intravaginal ejaculation occurs. For more extensive discussion on this topic, the EAU Male Sexual Dysfunction guidelines should be consulted.

13.2.7 ***Painful ejaculation***

Painful ejaculation is usually an acquired condition that is often related to lower urinary tract symptoms (6). It sometimes causes moderate sexual dysfunction. The painful sensation might be felt in the perineum, or urethra and urethral meatus (7). It can be caused by ejaculatory duct obstruction, all types of chronic prostatitis/CPPS, urethritis, urethrocele, antidepressant drugs, and psychological problems.

13.3 Diagnosis

Diagnostic management includes the following recommended procedures.

13.3.1 ***Clinical history***

The patient must be carefully checked for diabetes, neuropathy, trauma, urogenital infection, previous surgery, and medication. Particular attention must be paid to the characteristics of micturition and ejaculation (presence of nocturnal emission, ejaculatory ability in given circumstances, primary or acquired disorder), as well as to psychosexual aspects (education, features of affective relationship, pre-existent psychological trauma, previous psychological therapy).

13.3.2 ***Physical examination***

Genital and rectal examinations are conducted, including evaluation of the prostate, bulbo-cavernosus reflex and anal sphincter tone. Minimal neurological tests include:

- sensitivity of scrotum, testes, and perineum
- cremasteric and abdominal cutaneous reflex
- leg osteotendinous and plantar reflexes.

13.3.3 ***Post-ejaculatory urinalysis***

Post-ejaculatory urinalysis can be used to determine if there is total or partial retrograde ejaculation.

13.3.4 ***Microbiological examination***

Initial, mid-stream urine, EPS and/or urine after prostatic massage are cultured for evidence of prostatic infection. In cases of increased leukocytes in semen, semen culture is also suggested (8).

13.3.5 Optional diagnostic work-up

This diagnostic workup can include:

- neurophysiological tests (bulbocavernosus evoked response and dorsal nerve somatosensory evoked potentials);
- tests for autonomic neuropathy;
- psychosexual evaluation;
- video-cystometry;
- cystoscopy;
- transrectal ultrasonography;
- uroflowmetry;
- vibratory stimulation of the penis.

13.4 Treatment

Infertility caused by disorders of ejaculation is seldom treated on the basis of aetiology. Treatment usually involves retrieving spermatozoa for use in assisted reproduction techniques (ARTs). The following aspects must be considered when selecting treatment:

- age of patient and his partner;

- psychological problems of the patient and his partner;
- couple's willingness and acceptance of different fertility procedures;
- associated pathology;
- psychosexual counselling.

13.5 Aetiological treatment

If possible, any pharmacological treatment that is interfering with ejaculation should be stopped. In painful ejaculations, tamsulosin can be administered during antidepressant treatment (9). Treatment should be given for urogenital infections (i.e. in cases of painful ejaculation) (8). Dapoxetin, a selective serotonin re-uptake inhibitor (SSRI) has been introduced for the therapy of premature ejaculation (PE) (10), since it appears that PE is related to serotonin levels. If possible, any underlying urethral pathology or metabolic disorder (e.g. diabetes) should be corrected. Psychotherapy is usually not very effective.

13.6 Symptomatic treatment

13.6.1 ***Premature ejaculation (PE)***

Premature ejaculation can be treated with the selective SSRI dapoxetine, topical anaesthetic agents to increase intravaginal ejaculation latency time, behavioural therapy and/or psychotherapy. Off-label use of SSRIs (e.g. paroxetine, fluoxetine) should be applied with caution.

13.6.2 ***Retrograde ejaculation***

In the absence of spinal cord injury, anatomical anomalies of the urethra, or pharmacological agents, drug treatment must be used to induce antegrade ejaculation (Table 17). Alternatively, the patient can be encouraged to ejaculate when his bladder is full to increase bladder neck closure (11).

Table 17: Drug therapy for retrograde ejaculation

Drug	Dosage regimen	Ref.
Ephedrine sulphate	10-15 mg four times daily	12
Midodrin	5 mg three times daily	13
Brompheniramine maleate	8 mg twice daily	14
Imipramine	25-75 mg three times daily	15
Desipramine	50 mg every second day	16

Sperm collection from post-orgasmic urine for use in ART is recommended if:

- drug treatment is ineffective or intolerable as a result of side effects;
- the patient has a spinal cord injury;
- drug therapy inducing retrograde ejaculation cannot be interrupted.;

Sperm retrieval is timed to coincide with the partner's ovulation. Urine must be alkalinised (pH 7.2-7.8) and osmolarity must be 200-300 mOsmol/kg. The patient is asked to have intercourse or to masturbate. Within 10 minutes after ejaculation, urine must be voided and centrifuged, and the pellet resuspended in 0.5 mL Tyrode's or Ham's F-10 medium, and immediately inseminated (17). Alternatively, a catheter can be applied to the bladder and 10-50 mL Tyrode's or Ham's F-10 medium instilled into the bladder. The patient must ejaculate, and a second catheterisation is carried out immediately to retrieve spermatozoa. The latter treatment minimises contact between spermatozoa and urine (18). If the biological sperm preparation is not of sufficient quality for intrauterine insemination, the couple must undergo *in vitro* reproductive procedures (i.e. ICSI) with fresh orcryopreserved spermatozoa.

13.6.3 ***Anejaculation***

Drug treatment for anejaculation caused by lymphadenectomy and neuropathy or psychosexual therapy in anorgasmic men is not very effective. In all these cases, and in men who have a spinal cord injury, vibrostimulation (i.e. the application of a vibrator to the penis) is first-line therapy.

In anejaculation, vibrostimulation evokes the ejaculation reflex (19), which requires an intact lumbosacral spinal cord segment. Complete spinal injuries and injuries above T10 show a better response to vibrostimulation. Once the safety and efficacy of this procedure has been assessed, patients can manage the process in their own home. Intravaginal insemination using a 10-mL syringe during ovulation can be carried out. If the quality of semen is poor, or ejaculation is retrograde, the couple may enter an IVF programme.

If vibrostimulation has failed, electro-ejaculation is the therapy of choice (20). Electro-ejaculation

involves electric stimulation of the periprostatic nerves via a probe inserted into the rectum, which seems unaffected by reflex arc integrity. Anaesthesia is required except in cases of complete spinal cord injury. In 90% of patients, electrostimulation induces ejaculation, which is retrograde in one-third of cases. Semen quality is often poor and most couples will need to enter an IVF programme (21).

When electro-ejaculation fails or cannot be carried out, sperm can be retrieved from the seminal ducts by aspiration from the vas deferens (22) (*see* Chapter 5 Obstructive azoospermia) or seminal tract washout (23).

When sperm cannot be retrieved, epididymal obstruction or testicular failure must be suspected. TESE can then be used (8,24). Anejaculation following either surgery for testicular cancer or total mesorectal excision can be prevented using monolateral lymphadenectomy or autosomic nerve preservation (24), respectively.

13.7 Conclusion and recommendations for disorders of ejaculation

Conclusion
Ejaculation disorders can be treated using a wide range of drugs and physical stimulation, with a high level of efficacy.

Recommendations	**GR**
Aetiological treatments for ejaculatory disorders should be offered before sperm collection and ART is performed.	B
Premature ejaculation can be treated successfully with either topical anaesthetic creams or SSRIs (22).	A
In men with spinal cord injury, vibrostimulation and electro-ejaculation are effective methods of sperm retrieval.	B

14. SEMEN CRYOPRESERVATION

14.1 Definition

Cryopreservation is the storage of biological material at subzero temperatures [e.g. -80°C or -196°C (the boiling point of liquid nitrogen)], at which biochemical processes of cell metabolism are slowed or interrupted. At -196°C, the biochemical reactions that lead to cell death are stopped.

14.2 Introduction

Cryopreservation was first developed in the 1940s by veterinarians and adapted for human sperm in the 1950s. The first pregnancy that used cryopreservation took place in 1954 (1). In fertility practice, clinical indications for cryopreservation include storage of sperm, testicular and ovarian tissue and early embryos.

14.3 Indications for storage

Storage of sperm is available in many clinics for the following indications:

- Before potentially sterilising chemotherapy or radiotherapy for cancer (2) or for non-malignant diseases.
- Before surgery that might interfere with fertility (e.g. bladder neck surgery in a younger man or removal of a testical in a man with testicular malignancy, before vasectomy).
- For men with progressive decrease in semen quality as a result of diseases that have an associated

risk of subsequent azoospermia (i.e. pituitary macroadenoma, Craniopharyngioma, empty sella syndrome, chronic nephropathy, uncontrolled diabetes mellitus, multiple sclerosis).

- For men with paraplegia when sperm have been obtained by electro-ejaculation or obtained by using penile vibratory stimulation.
- For men with psychogenic anejaculation, after sperm have been obtained either by electro-ejaculation or a sperm retrieval procedure.
- After gonadotrophin treatment has induced spermatogenesis in men with hypogonadotrophic hypogonadism.
- For men with NOA, the chance of finding sperm using micro-TESE is approximately 60-70%. Cryopreservation can be used to separate sperm collection from ICSI, thus avoiding unnecessary hyperstimulation of the female partner. It can also be used to avoid repeated sperm retrieval procedures.
- In any situation where sperm have been obtained by a sperm retrieval procedure (e.g. after failed vasectomy reversal, or in some cases of epididymal obstruction not amenable to surgery).
- For storage of donor sperm, because cryopreservation and a quarantine period of 3-6 months reduces the risk of transmission of infection from sperm donors; in most countries, fresh sperm are no longer used.

14.4 Precautions and techniques

14.4.1 ***Freezing and thawing process***

The cryopreservation techniques currently used are not yet optimal as damage occurs to cells during cryopreservation and prolonged storage. Most damage occurs during freezing and thawing. Major causes of damage during freezing are ice crystal formation and cell dehydration that disrupt the cell wall and intracellular organelles. Sperm morphology, motility and vitality decrease significantly after thawing, and cryopreservation increases the damage done to sperm DNA (3-6). Further damage can be caused by contamination of samples with micro-organisms and high levels of superoxide radicals (7,8). To reduce ice crystal formation, a cryopreservation solution is added before freezing. Various cryopreservation solutions are available commercially, most of which contain varying proportions of glycerol and albumen. After freezing, the tissues are immersed in liquid nitrogen.

Several techniques have been developed to try to reduce damage caused by freezing and thawing, including:

- Rapid method (9,10): sample is held in the vapour phase for 10 minutes before being plunged into liquid nitrogen.
- Slow method (11): sample is gradually cooled in the vapour phase for approximately 40 minutes.
- Programmable automatic freezing machine, which is preset to cool at a rate of 1-10°C/min, is used.

The method available depends on the resources of the laboratory. Whichever freezing technique is used, it should be tested using donor sperm and post-thaw examination, and should regularly undergo a quality-control programme.

The likelihood of sperm survival decreases with increased storage time and repeated freezing and thawing. The maximum viable storage time for human sperm is not known. Many laboratory or regulatory authorities apply a storage time limit of up to 10 years (12). However, longer storage times are sometimes needed (e.g. for a 17-year-old man who has had sperm stored before undergoing chemotherapy for testicular cancer).

14.4.2 ***Cryopreservation of very small numbers of sperm***

Standard cryopreservation in straws is an efficient way of storing large number of sperm (e.g. for a donor insemination programme). However, in micro-TESE, very few sperm might be obtained, and the choice is either to freeze testicular tissue and find sperm after thawing the tissue, or to freeze very small numbers of sperm. If sperm are frozen in straws, it can be very difficult to find any sperm after thawing. Instead, the sperm should be frozen in a pellet (13) or in a container (14).

14.4.3 ***Testing for infections and preventing cross-contamination***

Sperm storage in straws is used extensively. Large numbers of straws are stored in canisters, with the straws being bathed in a pool of liquid nitrogen. Microbial contamination of the pool of liquid nitrogen results in contamination of the outside of all the straws. The most widely used safeguard is to accept samples for storage only from patients whose semen samples have been tested for infection and confirmed as safe. Donor samples should be tested for viral (hepatitis B and C, human immunodeficiency virus [HIV]) and sexually transmitted (*C. trachomatis*, gonorrhoea, syphilis) infections.

Until the test results are known, samples must be stored in an individual quarantine vessel (15)

(http://www.hfea.gov.uk/docs/8th_Code_of_Practice(2).pdf) [acces date December 2011]. Some laboratories use the additional safeguard of double-wrapping the straws before freezing, although this is more costly and can interfere with the freezing process, thus reducing sample quality upon thawing. Some centres carry out cytomegalovirus (CMV) testing and store CMV-negative and CMV-positive samples separately.

Considerable ethical issues surround the storage of samples before cancer chemotherapy for a man who is hepatitis-virus- or HIV-positive. Very few clinics have separate storage facilities for HIV-positive samples. However, the success of antiretroviral treatment is increasing the number of HIV-positive men who may wish to store sperm. There is also concern about HIV transmission to children conceived using HIV-positive sperm, as sperm-washing techniques fail in about 5%.

14.4.4 ***Fail-safe precautions to prevent loss of stored materials***

Any laboratory that undertakes long-term storage of human biological materials should have procedures that guard against accidental loss of material caused by storage vessel failure. This is particularly important for sperm stored before potentially sterilising cancer chemotherapy because these patients may not be able to obtain further sperm. The level of precaution depends on the cost and resources available to the laboratory, but if possible the following safeguards should be in place:

- All in-use storage vessels should be fitted with an alarm system that is activated by rising temperature or liquid nitrogen leakage.
- The alarm system should alert a laboratory staff member, according to a 24-h, 365-day rota.
- Ideally, there should be a spare storage container, in which samples can be transferred following a vessel failure.

14.4.5 ***Orphan samples***

In malignancy and some other situations, several years might pass before stored samples are required. Inevitably, during this time, the owners of some samples might disappear or die, leaving behind orphan samples for which the owner is no longer contactable. The duty of the laboratory and the legal ownership of these samples can create considerable problems.

It is best to obtain instructions from the owner of the sample at the time of, or very shortly after storage, about what to do with the sample in the event of death or untraceability. In some countries, owners are legally required to provide instructions/consent. Choices available for the owner of the sample depend on the laws of the country, might not be appropriate in all situations, and include:

- a request that the sample should be destroyed;
- use of the sample by their wife or partner;
- use of the sample in research;
- donation of the sample to help another infertile couple.

14.5 Biological aspects

Cryopreservation induces deterioration of the seminal quality. After the sample has been thawed, motility (16) and morphology (17,18) are worsened, including mitochondrial acrosomal and sperm tail damage (19). Sperm freezing decreases motility by 31% and mitochondrial activity by 36%, and causes morphological disruption in 37% of sperm (9). Motility is correlated best with IVF capacity of the thawed sample. Further improvement can be achieved by selecting the subpopulation of sperm with the best motility and DNA integrity and freezing these sperm in seminal plasma (13).

14.6 Conclusions and recommendations for semen cryopreservation

Conclusions
The purpose of sperm cryopreservation is to enable future ART procedures.
Cryopreservation techniques are not optimal, and future efforts are needed to improve the outcome of sperm banking.
Cryopreservation should be offered and explained in patients with specific diseases, or before a patient undergoes surgery, chemotherapy or radiotherapy that might damage his reproductive integrity.
If testicular biopsies are indicated, sperm cryopreservation is strongly advised.

Recommendations	GR
Cryopreservation of semen should be offered to all men who are candidates for chemotherapy, radiation or surgical interventions that might interfere with spermatogenesis or cause ejaculatory disorders.	B
If cryopreservation is not available locally, patients should be advised about the possibility of visiting, or transferring to, the nearest cryopreservation unit before therapy starts.	C
Consent for cryopreservation should include a record of the man's wishes for his samples if he dies or is otherwise untraceable.	C
Precautions should be taken to prevent transmission of viral, sexually transmitted or any other infection by cryostored materials from donor to recipient, and to prevent contamination of stored samples. These precautions include testing of the patient and the use of rapid testing and quarantine of samples until test results are known. Samples from men who are positive for hepatitis virus or HIV should not be stored in the same container as samples from men who have been tested and are free from infection.	C

15. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

ABP	acute bacterial prostatitis
ART	assisted reproduction techniques
CAIS	complete androgen insensitivity syndrome
CBAVD	congenital bilateral absence of the vas deferens
CBP	chronic bacterial prostatitis
CF	cystic fibrosis
CFTR	cystic fibrosis transmembrane conductance regulator
CIS	carcinoma *in situ*
CMV	cytomegalovirus
CPPS	chronic pelvic pain syndrome
EAA	European Academy of Andrology
EPS	espressed prostatic excretion
FISH	(multicolour) fluorescent *in situ* hybridisation
FSH	follicle-stimulating hormone
GnRH	gonadotrophin-releasing hormone
GR	grade of recommendation
GREAT	G-protein-coupled receptor affecting testis descent
hCG	human chorionic gonadotrophin
HIV	human immunodeficiency virus
ICSI	intracytoplasmic sperm injection
IHH	idiopathic hypogonadotrophic hypogonadism
IL-6	interleukin-6
ITGCNU	intratubular germ cell neoplasia of unclassified type
IVF	in vitro fertilisation
LE	level of evidence
LH	luteinising hormone
MAGI	male accessory gland infection
MAR	mixed antiglobulin reaction
MESA	microsurgical epididymal sperm aspiration
NBP	non- or abacterial prostatitis
NIDDK	National Institute of Diabetes and Digestive and Kidney Diseases
NIH	National Institutes of Health
NOA	non-obstructive azoospermia
OA	obstructive azoospermia
OAT	oligo-astheno-teratozoospermia [syndrome]
PE	premature ejaculation
PGD	preimplantation genetic diagnosis
SHBG	sex hormone binding globulin
SSRIs	selective serotonin reuptake inhibitors
TDS	testicular dysgenesis syndrome
TEFNA	testicular fine-needle aspiration
TESE	testicular sperm extraction
TGCT	testicular germ cell tumour
TM	testicular microlithiasis
TRUS	transurethral ultrasound
TURED	transurethral resection of the ejaculatory ducts
UTI	urinary tract infection
WBC	white blood cell
VB1	first-voided urine
WHO	World Health Organization

Conflict of interest

All members of the Male Infertility guidelines writing panel have provided disclosure statements of all relationships they have that may be perceived as a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on
Male Hypogonadism

TABLE OF CONTENTS PAGE

1. INTRODUCTION AND DEFINITION

Definition: male hypogonadism is a clinical syndrome caused by androgen deficiency which may adversely affect multiple organ functions and quality of life (1).

Androgens play a crucial role in the development and maintenance of male reproductive and sexual functions. Low levels of circulating androgens can cause disturbances in male sexual development, resulting in congenital abnormalities of the male reproductive tract. Later in life, this may cause reduced fertility, sexual dysfunction, decreased muscle formation and bone mineralisation, disturbances of fat metabolism, and cognitive dysfunction. Testosterone levels decrease as a process of ageing: signs and symptoms caused by this decline can be considered a normal part of ageing. However, low testosterone levels are also associated with several chronic diseases, and symptomatic patients may benefit from testosterone treatment.

This document presents the European Association of Urology (EAU) guidelines on diagnosis and treatment of male hypogonadism. This guideline aims to provide practical recommendations on how to deal with primary low testosterone and ageing-related decline in testosterone in male patients, as well as the treatment of testosterone disruption and deficiencies caused by other illnesses.

2. METHODOLOGY

The EAU Male Hypogonadism panel consists of a multidisciplinary group of experts, including urologists specialising in the treatment of infertility, endocrinologists and andrologists. There is a need for ongoing re-evaluation of the information presented in the current guideline by an expert EAU panel. It must be emphasised that clinical guidelines present the best evidence available to the experts at the time of writing. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when treatment decisions for individual patients are being taken. Guidelines help to focus decisions. Clinical decisions must also take into account patients' personal values and preferences and their individual circumstances.

2.1 Data identification

The recommendations provided in the current guidelines are based on a systematic literature search performed by the panel members. MedLine, Embase and Cochrane databases were searched to identify original articles and review articles. The controlled vocabulary of the Medical Subject Headings (MeSH) database was used alongside a 'free-text' protocol, combining 'male hypogonadism' with the terms 'diagnosis', 'epidemiology', 'investigations', 'treatment', 'testosterone', 'androgens' and 'hypogonadism'.

All articles published before January 2012 were considered for review. The expert panel reviewed these records and selected articles with the highest level of evidence in accordance with a rating schedule adapted from the Oxford Centre for Evidence-Based Medicine levels of evidence.

2.2 Levels of evidence and grades of recommendation

References used in the text have been assessed according to their level of scientific evidence (Table 1). Guideline recommendations have been graded (Table 2) in accordance with the Oxford Centre for Evidence-Based Medicine levels of evidence (LE) (1). The aim of grading recommendations (GR) is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Levels of evidence*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials.
1b	Evidence obtained from at least one randomised trial.
2a	Evidence obtained from one well-designed controlled study without randomisation.
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study.

3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports.
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities.

** Modified from Sackett et al. (1).*

It should be noted that when recommendations are graded, there is not an automatic relationship between the level of evidence and the grade of recommendation. The availability of RCTs may not necessarily translate into a grade A recommendation if there are methodological limitations or disparities in the published results. Conversely, an absence of high-level evidence does not necessarily preclude a grade A recommendation if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations in which corroborating studies cannot be performed, perhaps for ethical or other reasons. In this case, unequivocal recommendations are considered helpful for the reader. Whenever this occurs, it has been clearly indicated in the text with an asterisk as 'upgraded based on panel consensus'. The quality of the underlying scientific evidence is a very important factor, but it has to be balanced against benefits and burdens, values and preferences and costs when a grade is assigned (2-4).

The EAU Guidelines Office does not perform cost assessments, nor can they address local/national preferences in a systematic fashion. However, whenever such data are available, the expert panels will include the information.

Table 2: Grades of recommendation*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial.
B	Based on well-conducted clinical studies, but without randomised clinical trials.
C	Made despite the absence of directly applicable clinical studies of good quality.

** Modified from Sackett et al. (1).*

2.3 Publication history

The present male hypogonadism guidelines are a new publication that underwent a blinded peer-review process before publication. The standard procedure will be an annual assessment of newly published literature in this field, guiding future updates. An ultra-short reference document is being published alongside this publication. All documents are available with free access through the EAU website Uroweb (http://www.uroweb.org/guidelines/online-guidelines/).

3. EPIDEMIOLOGY

3.1 Introduction

Androgen deficiency increases with age; an annual decline in circulating testosterone of 0.4-2.0% has been reported (1,2). In middle-aged men, the incidence was found to be 6% (3). It is more prevalent in older men, in men with obesity, those with co-morbidities, and in men with a poor health status.

3.2 Role of testosterone for male reproductive health

Androgens, which are produced by the testis and the adrenal glands, play a pivotal role in male reproductive and sexual function. Androgens are also crucial for the development of male reproductive organs, such as the epididymis, vas deferens, seminal vesicle, prostate and penis. In addition, androgens are needed for puberty, male fertility, male sexual function, muscle formation, body composition, bone mineralisation, fat metabolism, and cognitive functions (4).

3.3 Physiology

Male sexual development starts between the 7th and 12th week of gestation. The undifferentiated gonads develop into a foetal testis through expression of the sex-determining region Y gene (SRY), a gene complex located on the short arm of the Y chromosome (5). The foetal testis produces two hormones: testosterone and anti-Müllerian hormone (AMH).

Testosterone is needed for the development of the Wolffian ducts, resulting in formation of the epididymis, vas deferens and seminal vesicle. AMH activity results in regression of the Müllerian ducts (Figure 1). Under the influence of intratesticular testosterone, the number of gonocytes per tubule increases threefold during the foetal period (6).

In addition, testosterone is needed for development of the prostate, penis and scrotum. However, in these organs testosterone is converted into the more potent metabolite dihydrotestosterone (DHT) by the enzyme 5α-reductase (7). The enzyme is absent in the testes, which explains why 5α-reductase inhibitors do not have a marked effect on spermatogenesis. Testosterone and DHT are required for penile growth, both activating the androgen receptor. The androgen receptor (AR) in the penis disappears after puberty, thus preventing further growth of the penis (8).

Intratesticular testosterone is needed to maintain the spermatogenic process and to inhibit germ cell apoptosis (9). The seminiferous tubules of the testes are exposed to concentrations of testosterone 25-100 times greater than circulating levels. Suppression of gonadotrophins (e.g. through excessive testosterone abuse) results in a reduced number of spermatozoa in the ejaculate and hypospermatogenesis (10). Complete inhibition of intratesticular testosterone results in full cessation of meiosis up to the level of spermatids (11,12). Testosterone does not appear to act directly on the germ cells, but functions through the Sertoli cells by expression of the AR and influencing the seminiferous tubular microenvironment (12).

Testosterone can also be metabolised into estradiol by aromatase, present in fatty tissue, the prostate and bone. Estradiol is essential for bone mineralisation, also in men (13).

The production of testosterone is controlled by luteinizing hormone (LH) from the pituitary gland. Immediately after birth, serum testosterone levels reach adult concentrations over several months. Thereafter and until puberty, testosterone levels are low, thus preventing male virilisation. Puberty starts with the production of gonadotrophins, initiated by GnRH secretion from the hypothalamus and resulting in testosterone production, male sexual characteristics and spermatogenesis (14). Figure 1 shows the development of the male reproductive system.

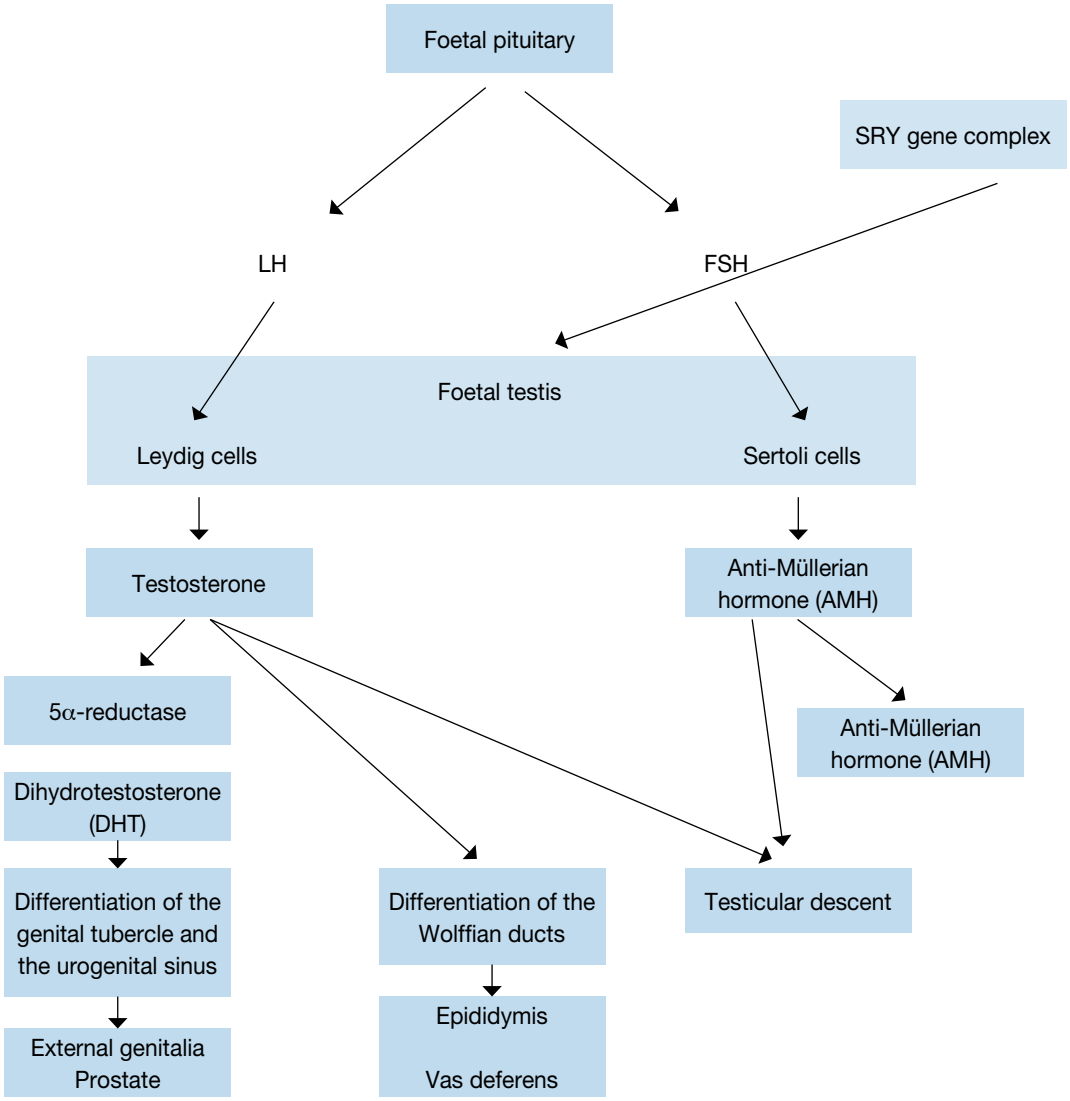
3.4 The androgen receptor

Testosterone exerts its action through the androgen receptor (AR), located in the cytoplasm and nucleus of target cells. During the foetal period, testosterone increases the number of androgen receptors by increasing the number of cells with the AR, but also by increasing the number of ARs in each individual cell (8,13).

The AR gene is located on the X chromosome (Xq 11-12): defects and mutations in the AR gene can result in male sexual maldevelopment, which may cause testicular feminisation or low virilisation. Less severe mutations in the AR gene may cause mild forms of androgen resistance and male infertility (15). In exon 1 of the gene, the transactivation domain consists of a trinucleotide tract (cytosine–adenine–guanine [CAG-repeats]) of variable length. Androgen sensitivity may be influenced by the length of the CAG repeats in exon 1 of the AR gene (15). The AR CAG repeat length is inversely correlated with serum total and bioavailable testosterone in ageing men. Shorter repeats have been associated with an increased risk for prostate disease, and longer repeats with reduced androgen action in several tissues (16). CAG repeat number may influence androgenic phenotypical effects, even in case of normal testosterone levels (17).

Conclusion
Testosterone is essential for normal male development.

Figure 1: Development of the male reproductive system



FSH = follicle-stimulating hormone; LH = luteinizing hormone; SRY = sex region of the Y chromosome.

4. AETIOLOGY (PRIMARY AND SECONDARY FORMS AND LATE-ONSET HYPOGONADISM)

4.1 Introduction

Hypogonadism results from testicular failure, or is due to the disruption of one or several levels of the hypothalamic-pituitary-gonadal axis (Table 3).

Male hypogonadism can be classified in accordance with disturbances at the level of:

- the hypothalamus and pituitary (secondary hypogonadism);
- the testes (primary hypogonadism);
- the hypothalamus/pituitary and gonads (late-onset hypogonadism);
- androgen target organs (androgen insensitivity/resistance).

4.2 Male hypogonadism of hypothalamic-hypopituitary origin (secondary hypogonadism)

Central defects of the hypothalamus or pituitary cause secondary testicular failure. Identifying secondary hypogonadism is of clinical importance, as it can be a consequence of pituitary pathology (including prolactinomas) and can cause infertility, which can be restored by hormonal stimulation in most patients with secondary hypogonadism.

The most relevant forms of secondary hypogonadism are:

- *Hyperprolactinemia* (HP), caused by prolactin-secreting pituitary adenomas (prolactinomas) (microprolactinomas < 10 mm in diameter vs. macroprolactinomas) or drug-induced (by dopamine-antagonistic effects of substances such as phenothiazine, imipramine and metoclopramide); additional causes may be chronic renal failure or hypothyroidism.
- *Isolated hypogonadotropic hypogonadism* (IHH) (formerly termed idiopathic hypogonadotropic hypogonadism, IHH).
- *Kallmann syndrome* (hypogonadotropic hypogonadism with anosmia, genetically determined, prevalence one in 10,000).

These disorders are characterised by disturbed hypothalamic secretion or action of GnRH, as a pathophysiology common to the diseases, resulting in impairment of pituitary LH and FSH secretion. An additional inborn error of migration and homing of GnRH-secreting neurons results in Kallmann syndrome (1,2).

The most important differential diagnosis is the constitutional delay of puberty, as the most common cause of delayed puberty (pubertas tarda) with a prevalence of one in 40 in males, caused by a delayed increase in pulsatile GnRH secretion with an autosomal-dominant pattern of inheritance (3). Other rare forms of secondary hypogonadism are listed in Table 3.

4.3 Male hypogonadism of gonadal origin (primary hypogonadism)

Primary testicular failure results in low testosterone levels, impairment of spermatogenesis and elevated gonadotrophins. The most important clinical forms of primary hypogonadism are Klinefelter syndrome (one in 500 males) and testicular tumours (12 per 100,000 males).

- *Klinefelter syndrome* affects 0.2% of the male population. It is the most frequent form of male hypogonadism and the most common numerical chromosomal aberration, with 47,XXY in 90% of cases (4). It arises due to non-disjunction during paternal or maternal meiotic division of germ cells (5).
- *Testicular tumours* are the most frequent type of cancer in young males during reproductive age. Risk factors are contralateral germ cell cancer, maldescended testes, gonadal dysgenesis, infertility and familial germ cell cancer. Twenty-five per cent of patients suffer from testosterone deficiency after treatment (6-8).

Other reasons for primary testicular failure are summarised in Table 4.

4.4 Male hypogonadism due to mixed dysfunction of hypothalamus/pituitary and gonads

Combined primary and secondary testicular failure results in low testosterone levels, impairment of spermatogenesis and variable gonadotrophin levels. Gonadotrophin levels depend on the predominant primary or secondary failure. This form was recently named late-onset hypogonadism (9,10).

4.5 Male hypogonadism due to defects of androgen target organs

These forms are primarily rare defects and will not be further discussed in detail in this guideline. There are androgen receptor defects with complete, partial and minimal androgen insensitivity syndrome; Reifenstein syndrome; bulbospinal muscular atrophy (Kennedy disease); as well as 5α-reductase deficiency (for a review, see Nieschlag et al. 2010) (11).

The classification of hypogonadism has therapeutic implications. In patients with secondary hypogonadism, hormonal stimulation with hCG and FSH or alternatively GnRH can restore fertility in most cases (12,13). However, fertility options for males with primary hypogonadism are limited. Detailed evaluation may for example detect pituitary tumours, systemic disease, or testicular tumours.

Combined forms of primary and secondary hypogonadism can be observed in older men, with a concomitant age-related decline in testosterone levels resulting from defects in testicular as well as hypothalamic-pituitary function. A significant percentage of men over the age of 60 years have serum testosterone levels below the lower reference limits in young adults (14-18).

Table 3: Forms of secondary hypogonadism

Disease	Causes for deficiency
Hyperprolactinemia	Prolactin-secreting pituitary adenomas (prolactinomas) or drug-induced.
Isolated hypogonadotropic hypogonadism (IHH) (formerly termed idiopathic hypogonadotropic hypogonadism, IHH)	GnRH deficiency.
Kallmann syndrome (hypogonadotropic hypogonadism with anosmia (prevalence 1 in 10,000)	GnRH deficiency and anosmia, genetically determined.
Secondary GnRH deficiency	Medication, drugs, toxins, systemic diseases.
Hypopituitarism	Radiotherapy, trauma, infections, hemochromatosis and vascular insufficiency or congenital.
Pituitary adenomas	Hormone-secreting adenomas; hormone-inactive pituitary adenomas; metastases from the pituitary or pituitary stalk.
Prader-Willi syndrome (PWS) (formerly Prader-Labhart-Willi syndrome) (prevalence 1 in 10,000 individuals)	Congenital disturbance of GnRH secretion.
Congenital adrenal hypoplasia with hypogonadotropic hypogonadism (prevalence 1 in 12,500 individuals)	X-chromosomal recessive disease, in the majority of patients caused by mutations in the DAX1 gene.
Pasqualini syndrome	Isolated LH deficiency.

Table 4: Forms of primary hypogonadism

Disease	Causes of deficiency
Maldescended or ectopic testes	Failure of testicular descent, 85% idiopathic.
Orchitis	Viral or unspecific orchitis.
Acquired anorchia	Traumatic, tumour, torsion, inflammation, iatrogenic, surgical removal.
Secondary testicular dysfunction	Medication, drugs, toxins, systemic diseases.
(Idiopathic) testicular atrophy	Male infertility (Idiopathic or specific causes).
Congenital anorchia (bilateral in 1 in 20,000 males, unilateral 4 times as often)	Intrauterine torsion is the most probable cause.
46,XY disorders of sexual development (DSD) (formerly male pseudohermaphroditism)	Disturbed testosterone synthesis due to enzymatic defects of steroid biosynthesis (17,20-desmolase defect, 17β-hydroxsteroid dehydrogenase defect).
Gonadal dysgenesis (synonym ‘streak gonads’)	XY gonadal dysgenesis can be caused by mutations in different genes.
46,XX male syndrome (prevalence of 1 in 10,000-20,000)	Males with presence of genetic information from the Y chromosome after translocation of a DNA segment of the Y to the X chromosome during paternal meiosis.
47,XYY syndrome (prevalence of 1 in 2,000)	Caused by non-disjunction in paternal meiosis.
Noonan syndrome (prevalence of 1 in 1,000 to 1 in 5,000)	Genetic origin.
Inactivating LH receptor mutations, Leydig cell hypoplasia (prevalence of 1 in 1,000,000 to 1 in 20,000)	Leydig cells are unable to develop due to the mutation (19).

Recommendation	LE	GR
The two forms of hypogonadism have to be differentiated, as this has implications for patient evaluation and treatment and makes it possible to identify patients with associated health problems and infertility.	1b	B

5. DIAGNOSIS

5.1 Introduction

Hypogonadism is diagnosed on the basis of persistent symptoms and signs related to androgen deficiency and assessment of consistently low testosterone levels (at least on two occasions) with a reliable method (1-5).

5.2 Clinical symptoms

Low levels of circulating androgens may be associated with signs and symptoms (Table 5).

Table 5: Clinical symptoms and signs suggestive for androgen deficiency

Delayed puberty
Small testes
Male-factor infertility
Decreased body hair
Gynaecomastia
Decrease in lean body mass and muscle strength
Visceral obesity
Decrease in bone mineral density (osteoporosis) with low trauma fractures
Reduced sexual desire and sexual activity
Erectile dysfunction
Diminished nocturnal erections
Hot flushes
Changes in mood, fatigue and anger
Sleep disturbances
Metabolic syndrome
Insulin resistance and type 2 diabetes mellitus
Diminished cognitive function

The most prevalent symptoms of male hypogonadism in ageing men are reduced sexual desire and sexual activity, erectile dysfunction, and hot flushes (1).

Symptoms and signs of androgen deficiency vary depending on age of onset, duration and the severity of the deficiency. Reference ranges for the lower normal level of testosterone (percentile 2.5) have recently been compiled from three large community-based samples, suggesting a cut-off of 12.1 nmol/L for total serum testosterone and calculated free testosterone 243 pmol/L to distinguish between normal levels and levels possibly associated with deficiency (6). Symptoms suggesting the presence of hypogonadism (1,7) are summarised in Table 5.

In men aged 40-79 years, the threshold for total testosterone was 8 nmol/L for decreased frequency of sexual thoughts, 8.5 nmol/L for erectile dysfunction, 11 nmol/L for decreased frequency of morning erections and 13 nmol/L for diminished vigour (8). The strongest predictor for hypogonadism in this age group was three sexual symptoms (decreased sexual thoughts, weakened morning erections, erectile dysfunction) and either a total testosterone level of < 8 nmol/L or serum testosterone in the range of 8-11 nmol/L and free testosterone < 220 pmol/L. These data are based on serum samples taken in the morning, when levels are highest and best reproducible (9).

Hypogonadism may be more subtle and not always evident by low testosterone levels. For example, men with primary testicular damage often have normal T levels but high LH: this could be considered a subclinical or compensated form of hypogonadism. The clinical consequences of an isolated elevation of LH is not clear yet, but potentially these men may already have signs or symptoms of hypogonadism or will become hypogonadal in the future.

To differentiate between primary and secondary forms of hypogonadism and to clarify late-onset hypogonadism determination of LH serum levels is required. Both LH and testosterone serum levels should be analysed twice.

5.3 History-taking and questionnaires

Symptoms of hypogonadism are listed in Table 5 and should be addressed during history-taking. Early onset of hypogonadism causes a lack of or minimal pubertal development, lack of development of secondary sex characteristics, possibly eunuchoid body proportions and a high-pitched voice. These signs and symptoms strongly suggest hypogonadism. Postpubertal development of hypogonadism causes a loss of androgen-dependent functions and symptoms that may have other etiological backgrounds than low testosterone levels. Published questionnaires are unreliable and have low specificity, while their sensitivity is high, and are not effective for case-finding (10-13). It is important to assess and exclude systemic illnesses, signs of malnutrition and malabsorption, as well as ongoing acute disease. Pharmacological treatments with corticosteroids, abuse of drugs such as marihuana, opiates and alcohol and previous treatment or use of testosterone or abuse of anabolic steroids should also be included in history-taking.

5.4 Physical examination

Assessment of body mass index (BMI), the waist-hip ratio (or sagittal abdominal diameter), body hair, male-pattern hair loss, presence of gynaecomastia and testicular size (measured with an orchidometer or ultrasound) and a structural examination of the penis as well as a digital rectal examination of the prostate should be included.

Conclusion
The diagnosis of male hypogonadism is based on symptoms and signs of androgen deficiency, together with consistently low serum testosterone levels.

Recommendations	**LE**	**GR**
The diagnosis of testosterone deficiency should be restricted to men with persistent symptoms suggesting hypogonadism (Table 5) (1-7).	3	C
Total testosterone assessment should be repeated at least on two occasions with a reliable method in men with: - Total testosterone levels close to the lower normal range (8-12 nmol/l), the free testosterone level should be measured to strengthen the laboratory assessment. - Suspected or known abnormal sex hormone-binding globulin (SHBG) levels, free testosterone should also be included (6,8).	1	A
Currently available diagnostic instruments (questionnaires) are not reliable as case-finding tools (10), as they have not been validated.	3	C
Testosterone assessment is recommended in men with a disease or treatment in which testosterone deficiency is common and in whom treatment may be indicated. This includes men with: - Pituitary mass, following radiation involving the sellar region and other diseases in the hypothalamic and sellar region; - End-stage renal disease receiving haemodialysis; - Treatment with medications that cause suppression of testosterone levels - e.g. corticosteroids and opiates; - Moderate to severe chronic obstructive lung disease; - Infertility; - Osteoporosis or low-trauma fractures; - HIV infection with sarcopenia; - Type 2 diabetes (14-18).	2	B
LH serum levels should be analysed to differentiate between primary, secondary, and late-onset hypogonadism.

6. CLINICAL CONSEQUENCES OF HYPOGONADISM

6.1 Introduction

The clinical consequences of hypogonadism are determined by the age of onset and the severity of hypogonadism.

6.2 Foetal androgen deficiency

During the first 14 weeks of gestation, the presence of testosterone is crucial for normal virilisation of the external male genitalia. Androgen deficiency or androgen resistance due to deficient androgen receptor

function during this stage of life may result in abnormal genital development, ranging from hypospadias to female external genitalia with intra-abdominal testis. Frequently, patients with disorders of sexual development are diagnosed at an early age because of clearly abnormal external genitalia. However, patients at both ends of the phenotypic spectrum may go unnoticed in childhood and are diagnosed during puberty because of delayed pubertal development in phenotypic men or primary amenorrhoea in XY women.

6.3 Prepubertal onset of androgen deficiency

At the start of puberty, rising gonadotrophin levels result in increasing testicular volume and the activation of spermatogenesis and testosterone secretion. During puberty, rising testosterone levels result in the development of male secondary sex characteristics, comprising deepening of the voice, development of terminal body hair, stimulation of hair growth in sex-specific regions, facial hair, increasing penile size, increase in muscle mass and bone size and mass, growth spurt induction and eventually closing of the epiphyses. In addition, testosterone has explicit psychosexual effects, including increased libido.

Delayed puberty is defined as an absence of testicular enlargement at the age of 14. As this is a 'statistical' definition, based on reference ranges for the onset of puberty in the normal population, delayed puberty does not necessarily indicate the presence of a disease. In cases of severe androgen deficiency, the clinical picture of prepubertal-onset hypogonadism is evident (Table 6) and diagnosis and treatment are fairly straightforward. The major challenge in younger individuals with presumed idiopathic hypogonadotropic hypogonadism is to differentiate the condition from a constitutional delay in puberty and to determine when to start androgen treatment. In milder cases of androgen deficiency, such as are seen in patients with Klinefelter syndrome, pubertal development can be incomplete or delayed, resulting in a more subtle phenotypic picture. In these patients, several clues may lead to a diagnosis of hypogonadism. These include: small testes, (a history of) cryptorchidism, gynaecomastia, sparse body hair, eunuchoid habitus, low bone mass and subfertility (1).

Table 6: Signs and symptoms suggesting prepubertal-onset hypogonadism

Small testes
Cryptorchidism
Gynaecomastia
High voice
Unclosed epiphyses
Linear growth into adulthood
Eunuchoid habitus
Sparse body hair / facial hair
Infertility
Low bone mass
Sarcopenia
Reduced sexual desire / activity

6.4 Late-onset hypogonadism

Definition: Late-onset hypogonadism is defined as hypogonadism in a person who has had normal pubertal development and as a result developed normal male secondary sex characteristics.

Depending on the underlying cause of hypogonadism, the decline in gonadal function may be gradual and partial. The resulting clinical picture may be variable, and the signs and symptoms may be obscured by the physiological phenotypic variation. Symptoms that have been associated with late-onset androgen deficiency include: loss of libido, erectile dysfunction, sarcopenia, low bone mass, depressive thoughts, fatigue, loss of vigour, erectile dysfunction, loss of body hair, hot flushes and reduced fertility (Table 7). Most of these symptoms have a multifactorial aetiology, are reminiscent of normal aging and can also be found in men with completely normal testosterone levels (2). As a result, signs and symptoms of adult-onset hypogonadism may be non-specific, and confirmation of a clinical suspicion by hormonal testing is mandatory. For most of the symptoms mentioned above, the probability of their presence increases with lower plasma testosterone levels. Most studies indicate a threshold level below which the prevalence of symptoms starts to increase (3,4). This threshold level is near the lower level of the normal range for plasma testosterone levels in young men, but there appears to be wide variation between individuals, and even within one individual the threshold level may

be different for different target organs.

Table 7: Signs and symptoms associated with late-onset hypogonadism

Loss of libido
Erectile dysfunction
Sarcopenia
Low bone mass
Depressive thoughts
Fatigue
Loss of body hair
Hot flushes
Loss of vigour

Recommendations	LE	GR
Screening of testosterone deficiency is only recommended in adult men with consistent and preferably multiple signs and symptoms listed in Table 7.	3	C
Adult men with established severe hypogonadism should be screened for concomitant osteoporosis.	2	B

7. INDICATIONS AND CONTRAINDICATIONS FOR TREATMENT

Testosterone treatment aims to restore testosterone levels to the physiological range in men with consistently low levels of serum testosterone and associated symptoms of androgen deficiency. The aim is to improve quality of life, sense of well-being, sexual function, muscle strength and bone mineral density. Table 8 highlights the main indications for testosterone treatment. Table 9 lists the main contraindications against testosterone therapy.

Table 8: Indications for testosterone treatment

Delayed puberty (idiopathic, Kallmann syndrome)
Klinefelter syndrome with hypogonadism
Sexual dysfunction and low testosterone
Low bone mass in hypogonadism
Adult men with consistent and preferably multiple signs and symptoms of hypogonadism (listed in Table 7)
Hypopituitarism
Testicular dysgenesis and hypogonadism

Table 9: Contraindications against testosterone treatment

Prostate cancer
PSA > 4 ng/mL
Male breast cancer
Severe sleep apnoea
Male infertility
Haematocrit > 50%
Severe lower urinary tract symptoms due to benign prostatic hyperplasia

8. BENEFITS OF TREATMENT

Testosterone replacement therapy (TRT) provides several benefits in relation to body composition, metabolic control and psychological and sexual parameters. Randomised trials have shown a correlation between restored physiological testosterone levels, muscle mass and strength measured as leg press strength and quadriceps muscle volume (1-4). Similar positive results have been reported in meta-analyses evaluating the role of exogenous testosterone in relation to bone mineral density: it is evident that testosterone therapy improves mineral density at the lumbar spine, producing a reduction in bone resorption markers. The available trials failed to demonstrate a similar effect at the femoral neck (4-6). Body composition is influenced by testosterone therapy in hypogonadal men, with a consequent decrease in fat mass and an increase in lean body mass (4). Several studies based on experience with testosterone undecanoate have demonstrated a significant reduction in trunk and waist fat, with a clear decrease in waist size (7,8). In the same trials, testosterone undecanoate administration was associated with an improvement in body weight, body mass index and lipid profile after 3 months of therapy. Testosterone replacement therapy has positive effects on glycaemic and lipid control, insulin resistance and visceral adiposity in hypogonadal men with impaired glucose tolerance and lipid profiles, with a consequent decrease in the cardiovascular risk (9). Benefits on libido, erection and ejaculation have been reported in several retrospective studies and case reports. In a recent multicentre prospective study, Moon et al. (10) reported a significant increase in the International Index of Erectile Function (IIEF) score for sexual desire, intercourse satisfaction and overall satisfaction starting 6 weeks after the beginning of treatment. Testosterone replacement therapy has also shown encouraging results in several case reports in which satisfactory sexual intercourse was reported after at least 3 months from therapy induction in hypogonadal men suffering from veno-occlusive erectile dysfunction (4,11). Significant improvement in depressive symptoms in men treated with testosterone undecanoate is reported in a recent randomised trial, while benefits in relation to the cognitive spectrum have been reported in studies with a lower impact (12,13).

Conclusion	**LE**
Benefits including a reduction in BMI and waist size and improved glycaemic control and lipid profile are observed in hypogonadal men receiving TRT.	2a

Recommendations	LE	GR
Testosterone replacement therapy is recommended in patients with:		
A decline in muscle mass and strength	1b	A
Reduced bone mineral density at the lumbar spine	1a	A
Decreased libido and erection	3	B

9. CHOICE OF TREATMENT

9.1 Introduction

The aim of TRT is to restore physiological testosterone levels in hypogonadal men (1). During TRT, periodic observation of the serum concentration of the hormone and its metabolites is recommended in order to alleviate treatment-related side effects (1). Several preparations are available, which differ in the route of administration and pharmacokinetics, and the selection should be a joint decision by both the patient and the physician (2). Short-acting preparations may be preferred to long-acting depot administration in the initial treatment phase, so that any adverse events that may develop can be observed and treatment can be discontinued if needed (3).

Testosterone replacement therapy is safe and effective and the agents are available as oral preparations, intramuscular injections and transdermal gel or patches (4).

9.2 Preparations

*9.2.1 **Testosterone undecanoate***

Testosterone undecanoate is the most widely used and safest oral delivery system. It rarely causes a rise in testosterone levels above the mid-range and it is therefore infrequently associated with side effects (1). In oral administration, resorption depends on simultaneous intake of fatty food.

Testosterone undecanoate is also available as a long-acting intramuscular injection (with intervals of up to 3 months). This long period of action ensures a normal testosterone serum concentration for the entire period, but the relatively long wash-out period may cause problems if complications appear (5).

*9.2.2 **Testosterone cypionate and enanthate***

Testosterone cypionate and enanthate are available as short-acting intramuscular delivery systems (with intervals of 2-3 weeks) and represent safe and valid preparations. However, these preparations may cause fluctuations in serum testosterone from high levels to subnormal levels, and they are consequently associated with periods of well-being alternating with periods of unsatisfactory clinical response (6,7).

*9.2.3 **Transdermal testosterone***

Transdermal testosterone preparations are available as skin patches or gel. They provide a uniform and normal serum testosterone level for 24 hours (daily interval). Common side effects consist of skin irritation at the site of application (patches) and risk of interpersonal transfer if appropriate precautions are not taken (gel) (8,9).

*9.2.4 **Sublingual and buccal testosterone***

Sublingual and buccal testosterone tablets are effective and well-tolerated delivery systems that can provide a rapid and uniform achievement of a physiological testosterone level with daily administration (10,11).

*9.2.5 **Subdermal depots***

Subdermal depots need to be implanted every 5-7 months and offer a long period of action without significant serum fluctuation of the testosterone level. The risk with this kind of delivery system lies in infections and extrusions, which may occur up to 10% of cases (1,12,13).

9.3 Hypogonadism and fertility issues

Exogenous testosterone reduces endogenous testosterone production by negative feedback on the hypothalamic-pituitary-gonadal axis. If hypogonadism coincides with fertility issues, hCG treatment should be considered.

Human chorionic gonadotrophin (hCG) stimulates testosterone production of Leydig cells. Its administration should be restricted to patients with secondary hypogonadism, if fertility issues are important. Normal physiological serum levels can be achieved with a standard dosage of 1500-5000 IU administered intramuscularly or subcutaneously twice weekly. In patients with secondary hypogonadism, hCG treatment is combined with FSH treatment (usually 150 IU three times weekly i.m. or s.c.) to induce spermatogenesis.

In patients with secondary hypogonadism and fertility issues, and in selected cases of primary hypogonadism, hCG treatment can be chosen to support endogenous testosterone production for the period of infertility treatment. The dosage has to be adjusted individually to prevent suppression of FSH serum levels. hCG treatment has higher costs than testosterone treatment. There is insufficient information about the therapeutic and adverse effects of long-term hCG treatment. This type of treatment can therefore not be recommended for male hypogonadism, except in patients in whom fertility treatment is an issue.

Table 10: Testosterone preparations for replacement therapy

Formulation	Administration	Advantages	Disadvantages
Testosterone undecanoate	Oral; 2-6 cps every 6 h	Absorbed through the lymphatic system, with consequent reduction of liver involvement.	Variable levels of testosterone above and below the mid-range (1) Need for several doses per day with intake of fatty food.
Testosterone cypionate	Intramuscular; one injection every 2-3 weeks	Short-acting preparation that allows drug withdrawal in case of onset of side effects.	Possible fluctuation of testosterone levels (5,6).
Testosterone enanthate	Intramuscular; one injection every 2-3 weeks	Short-acting preparation that allows drug withdrawal in case of onset of side effects.	Possible fluctuation of testosterone levels (5,6).
Testosterone undecanoate	Intramuscular; one injection every 10-14 weeks	Steady-state testosterone levels without fluctuation.	Long-acting preparation that cannot allow drug withdrawal in case of onset of side effects (7).
Transdermal testosterone	Gel or skin patches; daily application	Steady-state testosterone level without fluctuation.	Skin irritation at the site of application and risk of interpersonal transfer (8,9).
Sublingual testosterone	Sublingual; daily doses	Rapid absorption and achievement of physiological serum level of testosterone.	Local irritation (10,11).
Buccal testosterone	Buccal tablet; two doses per day	Rapid absorption and achievement of physiological serum level of testosterone.	Irritation and pain at the site of application (10,11).
Subdermal depots	Subdermal implant every 5-7 months	Long duration and constant serum testosterone level.	Risk of infection and extrusion of the implants (1,12,13).

Recommendations	LE	GR
The patient should be fully informed about expected benefits and side effects of each treatment option. The selection of the preparation should be a joint decision by an informed patient and the physician.	1a	A
Short-acting preparations may be preferred to long-acting depot administration when starting the initial treatment.	3	B
hCG treatment can only be recommended for hypogonadal patients with simultaneous fertility treatment.	1b	B

10. RISK FACTORS IN TESTOSTERONE TREATMENT

10.1 Introduction

Physicians are often reluctant to offer TRT, especially in elderly men, due to the potential risk of this form of treatment (1). The most common doubts are associated with the possible consequences for prostatic and breast tissues, the cardiovascular system and sleep apnoea.

10.2 Male breast cancer

Male breast cancer is a rare disease, with an incidence of less than 1% of all male cancers (2). The incidence is higher in men with Klinefelter syndrome. Testosterone treatment is contraindicated in men with a history of breast cancer (3). An association between TRT and the development of breast cancer is not supported by strong evidence, although there have been some reports based on small numbers of patients (4).

10.3 Prostate cancer

Prostate cancer growth may be influenced by testosterone. Studies have reported that hypogonadism is associated with a lower incidence of prostate cancer, but if prostate cancer occurs in hypogonadal men, it is usually at an advanced stage and with a higher Gleason score (5,6). Randomised controlled trials support

the hypothesis that TRT does not result in changes in prostatic histology, nor in a significant increase in intraprostatic testosterone and DHT (7,8). The most recent studies indicate that testosterone therapy does not increase the risk of prostate cancer (7-10), but long-term follow-up data are not yet available. A recent meta-analysis showed a higher (but not statistically significant) percentage of prostate events in middle-aged and older men receiving TRT (11). In view of these observations, PSA testing and digital examination of the prostate before and during therapy are highly recommended (11).

Testosterone therapy is clearly contraindicated in men with prostate cancer. A topic currently under debate involves the use of TRT in hypogonadal men with a history of prostate cancer and no evidence of active disease. So far, only studies with limited numbers of patients and relatively short follow-up periods are available, and these indicate no increased risk for recurrent prostate cancer. No randomised and placebo-controlled trials are available yet to document the long-term safety of the treatment in these patients (12). Men who have been surgically treated for localised prostate cancer and who are currently without evidence of active disease (i.e. measurable PSA, abnormal rectal examination, evidence of bone/visceral metastasis) and showing symptoms of testosterone deficiency can be cautiously considered for TRT, although this approach is still an 'off-label' treatment (13,14). In these patients, treatment should be restricted to patients with a low risk for recurrent prostate cancer (pre-surgery Gleason < 8; pT1-2; PSA < 10 ng/mL). Therapy should not start before 1 year of follow-up after surgery and there should be no PSA recurrence (13-15). Patients who have undergone brachytherapy or external-beam radiotherapy (EBRT) for low-risk prostate cancer can also be cautiously treated with TRT in case of hypogonadism, with close monitoring for prostate cancer recurrence (14-16).

10.4 Cardiovascular diseases

Testosterone treatment is not related to the development of de novo cardiovascular events (17,18). Caution, however, should be used in men with existing cardiovascular diseases, since an increase in red blood cells is a common side effect of testosterone. Haemoglobin and haematocrit measurements are recommended before treatment and periodically thereafter (9,11,19). Patients with erythrocytosis and serious congestive heart failure (NYHA classes III-IV) are at risk of developing cardiovascular deterioration, and testosterone therapy should be discontinued until the resolution of congestive heart failure (9). Cardiovascular adverse events are more frequent in patients with multiple co-morbidities and with limited physical activity (19).

10.5 Obstructive sleep apnoea

There is no consistent evidence correlating TRT with obstructive sleep apnoea (OSA). There is also no evidence that TRT can result in the onset or worsening of the condition (20).

Conclusions	LE
Case reports and small cohort studies point to a possible correlation between TRT and the onset of breast cancer, but there is as yet a lack of strong evidence for this relationship.	3
Randomised controlled trials support the hypothesis that TRT does not result in changes in prostatic histology.	1b
Testosterone therapy is not related to the development of de novo cardiovascular events.	1a
There is no evidence for a relationship between TRT and OSA.	3

Recommendations	LE	GR
Haematological, cardiovascular, breast and prostatic assessment should be performed before the start of treatment.	1a	A
Haematocrit and haemoglobin monitoring, PSA and digital rectal examination of prostate and breast examination are recommended assessments during TRT therapy.	1a	A
In patients operated on for localised prostate cancer, testosterone therapy should not start before 1 year of follow-up without PSA recurrence has been completed.	4	B

11. MONITORING OF PATIENTS RECEIVING TESTOSTERONE REPLACEMENT THERAPY

11.1 Introduction

Regular follow-up is needed in patients receiving testosterone therapy, as potentially androgen-dependent symptoms and conditions may occur as a result of TRT. The side effects of TRT are limited, but their incidence and clinical relevance is as yet unclear.

The primary aim of TRT is to alleviate the clinical symptoms of testosterone deficiency. Careful monitoring of changes in the clinical manifestations of testosterone deficiency should therefore be an essential part of every follow-up visit. Effects of TRT on sexual interest may already appear after 3 weeks of treatment, and reach a plateau at 6 weeks (1). Changes in erectile function and ejaculation may require up to 6 months (1). Effects on quality of life, and also on depressive mood, may become detectable within 1 month, but the maximum effect may take longer (1).

11.2 Testosterone level

There are as yet insufficient data to define optimal serum levels of testosterone during TRT. Expert opinion suggests that TRT should restore the serum testosterone level to the mid-normal range of specific age groups of men, which is usually sufficient to alleviate various manifestations of hormone deficiency. An optimal monitoring schedule for serum testosterone level is also dependent on the formulation of TRT used (LE: 4; GR: C).

11.3 Bone density

Bone mineral density (BMD) should be monitored only in men whose BMD was abnormal before initiation of TRT. An increase in lumbar spine BMD may already be detectable after 6 months of TRT and may continue for 3 more years (1).

11.4 Haematocrit

It is important to use only minimal or no venous occlusion when taking a blood sample for haematocrit measurements (2). Elevated haematocrit is the most frequent side effect of TRT. The clinical significance of a high haematocrit level is unclear, but it may be associated with hyperviscosity and thrombosis (3). The effect of erythropoiesis may become evident at 3 months and peaks at 12 months (1).

11.5 Prostate safety

Testosterone replacement therapy results in a marginal increase in PSA and prostate volume, plateauing at 12 months (1). Previous fears that TRT might increase the risk of prostate cancer have been contradicted by recent meta-analyses (4-7). However, there are insufficient long-term data available to conclude that there is safety from prostate cancer with TRT.

11.6 Cardiovascular system

Testosterone replacement therapy is not associated with the development of any unsafe cardiovascular events, and special monitoring in this respect is not needed (7,8). There has been one study (9) indicating that testosterone therapy in older men with a high prevalence of chronic diseases may result in a higher risk of cardiovascular adverse events. These patients may need individualised monitoring schemes.

Recommendations	LE	GR
The response to treatment should be assessed 3, 6 and 12 months after the onset of treatment, and thereafter annually.	4	C
In men with an abnormal BMD, BMD measurements should be repeated 6 and 12 months after the start of TRT and thereafter annually.	4	C
Haematocrit should be monitored at 3, 6 and 12 months and thereafter annually. The testosterone dosage should be decreased, or therapy discontinued if the haematocrit increases above normal levels.	4	C
Prostate health should be assessed by digital rectal examination (DRE) and PSA before the start of TRT. Follow-up by PSA at 3, 6 and 12 months and thereafter annually.	4	C
Routine screening of potential cardiovascular side effects is not indicated in men receiving TRT.	1B	A
Men with cardiovascular co-morbidity should be assessed by a cardiologist before TRT is initiated and there should be close cardiovascular monitoring during TRT.	3	C

Conflict of interest statement

All members of the Male Hypogonadism Guidelines working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on Urological Infections

M. Grabe (chairman), T.E. Bjerklund-Johansen, H. Botto, B. Wullt, M. Çek, K.G. Naber, R.S. Pickard, P. Tenke, F. Wagenlehner

European Association of Urology

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Background

Urinary tract infections (UTIs) are among the most prevailing infectious diseases with a substantial financial burden on society. There are only limited data from Europe. In the USA, UTIs are responsible for over 7 million physician visits annually (1). Approximately 15% of all community-prescribed antibiotics in the USA are dispensed for UTI (2) and data from some European countries suggest a similar rate (3). In the US, UTIs account for more than 100,000 hospital admissions annually, most often for pyelonephritis (1). These data do apparently not account for complicated UTI associated with urological patients, the prevalence of which is not clear. UTIs represents at least 40% of all hospital acquired infections and are, in the majority of cases, catheter associated (4). Bacteriuria develops in up to 25% of patients who require a urinary catheter for one week or more with a daily risk of 5-7% (5,6). The recent Global Prevalence Infection in Urology (GPIU) studies have shown that 10-12 % of patients hospitalised in urological wards have a healthcare-associated infection (HAI). The strains retrieved from these patients are even more resistant (7).

1.2 Bacterial resistance development

The present state of microbial resistance development is alarming (8). The use of antibiotics in the different countries and communities of Europe mirrors the global increase in resistant strains. There is a clear association between antibiotic use and the level of resistance on both individual and community levels (8). Multi-resistant microbial strains such as well known meticillin-resistant *Staphylococcus aureus* (MRSA) are found in an increasing number of patients. The presence of extended-spectrum β-lactamase producing *E. coli* (ESBL) showing resistance to most antibiotics, except for the carbapenem class, is steadily increasing in the population (9). Particularly troublesome is the increasing resistance to broad-spectrum antibiotics such as fluoroquinolones and cephalosorines. The microbes are harboured in the faecal reservoir and become a threat for urological patients in general, and men undergoing prostate biopsy in particular. The most important risk factors for this colonisation are recurrent infections and exposure to these antibiotics (10). Aggravating the situation is the observation of co-resistance to alternative antibiotics such as gentamicin (10).
A strong grip on this threatening development is thus required. With few new antibiotics in the development chain, prudent use of antibiotics is the only option to delay the development of resistance (8). The urological community has a responsibility to engage in evidence-based practices regarding the use of antimicrobial agents. It is also essential to consider the local microbial environment and resistance pattern as well as each individual patient's risk factor for harbouring resistant strains.

1.3 The aim of the guidelines

It is the ambition of the present guidelines to provide both urologist and physicians from other medical specialities with evidence-based guidance regarding the treatment and prophylaxis of UTI. These guidelines cover male and female UTIs, male genital infections and special fields such as UTI in paediatric urology, immunosuppression, renal insufficiency and kidney transplant recipients. Much attention is given to antibiotic prophylaxis, aiming to reduce the misuse and overuse of peri-operative prophylactic antibiotics. High quality clinical research using strict internationally recognised definitions and classifications as presented in this section are encouraged.

1.4 Pathogenesis of UTIs

Microorganisms can reach the urinary tract by haematogenous or lymphatic spread, but there is abundant clinical and experimental evidence to show that the ascent of microorganisms from the urethra is the most common pathway that leads to a UTI, especially organisms of enteric origin (e.g. *E. coli* and other Enterobacteriaceae). This provides a logical explanation for the greater frequency of UTIs in women than in men, and for the increased risk of infection following bladder catheterisation or instrumentation. A single insertion of a catheter into the urinary bladder in ambulatory patients results in urinary infection in 1-2% of cases. Indwelling catheters with open-drainage systems result in bacteriuria in almost 100% of cases within 3-4 days. The use of a closed-drainage system, including a valve to prevent retrograde flow, delays the onset of infection, but ultimately does not prevent it. It is thought that bacteria migrate within the mucopurulent space between the urethra and catheter, and that this leads to the development of bacteriuria in almost all patients within about 4 weeks.

Haematogenous infection of the urinary tract is restricted to a few relatively uncommon microbes, such as *Staphylococcus aureus, Candida* sp., *Salmonella* sp. and *Mycobacterium tuberculosis*, which cause primary infections elsewhere in the body. Candida albicans readily causes a clinical UTI via the haematogenous route, but is also an infrequent cause of an ascending infection if an indwelling catheter is present, or following antibiotic therapy.

The concept of bacterial virulence or pathogenicity in the urinary tract infers that not all bacterial

species are equally capable of inducing infection. The more compromised the natural defence mechanisms (e.g. obstruction, or bladder catheterisation), the fewer the virulence requirements of any bacterial strain to induce infection. This is supported by the well-documented *in vitro* observation that bacteria isolated from patients with a complicated UTI frequently fail to express virulence factors. The virulence concept also suggests that certain bacterial strains within a species are uniquely equipped with specialised virulence factors, e.g. different types of pili, which facilitate the ascent of bacteria from the faecal flora, introitus vaginae or periurethral area up the urethra into the bladder, or less frequently, allow the organisms to reach the kidneys to induce systemic inflammation.

1.5 Microbiological and other laboratory findings

The number of bacteria is considered relevant for the diagnosis of a UTI. In 1960, Kass developed the concept of significant bacteriuria ($\geq 10^5$ cfu/mL) in the context of pyelonephritis in pregnancy (11). Although this concept introduced quantitative microbiology into the diagnosis of infectious diseases, and is therefore still of general importance, it has recently become clear that there is no fixed bacterial count that is indicative of significant bacteriuria, which can be applied to all kinds of UTIs and in all circumstances. As described in Appendix 16.1, the following bacterial counts are clinically relevant:

- $\geq 10^3$ cfu/mL of uropathogens in a mid-stream sample of urine (MSU) in acute uncomplicated cystitis in women.
- $\geq 10^4$ cfu/mL of uropathogens in an MSU in acute uncomplicated pyelonephritis in women.
- $\geq 10^5$ cfu/mL of uropathogens in an MSU in women, or $\geq 10^4$ cfu/mL uropathogens in an MSU in men, or in straight catheter urine in women, in a complicated UTI.

In a suprapubic bladder puncture specimen, any count of bacteria is relevant. The problem of counting low numbers, however, has to be considered. If an inoculum of 0.1 mL of urine is used and 10 identical colonies are necessary for statistical reasons of confidence, then in this setting, the lowest number that can be counted is 100 cfu/mL of uropathogens. Asymptomatic bacteriuria is diagnosed if two cultures of the same bacterial strain (in most cases the species only is available), taken $\geq$ 24 h apart, show bacteriuria of $\geq 10^5$ cfu/mL of uropathogens.

It is obvious that methods of urine collection and culture, as well as the quality of laboratory investigations, may vary. Two levels of standard must therefore be used for the management of patients. A basic standard level is necessary for routine assessment, whereas a higher standard level is required for scientific assessment and in special clinical circumstances, e.g. fever of unknown origin in immunocompromised patients. In research, the need for a precise definition of sampling methods, such as the time that urine is kept in the bladder, must be recognised, and these parameters carefully recorded.

In clinical routine assessment, a number of basic criteria must be looked at before a diagnosis can be established, including:

- clinical symptoms;
- results of selected laboratory tests (blood, urine or expressed prostatic secretion [EPS]);
- evidence of the presence of microorganisms by culturing or other specific tests;
- most of these investigations can today be performed in any laboratory.

It has to be considered, however, that microbiological methods and definitions applied must follow accepted standards with regard to specimen transport, pathogen identification, and antimicrobial susceptibility testing. These methods and microbiological definitions may vary between countries and institutions. One example is the breakpoints for classification of pathogen susceptibility. It is important to report not only the results, but also which methods and standards were applied, such as the European Committee for Antimicrobial Susceptibility Testing (EUCAST) (12,13), or the National Committee for Clinical Laboratory Standards (NCCLS) (14). Mixing results obtained by different methods, e.g. rates of bacterial resistance, can be problematic and requires careful interpretation. Histological investigation sometimes shows the presence of non-specific inflammation. Only in some cases, such findings (e.g. prostatitis in patients who have elevated levels of prostate-specific antigen [PSA]) might help determine the appropriate treatment, whereas in more specific inflammation, such as tuberculosis and actinomycosis, histology can be diagnostic. In general, however, histological findings usually contribute very little to the treatment decisions.

1.6 Methodology

The EAU Urological Infections guidelines panel consists of a group of urologists, specialised in the treatment of UTIs. It must be emphasised that clinical guidelines present the best evidence available to the experts at the time of writing. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when treatment decisions for individual patients are being taken. Guidelines help to focus decisions. Clinical decisions must also take into account patients' personal values and

preferences and their individual circumstances.

1.6.1 Level of evidence and grade of guideline recommendations

References used in the text have been assessed according to their level of scientific evidence (Table 1). Guideline recommendations have been graded (Table 2) in accordance with the Oxford Centre for Evidence-Based Medicine levels of evidence (LE) (15). The aim of grading recommendations (GR) is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from at least one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

**Modified from Sackett et al. (15).*

It should be noted that when recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of randomised controlled trials (RCTs) may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Conversely, an absence of high level evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful for the reader. The quality of the underlying scientific evidence - although a very important factor - has to be balanced against benefits and burdens, values and preferences and cost when a grade is assigned (16-18).

The EAU Guidelines Office, do not perform cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever this data is available, the expert panels will include the information.

Table 2: Grade of recommendation*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial.
B	Based on well-conducted clinical studies, but without randomised clinical trials.
C	Made despite the absence of directly applicable clinical studies of good quality.

**Modified from Sackett et al. (15).*

1.6.2 Publication history

A first version of the guidelines on the management of UTI and male genital infections was published in the EAU guidelines 2001 and in European Urology (19). A second updated version was included in the EAU guidelines 2006. The EAU/ICUD textbook on Urogenital Infections (20) has become the book of reference for the Guidelines and the recent update 2011. This version included an improved classification of UTI, a chapter on Fournier's gangrene and the updates following a systematic review of the literature on uncomplicated UTI and antibiotic prophylaxis in urological surgery. Guidelines on special conditions of the urogenital tract have also been published elsewhere (21-23).

Standard procedure for EAU publications includes an annual assessment of newly published literature in this field, guiding future updates. An ultra-short reference document is being published alongside this publication. All documents are available with free access through the EAU website Uroweb (http://www.uroweb.org/guidelines/online-guidelines/).

2. CLASSIFICATION OF UTIs

2.1 Introduction

Traditionally, UTIs are classified based on clinical symptoms, laboratory data, and microbiological findings. Practically, UTIs have been divided in uncomplicated and complicated UTIs, and sepsis. It is important to underline that the following proposed classification is still not validated or recognised. It is a working instrument.

A critical review of present classifications was undertaken for the EAU/ICUD Urogenital Infections initiative (1) in Appendix 16.1. The overall aim is to provide the clinician and researcher with a standardised tool and nomenclature for UTI. The present guidelines give a short summary of a tentative improved system of classification of UTI based on:

- anatomical level of infection;
- grade of severity of infection;
- underlying risk factors;
- microbiological findings.

The symptoms, signs and laboratory finding focus on the anatomical level and the degree of severity of the infection. The risk factor analysis contributes to define any additional therapeutic measure required (i.e. drainage).

2.2 Level of infection

The symptoms, as presented in the Appendix 16.1, focus on the level of infection, defined as:

- urethritis (UR);
- cystitis (CY);
- pyelonephritis (PN);
- sepsis (US).

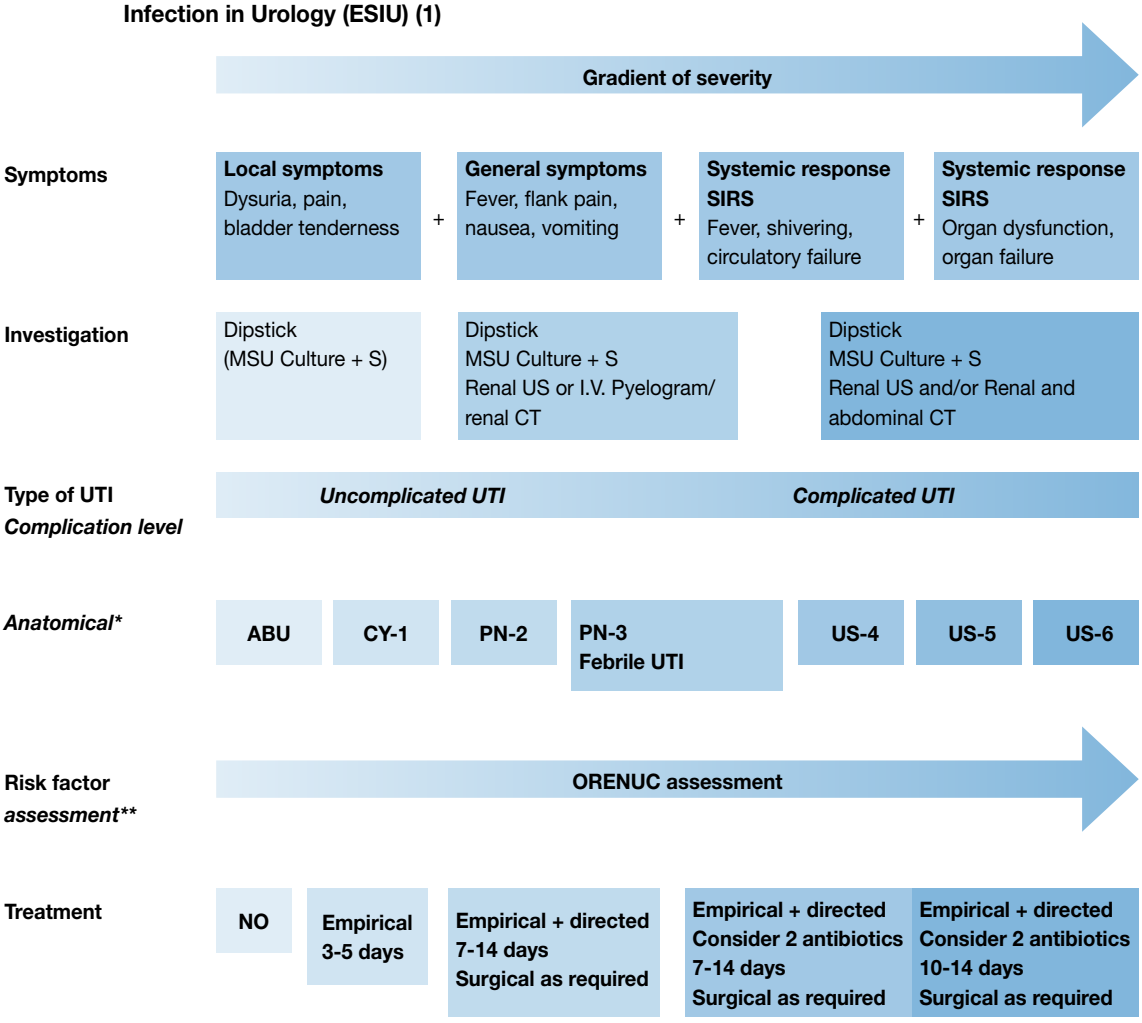
Urethritis being poorly understood is for the time being not included in the algorithm and treatment strategy of pure UTI. The male genital infections prostatitis and epididymitis are also not included.

Asymptomatic bacteriuria (ABU) needs to be considered a special entity because it can have its source in both the lower and upper urinary tracts, and requires no treatment unless the patient is subjected to urological surgery.

2.3 Grade of severity

The grade of severity is set on a scale of 1-6 that is related to the risk of fatal outcome (Figure 2.1)

Figure 2.1: Traditional and improved classification of UTI as proposed by the EAU European Section of Infection in Urology (ESIU) (1)



** see Figure 2.2*
*** see Table 2.1*

Table 2.1: Host risk factors in UTI

Type	Category of risk factor	Examples of risk factors
O	No known/associated RF	- Healthy premenopausal women
R	RF of recurrent UTI, but no risk of severe outcome	- Sexual behaviour and contraceptive devices - Hormonal deficiency in post menopause - Secretory type of certain blood groups - Controlled diabetes mellitus
E	Extra-urogenital RF, with risk or more severe outcome	- Pregnancy - Male gender - Badly controlled diabetes mellitus - Relevant immunosuppression* - Connective tissue diseases* - Prematurity, new-born
N	Nephropathic disease, with risk of more severe outcome	- Relevant renal insufficiency* - Polycystic nephropathy

U	Urological RF, with risk or more severe outcome, which can be resolved during therapy	- Ureteral obstruction (i.e. stone, stricture) - Transient short-term urinary tract catheter - Asymptomatic Bacteriuria** - Controlled neurogenic bladder dysfunction - Urological surgery
C	Permanent urinary Catheter and non resolvable urological RF, with risk of more severe outcome	- Long-term urinary tract catheter treatment - Non resolvable urinary obstruction - Badly controlled neurogenic bladder

*RF = Risk Factor; * = not well defined; ** = usually in combination with other RF (i.e. pregnancy, urological internvention).*

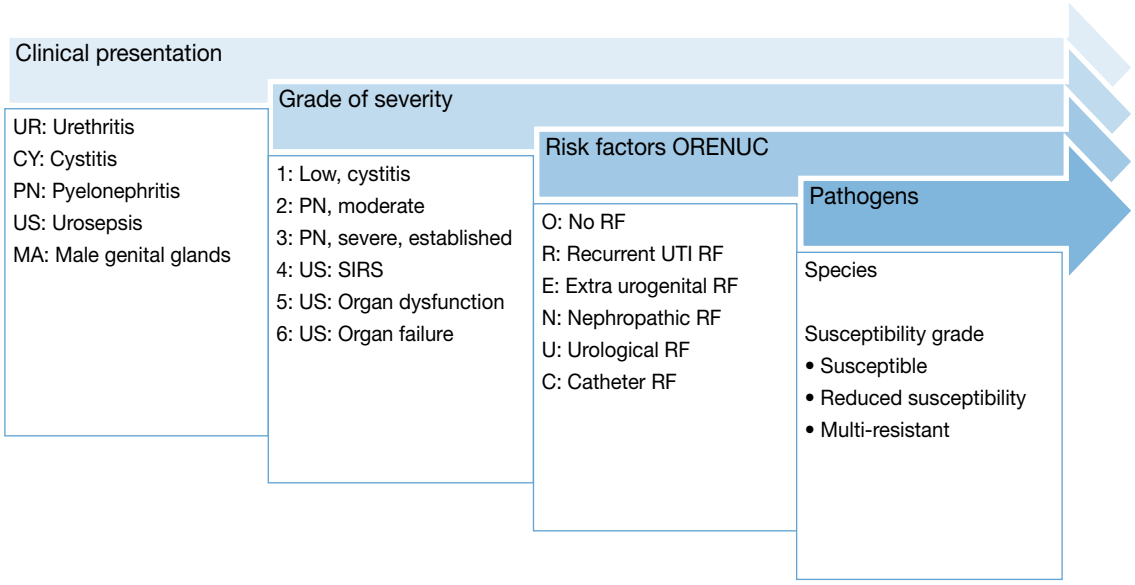
2.4 Pathogens

Urine culture will usually identify the causative pathogen (≥ 10^4 cfu/mL) and its susceptibility pattern. Both characteristics can be introduced in the final classification of the clinical stage of infection. The degree of susceptibility is defined as grade a (susceptible) to c (resistant).

2.5 Classification of UTI

Figure 2.2 shows a summary of the additive parameters that make up an individual class of UTI.

Figure 2.2: Additive parameters of UTI classification and severity assessment



By cumulating the different parameters, a UTI can be classified as follows (1):

- CY-1R: *E. coli* (a): simple cystitis but recurrent with susceptibility to standard antibiotics.
- PN-3U: *K pneumonia* (b): severe pyelonephritis (with high fever and vomiting), with underlying urological disease (e.g. stones or obstruction) due to Klebsiella sp., with a moderate antibiotic resistance profile.
- US-5C: *Enterococcus* sp (a): severe urosepsis with an antibiotic-sensitive Enterococcus sp. in a patient with an indwelling catheter.

3. UNCOMPLICATED UTIs IN ADULTS

3.1 Summary and recommendations

This chapter is by itself the summary of the EAU/ICUD initiative on urogenital infections, chapter 3 on uncomplicated UTI (1).

3.2 Definition

Acute, uncomplicated UTIs in adults include episodes of acute cystitis and acute pyelonephritis in otherwise healthy individuals. These UTIs are seen mostly in women without structural and functional abnormalities within the urinary tract, kidney diseases, or comorbidity that could lead to more serious outcomes and therefore require additional attention (2).

*3.2.1 **Aetiological spectrum***

The spectrum of aetiological agents is similar in uncomplicated upper and lower UTIs, with *E. coli* the causative pathogen in 70-95% of cases and *Staphylococcus saprophyticus* in 5-10%. Occasionally, other Enterobacteriaceae, such as *Proteus mirabilis* and *Klebsiella sp*., are isolated (3) (LE: 2a).

3.3 Acute uncomplicated cystitis in premenopausal, non-pregnant women

*3.3.1 **Diagnosis***

3.3.1.1 Clinical diagnosis

The diagnosis of acute uncomplicated cystitis can be made with a high probability based on a focused history of urinary irritative symptomatology (dysuria, frequency and urgency) and the absence of vaginal discharge or irritation, in those women who have no other risk factors for complicated UTIs (4) (LE: 2a, GR: B).

3.3.1.2 Laboratory diagnosis

Urine dipstick testing, as opposed to urinary microscopy, is a reasonable alternative to urinalysis for diagnosis of acute uncomplicated cystitis (5,6) (LE: 2a, GR: B).

Urine cultures are recommended for those with: (i) suspected acute pyelonephritis; (ii) symptoms that do not resolve or recur within 2-4 weeks after the completion of treatment; and (iii) those women who present with atypical symptoms (7,8) (LE: 4, GR: B).

A colony count of $\geq 10^3$ cfu/mL of uropathogens is microbiologically diagnostic in women who present with symptoms of acute uncomplicated cystitis (9) (LE: 3, GR: B).

Women who present with atypical symptoms of either acute uncomplicated cystitis or acute uncomplicated pyelonephritis, as well as those who fail to respond to appropriate antimicrobial therapy should be considered for additional diagnostic studies (LE:4, GR: B).

*3.3.2 **Therapy***

Antibiotic therapy is recommended because clinical success is significantly more likely in women treated with antibiotics compared with placebo (10) (LE: 1a, GR: A).

The choice of an antibiotic for therapy should be guided by:

- spectrum and susceptibility patterns of the aetiological uropathogens;
- efficacy for the particular indication in clinical studies;
- tolerability;
- adverse effects;
- cost;
- availability.

According to these principles and the available susceptibility patterns in Europe, fosfomycin trometamol 3 g single dose, pivmecillinam 400 mg for 3 days, and nitrofurantoin macrocrystal 100 mg bid for 5 days, are considered as drugs of first choice in many countries, when available (11-13) (LE: 1a, GR: A).

Cotrimoxazole 160/800 mg bid for 3 days or trimethoprim 200 mg for 5 days should only be considered as drugs of first choice in areas with known resistance rates for *E. coli* of < 20% (14,15) (LE: 1b, GR: B).

Alternative antibiotics are ciprofloxacin 250 mg bid, ciprofloxacin extended release 500 mg qd, levofloxacin 250 mg qd, norfloxacin 400 mg bid, and ofloxacin 200 mg bid, each as a 3-day course (16) (LE: 1b, GR: B). However, adverse effects have to be considered (Table 3.1).

Table 3.1: Recommended antimicrobial therapy in acute uncomplicated cystitis in otherwise healthy premenopausal women

Antibiotics	Daily dose	Duration of therapy
Fosfomycin trometamol°	3 g SD	1 day
Nitrofurantoin	50 mg q6h	7 days
Nitrofurantoin macrocrystal	100 mg bid	5-7 days
Pivmecillinam*	400 mg bid	3 days
Pivmecillinam*	200 mg bid	7 days
Alternatives		
Ciprofloxacin	250 mg bid	3 days
Levofloxacin	250 mg qd	3 days
Norfloxacin	400 mg bid	3 days
Ofloxacin	200 mg bid	3 days
Cefpodoxime proxetil	100 mg bid	3 days
*If local resistance pattern is known (*E. coli *resistance < 20%)*		
Trimethoprim-sulphamethoxazole	160/800mg bid	3 days
Trimethoprim	200 mg bid	5 days

°not available in all countries.
**available only in Scandinavia, the Netherlands, Austria, and Canada.*

3.3.3 ***Follow-up***

Routine post-treatment urinalysis or urine cultures in asymptomatic patients are not indicated (17) (LE: 2b, GR: B).

In women whose symptoms do not resolve by the end of treatment, and in those whose symptoms resolve but recur within 2 weeks, urine culture and antimicrobial susceptibility tests should be performed (LE: 4, GR: B). For therapy in this situation, one should assume that the infecting organism is not susceptible to the agent originally used. Retreatment with a 7-day regimen using another agent should be considered (LE: 4, GR: C).

3.4 Acute uncomplicated pyelonephritis in premenopausal, non-pregnant women

3.4.1 ***Diagnosis***

3.4.1.1 Clinical diagnosis

Acute pyelonephritis is suggested by flank pain, nausea and vomiting, fever (> 38°C), or costovertebral angle tenderness, and it can occur in the absence of symptoms of cystitis (18).

3.4.1.2 Laboratory diagnosis

Urinalysis (e.g. using a dipstick method), including the assessment of white and red blood cells and nitrites, is recommended for routine diagnosis (19) (LE: 4, GR: C).

Colony counts ≥ 10^4 cfu/mL of uropathogens are considered to be indicative of clinically relevant bacteriuria (20) (LE: 2b, GR: C).

3.4.1.3 Imaging diagnosis

Evaluation of the upper urinary tract with ultrasound should be performed to rule out urinary obstruction or renal stone disease (LE: 4, GR: C).

Additional investigations, such as an unenhanced helical computed tomography (CT), excretory urography, or dimercaptosuccinic acid (DMSA) scanning, should be considered if the patients remain febrile after 72 h of treatment (LE: 4, GR: C).

3.4.2 ***Therapy***

As a result of the lack of suitable surveillance studies, the spectrum and susceptibility patterns of uropathogens that cause uncomplicated cystitis can be used as a guide for empirical therapy (3) (LE: 4, GR: B). However, *S. saprophyticus* is less frequent in acute pyelonephritis as compared to acute cystitis (LE: 4, GR: B).

3.4.2.1 Mild and moderate cases of acute uncomplicated pyelonephritis (Table 3.2)

In mild and moderate cases of acute uncomplicated pyelonephritis, oral therapy of 10-14 days is usually sufficient (LE: 1b, GR: B).

A fluoroquinolone for 7-10 days can be recommended as first-line therapy if the resistance rate of *E. coli* is still < 10% (21) (LE: 1b, GR: A).

If the fluoroquinolone dose is increased, the treatment can probably be reduced to 5 days (22,23) (LE: 1b, GR: B). However, increasing numbers of fluoroquinolone-resistant *E. coli* in the community have already been found in some parts of the world, thus restricting the empirical use of fluoroquinolones.

A third-generation oral cephalosporin, such as cefpodoxime proxetil or ceftibuten, could be an alternative (24,25) (LE: 1b, GR: B). However, available studies have demonstrated only equivalent clinical, but not microbiological, efficacy compared with ciprofloxacin.

As a result of increasing *E. coli* resistance rates >10%, cotrimoxazole is not suitable for empirical therapy in most areas, but it can be used after sensitivity has been confirmed through susceptibility testing (26) (LE: 1b, GR: B).

Co-amoxiclav is not recommended as a drug of first choice for empirical oral therapy of acute pyelonephritis (LE: 4, GR: B). It is recommended when susceptibility testing shows a susceptible Gram-positive organism (LE: 4, GR: C).

In communities with high rates of fluoroquinolone-resistant and extended-spectrum β-lactamase (ESBL)-producing *E. coli* (> 10%), initial empirical therapy with an aminoglycoside or carbapenem has to be considered until susceptibility testing demonstrates that oral drugs can also be used (LE: 4, GR: B).

3.4.2.2 Severe cases of acute uncomplicated pyelonephritis (Table 3.2)

Patients with severe pyelonephritis who cannot take oral medication because of systemic symptoms such as nausea and vomiting, have to be treated initially with one of the following parenteral antibiotics:

	LE	**GR**
a parenteral fluoroquinolone, in communities with *E. coli* fluoroquinolone-resistance rates < 10%.	1b	B
a third-generation cephalosporin, in communities with ESBL-producing *E. coli* resistance rates < 10%.	1b	B
an aminopenicillin plus a β-lactamase-inhibitor in cases of known susceptible Gram-positive pathogens.	4	B
an aminoglycoside or carbapenem in communities with fluoroquinolone and/or ESBL-producing *E. coli* resistance rates > 10%.	1b	B

Hospital admission should be considered if complicating factors cannot be ruled out by available diagnostic procedures and/or the patient has clinical signs and symptoms of sepsis (LE: 4, GR: B).

After improvement, the patient can be switched to an oral regimen using one of the above-mentioned antibacterials, if active against the infecting organism, to complete the 1-2-week course of therapy (LE: 1b, GR: B).

Table 3.2: Recommended initial empirical antimicrobial therapy in acute uncomplicated pyelonephritis in otherwise healthy premenopausal women

I. Oral therapy in mild and moderate cases			
Antibiotics	Daily dose	Duration of therapy	Reference
Ciprofloxacin[1]	500-750 mg bid	7-10 days	(21)
Levofloxacin[1]	250-500 mg qd	7-10 days	(27)
Levofloxacin	750 mg qd	5 days	(22,23)
Alternatives (clinical but not microbiological equivalent efficacy compared with fluoroquinolones):			
Cefpodoxime proxetil	200 mg bid	10 days	(25)
Ceftibuten	400 mg qd	10 days	(24)
Only if the pathogen is known to be susceptible (not for initial empirical therapy):			

Trimethoprim-sulphamethoxazole	160/800 mg bid	14 days	(21)
Co-amoxiclav[2,3]	0.5/0.125 g tid	14 days	

[1]lower dose studied, but higher dose recommended by experts.
[2]not studied as monotherapy for acute uncomplicated pyelonephritis.
[3]mainly for Gram-positive pathogens.

II. Initial parenteral therapy in severe cases After improvement, the patient can be switched to an oral regimen using one of the above-mentioned antibacterials (if active against the infecting organism) to complete the 1-2-week course of therapy. Therefore, only daily dose and no duration of therapy are indicated.		
Antibiotics	Daily dose	Reference
Ciprofloxacin	400 mg bid	(21)
Levofloxacin[1]	250-500 mg qd	(27)
Levofloxacin	750 mg qd	(22)
Alternatives:		
Cefotaxime[2]	2 g tid	
Ceftriaxone[1,4]	1-2 g qd	(28)
Ceftazidime[2]	1-2 g tid	(29)
Cefepime[1,4]	1-2 g bid	(30)
Co-amoxiclav[2,3]	1.5 g tid	
Piperacillin/tazobactam[1,4]	2.5-4.5 g tid	(31)
Gentamicin[2]	5 mg/kg qd	
Amikacin[2]	15 mg/kg qd	
Ertapenem[4]	1 g qd	(28)
Imipenem/cilastatin[4]	0.5/0.5 g tid	(31)
Meropenem[4]	1 g tid	(29)
Doripenem[4]	0.5 g tid	(32)

[1]lower dose studied, but higher dose recommended by experts.
[2]not studied as monotherapy in acute uncomplicated pyelonephritis.
[3]mainly for Gram-positive pathogens.
[4]same protocol for acute uncomplicated pyelonephritis and complicated UTI (stratification not always possible).

*3.4.3 **Follow-up***

Routine post-treatment urinalysis and urine cultures in an asymptomatic patient might not be indicated (LE: 4, GR: C).

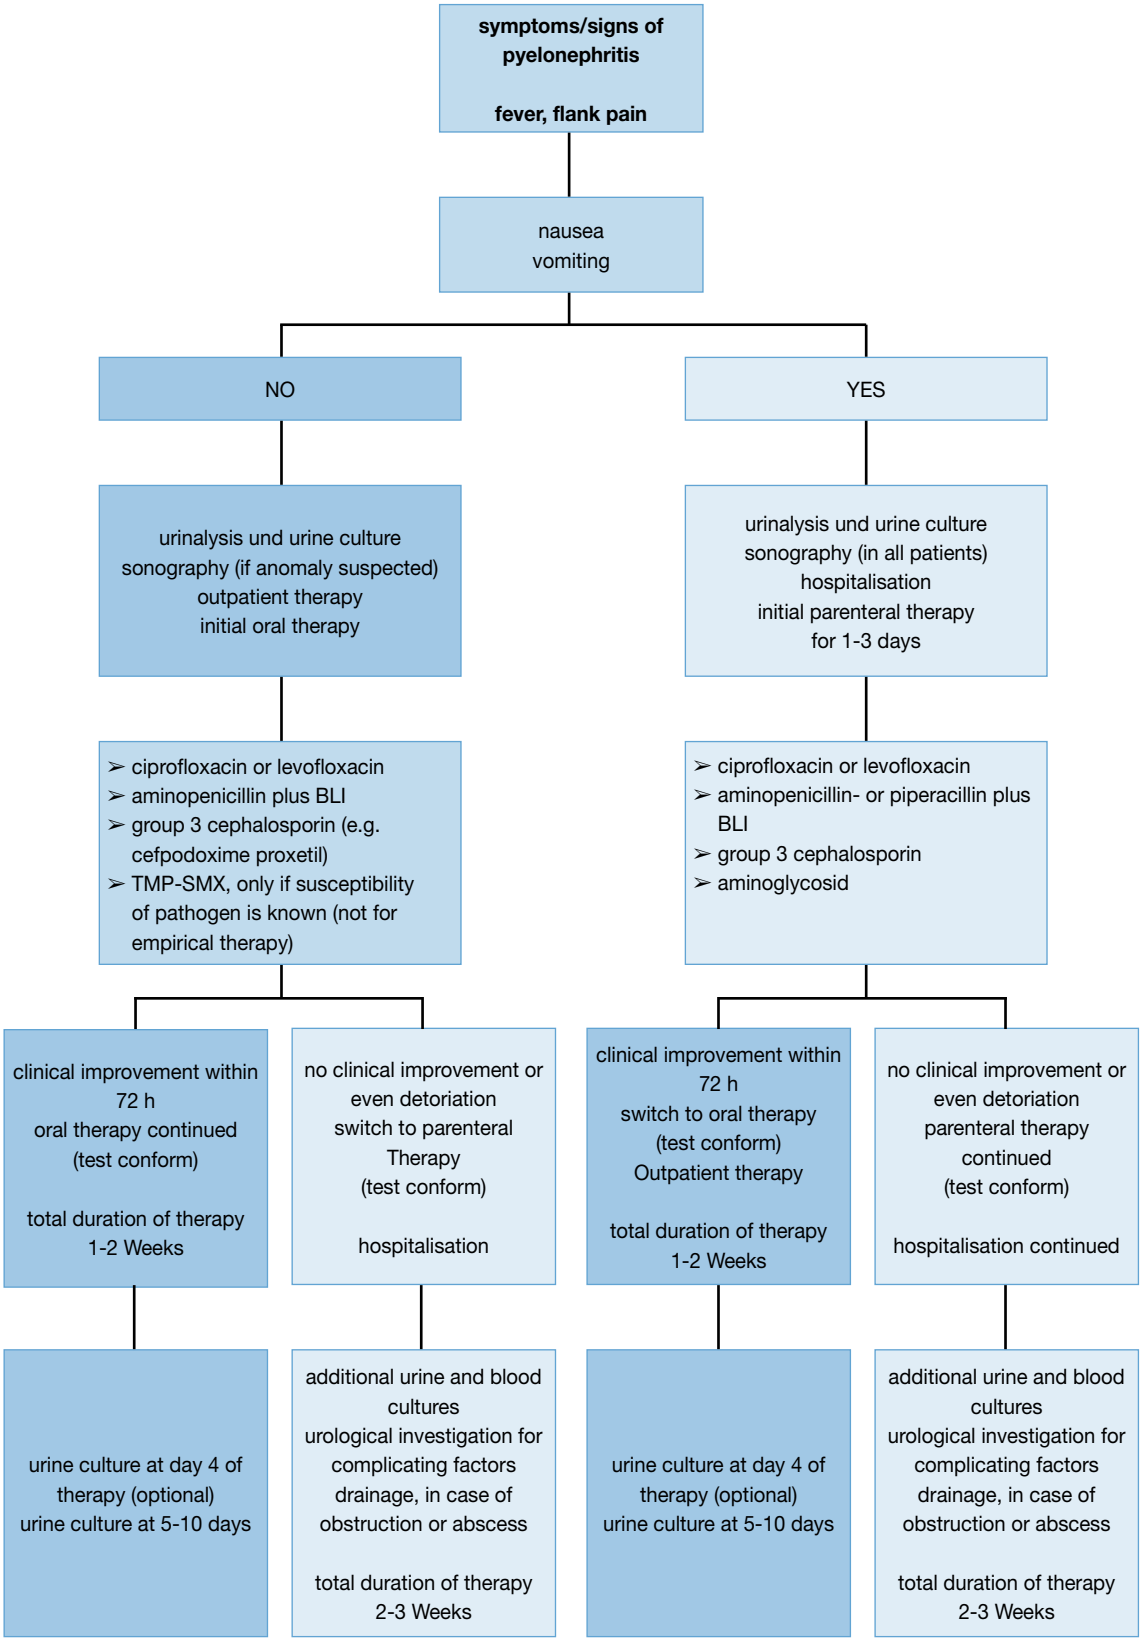
In women whose pyelonephritis symptoms do not improve within 3 days, or resolve and then recur within 2 weeks, repeated urine culture and antimicrobial susceptibility tests and an appropriate investigation, such as renal ultrasound, CT or renal scintigraphy, should be performed (LE: 4, GR: B).

In patients with no urological abnormality, it should be assumed that the infecting organism is not susceptible to the agent originally used, and an alternative tailored treatment should be considered based on culture results (LE: 4, GR: B).

For patients who relapse with the same pathogen, the diagnosis of uncomplicated pyelonephritis should be reconsidered. Appropriate diagnostic steps are necessary to rule out any complicating factors (LE: 4, GR: C).

An algorithm of the clinical management of acute pyelonephritis is shown in Figure 3.1.

Figure 3.1: Clinical management of acute pyelonephritis



BLI = β-lactamase inhibitor; TMP = trimethoprim; SMX = sulphamethoxazole.

3.5 Recurrent (uncomplicated) UTIs in women

3.5.1 ***Diagnosis***

Recurrent UTIs are common among young, healthy women, even though they generally have anatomically and physiologically normal urinary tracts (33) (LE: 2a).

Recurrent UTIs need to be diagnosed by urine culture (LE: 4, GR: A).

Excretory urography, cystography and cystoscopy are not routinely recommended for evaluation of women with recurrent UTIs (34) (LE: 1b, GR: B).

3.5.2 ***Prevention***

Different therapeutic options can be recommended to the patient.

3.5.2.1 Antimicrobial prophylaxis

Antimicrobial prophylaxis for prevention of recurrent UTI should be considered only after counselling and behavioural modification has been attempted (LE: 4, GR: A).

Before any prophylaxis regimen is initiated, eradication of a previous UTI should be confirmed by a negative urine culture 1-2 weeks after treatment (LE: 4, GR: A).

Continuous or postcoital antimicrobial prophylaxis should be considered to prevent recurrent uncomplicated cystitis in women in whom non-antimicrobial measures have been unsuccessful (35) (LE: 1a, GR: A). The choice of antibiotics should be based upon the identification and susceptibility pattern of the organism that causes the UTI and the patient's history of drug allergies. Drug regimens are shown in Tables 3.3 and 3.4.

Table 3.3: Continuous antimicrobial prophylaxis regimens for women with recurrent UTIs (33)

Regimens	Expected UTIs per year
TMP-SMX* 40/200 mg once daily	0-0.2
TMP-SMX 40/200 mg thrice weekly	0.1
Trimethoprim 100 mg once daily	0-1.5**
Nitrofurantoin 50 mg once daily	0-0.6
Nitrofurantoin 100 mg once daily	0-0.7
Cefaclor 250 mg once daily	0.0
Cephalexin 125 mg once daily	0.1
Cephalexin 250 mg once daily	0.2
Norfloxacin 200 mg once daily	0.0
Ciprofloxacin 125 mg once daily	0.0
Fosfomycin 3 g every 10 days	0.14

**Trimethoprim-sulfamethoxazole*

***high recurrence rates observed with trimethoprim use associated with trimethoprim resistance*

Table 3.4: Postcoital antimicrobial prophylaxis regimens for women with recurrent UTIs (33)

Regimens	Expected UTIs per year
TMP-SMX* 40/200 mg	0.30
TMP-SMX 80/400 mg	0.00
Nitrofurantoin 50 or 100 mg	0.10
Cephalexin 250 mg	0.03
Ciprofloxacin 125 mg	0.00
Norfloxacin 200 mg	0.00
Ofloxacin 100 mg	0.06

**Trimethoprim-sulfamethoxazole*

In appropriate women with recurrent uncomplicated cystitis, self-diagnosis and self-treatment with a short-course regimen of an antimicrobial agent should be considered (36) (LE: 2b, GR: A).

3.5.2.2 Immunoactive prophylaxis

OM-89 (Uro-Vaxom®) is sufficiently well-documented and has been shown to be more effective than placebo in several randomised trials. Therefore, it can be recommended for immunoprophylaxis in female patients with recurrent uncomplicated UTI (37,38) (LE: 1a, GR: B). Its efficacy in other groups of patients, and its efficacy relative to antimicrobial prophylaxis remain to be established.

For other immunotherapeutic products on the market, larger phase III studies are still missing. In smaller phase II studies, StroVac® and Solco-Urovac® have been shown to be effective when administered with a booster cycle of the same agents (LE: 1a, GR: C).

For other immunotherapeutic products, such as Urostim® and Urvakol®, no controlled studies are available. Therefore, no recommendations are possible.

3.5.2.3 Prophylaxis with probiotics

Accessibility of clinically proven probiotics for UTI prophylaxis is currently not universal. Only the Lactobacillus strains specifically tested in studies should be used for prophylaxis.

When commercially available, it is reasonable to consider the use of intravaginal probiotics that contain L. rhamnosus GR-1 and L. reuteri RC-14 for the prevention of recurrent UTI (39), and these products can be used once or twice weekly (LE: 4, GR: C).

Daily use of the oral product with strains GR-1 and RC-14 is worth testing given that it can restore the vaginal lactobacilli, compete with urogenital pathogens, and prevent bacterial vaginosis, a condition that increases the risk of UTI (39) (LE: 1b, GR: C).

3.5.2.4 Prophylaxis with cranberry

Despite the lack of pharmacological data and the small number of weak clinical studies, there is evidence to suggest that cranberry (Vaccinium macrocarpon) is useful in reducing the rate of lower UTIs in women (40,41) (LE: 1b, GR: C).

For everyday practice, the daily consumption of cranberry products, giving a minimum of 36 mg/day proanthocyanindin A (the active compound), is recommended (LE: 1b, GR: C). The best approach is to use those compounds that have demonstrated clear bioactivity in urine.

3.6 UTIs in pregnancy

Urinary tract infections are common during pregnancy. Most women acquire bacteriuria before pregnancy, and 20-40% of women with asymptomatic bacteriuria develop pyelonephritis during pregnancy.

3.6.1 ***Definition of significant bacteriuria***

- in an asymptomatic pregnant woman, bacteriuria is considered significant if two consecutive voided urine specimens grow $\geq 10^5$ cfu/mL of the same bacterial species on quantitative culture; or a single catheterised specimen grows $\geq 10^5$ cfu/mL of a uropathogen (17) (LE: 2a, GR: A).
- in a pregnant woman with symptoms compatible with UTI, bacteriuria is considered significant if a voided or catheterised urine specimen grows $\geq 10^3$ cfu/mL of a uropathogen (LE: 4, GR: B).

3.6.2 ***Screening***

Pregnant women should be screened for bacteriuria during the first trimester (42) (LE: 1a, GR: A).

3.6.3 ***Treatment of asymptomatic bacteriuria***

Asymptomatic bacteriuria detected in pregnancy should be eradicated with antimicrobial therapy (42) (LE: 1a, GR: A). Recommended antibiotic regimens are shown in Table 3.5.

Table 3.5: Treatment regimens for asymptomatic bacteriuria and cystitis in pregnancy (44)

Antibiotics	Duration of therapy	Comments
Nitrofurantoin (Macrobid®) 100 mg	q12 h, 3-5 days	Avoid in G6PD deficiency
Amoxicillin 500 mg	q8 h, 3-5 days	Increasing resistance
Co-amoxicillin/clavulanate 500 mg	q12 h, 3-5 days	
Cephalexin (Keflex®) 500 mg	q8 h, 3-5 days	Increasing resistance
Fosfomycin 3 g	Single dose	
Trimethoprim-sulfamethoxazole	q12 h, 3-5 days	Avoid trimethoprim in first trimester/term and sulfamethoxazole in third trimester/term

G6PD = glucose-6-phosphate dehydrogenase

3.6.4 *Duration of therapy*

Short courses of antimicrobial therapy (3 days) should be considered for the treatment of asymptomatic bacteriuria and cystitis in pregnancy (43) (LE: 1a, GR: A).

3.6.5 *Follow-up*

Urine cultures should be obtained soon after completion of therapy for asymptomatic bacteriuria and symptomatic UTI in pregnancy (LE: 4, GR: A).

3.6.6 *Prophylaxis*

Postcoital prophylaxis should be considered in pregnant women with a history of frequent UTIs before onset of pregnancy, to reduce their risk of UTI (44) (LE: 2b, GR: B).

3.6.7 *Treatment of pyelonephritis*

Outpatient management with appropriate antibiotics should be considered in women with pyelonephritis in pregnancy, provided symptoms are mild and close follow-up is feasible (45) (LE: 1b, GR: A). Recommended antibiotic regimens are shown in Table 3.6 (46).

Table 3.6: Treatment regimens for pyelonephritis in pregnancy

Antibiotics	Dose
Ceftriaxone	1-2 g IV or IM q24 h
Aztreonam	1 g IV q8-12 h
Piperacillin-tazobactam	3.375-4.5 g IV q6 h
Cefepime	1 g IV q12 h
Imipenem-cilastatin	500 mg IV q6 h
Ampicillin +	2 g IV q6 h
Gentamicin	3-5 mg/kg/day IV in 3 divided doses

3.6.8 *Complicated UTI*

Prolonged antibiotic therapy (7-10 days) should be considered in this patient population (LE: 4, GR: B). When indicated, ultrasonography or magnetic resonance imaging (MRI) should be used preferentially to avoid radiation risk to the foetus (LE: 4, GR: B).

3.7 UTIs in postmenopausal women

3.7.1 *Risk factors*

	Reference	LE
In older institutionalised women, urine catheterisation and functional status deterioration appear to be the most important risk factors associated with UTI.	47	2a
Atrophic vaginitis.	47	2a
Incontinence, cystocele and post-voiding residual urine.	47	2a
UTI before menopause.	47	2a
Non-secretor status of blood group antigens.	47	2a

3.7.2 *Diagnosis*

Diagnosis of UTI in postmenopausal women should always consider the following:

	Reference	LE	GR
History, physical examination and urinalysis, including culture.		4	B
Genitourinary symptoms are not necessarily related to UTI and an indication for antimicrobial treatment.	48	1b	B

3.7.3 ***Treatment***

	Reference	LE	GR
Treatment of acute cystitis in postmenopausal women is similar to that in premenopausal women, however, short-term therapy is not so well-established as in premenopausal women.	49	1b	C
Treatment of pyelonephritis in postmenopausal women is similar to that in premenopausal women.		4	C
Asymptomatic bacteriuria in elderly women should not be treated with antibiotics.	17	2b	A
Optimal antimicrobials, doses and duration of treatment in elderly women appear to be similar to those recommended for younger postmenopausal women.		4	C
Oestrogen (especially vaginal) can be administered for prevention of UTI, but results are contradictory.	50	1b	C
Alternative methods, such as cranberry and probiotic lactobacilli, can contribute but they are not sufficient to prevent recurrent UTI.	51	1b	C
If complicating factors, such as urinary obstruction and neurogenic bladder, are ruled out, antimicrobial prophylaxis should be carried out as recommended for premenopausal women.		4	C

3.8 Acute uncomplicated UTIs in young men

3.8.1 ***Men with acute uncomplicated UTI***

	Reference	LE	GR
Only a small number of 15-50-year-old men suffer from acute uncomplicated UTI.	52		
Such men should receive, as minimum therapy, a 7-day antibiotic regimen.		4	B

3.8.2 ***Men with UTI and concomitant prostate infection***

	Reference	LE	GR
Most men with febrile UTI have a concomitant infection of the prostate, as measured by transient increases in serum PSA and prostate volume.	53	2a	
Urological evaluation should be carried out routinely in adolescents and men with febrile UTI, pyelonephritis, or recurrent infection, or whenever a complicating factor is suspected.		4	A
A minimum treatment duration of 2 weeks is recommended, preferably with a fluoroquinolone since prostatic involvement is frequent.	54	2a	B

3.9 Asymptomatic bacteriuria

3.9.1 ***Diagnosis***

	Reference	LE	GR
For women, a count of $\geq 10^5$ cfu/mL of a microorganism in a voided urine specimen is diagnostic of bacteriuria.	17	2b	B
For men, a count of $\geq 10^3$ cfu/mL of a microorganism in a voided urine specimen is diagnostic of bacteriuria.	55	2a	B
For men with specimens collected using an external condom catheter, $\geq 10^5$ cfu/mL is an appropriate quantitative diagnostic criterion.	56	2a	B
For patients with indwelling urethral catheters, a count of $\geq 10^5$ cfu/mL is diagnostic of bacteriuria.	17	2b	B
For a urine specimen collected by in and out catheter, a count of ≥ 100 cfu/mL is consistent with bacteriuria.	17	2a	B
Pyuria in the absence of signs or symptoms in a person with bacteriuria should not be interpreted as symptomatic infection or as an indication for antimicrobial therapy.	17	2b	B

3.9.2 *Screening*

Screening for and treatment of asymptomatic bacteriuria is recommended:

	Reference	LE	GR
For pregnant women.	42	1a	A
Before an invasive genitourinary procedure for which there is a risk of mucosal bleeding.	17	1b	A

Screening for or treatment of asymptomatic bacteriuria is not recommended for:

	Reference	LE	GR
Premenopausal, non-pregnant women	17	1a	A
Postmenopausal women	17	1b	A
Women with diabetes	57	1b	A
Healthy men	58	2b	B
Residents of long-term care facilities	17	1a	A
Patients with an indwelling urethral catheter	17	1b	
Patients with nephrostomy tubes or ureteric stents		4	C
Patients with spinal cord injury	59	2a	B
Patients with candiduria	60	1b	A

Screening for or treatment of asymptomatic bacteriuria in renal transplant patients beyond the first 6 months is not recommended (LE: 2b, GR: B).

No recommendation can be made with respect to screening for or treatment of bacteriuria in patients with neutropenia (LE: 4).

4. COMPLICATED UTIs DUE TO UROLOGICAL DISORDERS

4.1 Summary and recommendations

A complicated UTI is an infection associated with a condition, such as a structural or functional abnormality of the genitourinary tract, or the presence of an underlying disease that interferes with host defence mechanisms, which increase the risks of acquiring infection or of failing therapy.

A broad range of bacteria can cause a complicated UTI. The spectrum is much larger than in uncomplicated UTIs, and bacteria are more likely to be resistant to antimicrobials, especially in a treatment-related complicated UTI.

Enterobacteriaceae are the predominant pathogens, with *E. coli* being the most common pathogen. However, non-fermenters (e.g. *Pseudomonas aeruginosa*) and Gram-positive cocci (e.g. staphylococci and enterococci) may also play an important role, depending on the underlying conditions.

Treatment strategy depends on the severity of the illness. Treatment encompasses three goals: management of the urological abnormality, antimicrobial therapy, and supportive care when needed. Hospitalisation is often required. To avoid the emergence of resistant strains, therapy should be guided by urine culture whenever possible.

If empirical therapy is necessary, the antibacterial spectrum of the antibiotic agent should include the most relevant pathogens (GR: A). A fluoroquinolone with mainly renal excretion, an aminopenicillin plus a β-lactamase inhibitor (BLI), a Group 2 or 3a cephalosporin or, in the case of parenteral therapy, an aminoglycoside, are recommended alternatives (LE: 1b, GR: B).

In case of failure of initial therapy, or in case of clinically severe infection, a broader-spectrum antibiotic should be chosen that is also active against *Pseudomonas* (LE: 1b, GR: B), e.g. a fluoroquinolone (if not used for initial therapy), an acylaminopenicillin (piperacillin) plus a BLI, a Group 3b cephalosporin, or a carbapenem, with or without combination with an aminoglycoside (LE: 1b, GR: B).

The duration of therapy is usually 7-14 days (LE: 1b, GR: A), but sometimes has to be prolonged for up to 21 days (LE: 1b, GR: A).

Until predisposing factors are completely removed, true cure without recurrent infection is usually not possible. Therefore, a urine culture should be carried out 5-9 days after completion of therapy and also 4-6 weeks later (GR: B).

4.2 Definitions and classification

A complicated UTI is an infection associated with a condition, such as structural or functional abnormalities of the genitourinary tract or the presence of an underlying disease, which increases the risks of acquiring an infection or of failing therapy (1-3). Two criteria are mandatory to define a complicated UTI: a positive urine culture and one or more of the factors listed in Table 4.1.

Table 4.1: Factors that suggest a potential complicated UTI

The presence of an indwelling catheter, stent or splint (urethral, ureteral, renal) or the use of intermittent bladder catheterisation
Post-void residual urine of > 100 mL
An obstructive uropathy of any aetiology, e.g. bladder outlet obstruction (including neurogenic urinary bladder), stones and tumour
Vesicoureteric reflux or other functional abnormalities
Urinary tract modifications, such as an ileal loop or pouch
Chemical or radiation injuries of the uroepithelium
Peri- and postoperative UTI
Renal insufficiency and transplantation, diabetes mellitus and immunodeficiency

Complicated UTI can arise in a heterogeneous group of patients. However, neither patient age nor sex *per se* are part of the definition of a complicated UTI. With regard to prognosis and clinical studies, it is advisable to stratify complicated UTIs due to urological disorders into at least two groups (4):

1. Patients in whom the complicating factors could be eliminated by therapy, e.g. stone extraction, removal of an indwelling catheter.
2. Patients in whom the complicating factor could not be or is not removed satisfactorily during therapy, e.g. permanent indwelling catheter, stone residues after treatment or neurogenic bladder.

*4.2.1 **Clinical presentation***

A complicated UTI may or may not be associated with clinical symptoms (e.g. dysuria, urgency, frequency, flank pain, costovertebral angle tenderness, suprapubic pain and fever). Clinical presentation can vary from severe obstructive acute pyelonephritis with imminent urosepsis to a catheter-associated postoperative UTI, which might disappear spontaneously as soon as the catheter is removed. It also has to be recognised that symptoms, especially lower urinary tract symptoms (LUTSs), are not only caused by UTIs but also by other urological disorders, such as benign prostatic hyperplasia (BPH), transurethral resection of the prostate (TURP).

Apart from urological abnormalities, concomitant medical conditions, such as diabetes mellitus (10%) and renal failure, which can be related to urological abnormalities (5), are often present in a complicated UTI. These are discussed in more details in Sections 8.1.3 and 8.1.4 on UTIs in renal insufficiency, transplant recipients, diabetes mellitus and immunosuppression.

*4.2.2 **Urine cultures***

Significant bacteriuria in a complicated UTI is defined by counts of $\geq 10^5$ cfu/mL and $\geq 10^4$ cfu/mL, in the mid-stream urine (MSU) of women and men, respectively (1,2). If a straight catheter urine sample is taken, $\geq 10^4$ cfu/mL can be considered relevant. For an asymptomatic patient, two consecutive urine cultures (at least 24 h apart) yielding $\geq 10^5$ cfu/mL of the same microorganism are required. The requirement for pyuria is ≥ 10 white blood cells (WBC) per high-power field (x400) in the resuspended sediment of a centrifuged aliquot of urine or per mm^3 in unspun urine. A dipstick method can also be used for routine assessment, including a leukocyte esterase test, haemoglobin and probably a nitrite reaction.

4.3 Microbiology

*4.3.1 **Spectrum and antibiotic resistance***

Patients with a complicated UTI, both community and hospital-acquired, tend to show a diversity of microorganisms with a higher prevalence of resistance against antimicrobials, and higher rates of treatment failure if the underlying abnormality cannot be corrected.

However, the presence of a resistant strain on its own is not enough to define a complicated UTI. Urinary abnormality (anatomical or functional) or the presence of an underlying disease predisposing to a UTI is also necessary.

A broad range of bacteria can cause a complicated UTI. The spectrum is much larger than with an uncomplicated UTI and the bacteria are more likely to be antibiotic-resistant (especially in a treatment-related complicated UTI) than those isolated in an uncomplicated UTI. *E. coli, Proteus, Klebsiella*, Pseudomonas and *Serratia* sp. and enterococci are the usual strains found in cultures. Enterobacteriaceae predominate (60-75%) (6-8), with *E. coli* as the most common pathogen; particularly if the UTI is a first infection. Otherwise, the bacterial spectrum may vary over time and from one hospital to another.

*4.3.2 **Complicated UTIs associated with urinary stones***

In the subset of complicated UTIs related to urinary stones, the frequency of *E. coli* and enterococci infection seems less important pathogens. In contrast, a greater portion of *Proteus* and *Pseudomonas* sp. (9) is found.

Of the urease-producing organisms, *Proteus, Providencia* and *Morganella* sp., and *Corynebacterium urealyticum* are predominant, but *Klebsiella, Pseudomonas* and *Serratia* sp. and staphylococci are also urease producers to a certain extent.

Among patients with staghorn calculus disease, 88% were found to have a UTI at the time of diagnosis, with 82% of patients infected with urease-producing organisms (10). The enzyme, urease, splits urea into carbon dioxide and ammonia. The resultant increase in ammonia in the urine injures the glycosaminoglycan layer, which in turn increases bacterial adherence (11) and enhances the formation of struvite crystals. These aggregate to form renal stones and incrustations on urinary catheters (12).

The pathogenic potential of coagulase-negative staphylococci and non-group D streptococci is controversial (13,14). Under certain circumstances, such as the presence of a stone or foreign bodies, staphylococci can be relevant pathogens. Otherwise, staphylococci are not so common in complicated UTIs (0-11%), according to published reports (6,15).

*4.3.3 **Complicated UTIs associated with urinary catheters***

In catheter-associated UTIs, the distribution of microorganisms is similar (16), and biofilm has to be considered. Antimicrobial therapy may only be effective in the early stages of the infection (15). For more details see chapter 6 on catheter-associated UTIs.

4.4 Treatment

*4.4.1 **General principles***

Treatment strategy depends on the severity of the illness. Appropriate antimicrobial therapy and the

management of the urological abnormality are mandatory. If needed, supportive care is given. Hospitalisation is often necessary depending on the severity of the illness.

4.4.2 ***Choice of antibiotics***

Empirical treatment of a symptomatic complicated UTI requires a knowledge of the spectrum of possible pathogens and local antibiotic resistance patterns, as well as assessment of the severity of the underlying urological abnormality (including the evaluation of renal function).

Bacteraemia is usually reported too late to influence the choice of antibiotics. However, suspicion of bacteraemia must influence the empirical treatment. The severity of the associated illness and the underlying urological condition are still of the utmost importance for prognosis.

Many therapeutic trials have been published on the use of specific antimicrobial therapies in complicated UTIs. Unfortunately, most reports are of limited use for the practical management of the patient in a day-to-day situation because of limitations such as:

- poor characterisation of the patient populations;
- unclear evaluation of the severity of the illness;
- nosocomial and community-acquired infections are not accurately distinguished;
- urological outcome is seldom taken into consideration.

Intense use of any antimicrobial, especially when used on an empirical basis in this group of patients with a high likelihood of recurrent infection, will lead to the emergence of resistant microorganisms in subsequent infections. Whenever possible, empirical therapy should be replaced by a therapy adjusted for the specific infective organisms identified in the urine culture. Therefore, a urine specimen for culture must be obtained before initiation of therapy, and the selection of an antimicrobial agent should be re-evaluated once culture results are available (7). To date, it has not been shown that any agent or class of agents is superior in cases in which the infective organism is susceptible to the drug administered.

In patients with renal failure, whether related to a urological abnormality or not, appropriate dose adjustments have to be made.

If empirical treatment is necessary, fluoroquinolones with mainly renal excretion are recommended because they have a large spectrum of antimicrobial activity that covers most of the expected pathogens, and they reach high concentration levels both in the urine and the urogenital tissues. Fluoroquinolones can be used orally as well as parenterally. An aminopenicillin plus a BLI, a Group 2 or 3a cephalosporin, or, in the case of parenteral therapy, an aminoglycoside, are alternatives. A new Group 1 oral carbapenem, ertapenem, in a prospective randomised trial, has been shown to be as effective as ceftriaxone (16).

In most countries, *E. coli* shows a high rate of resistance against TMP-SMX (18-25% in the latest evaluation in the USA) (17) and should therefore be avoided as a first-line treatment. Fosfomycin trometamol is licensed only for a single-dose therapy of uncomplicated cystitis (18). The aminopenicillins, ampicillin or amoxicillin, are no longer sufficiently active against *E. coli*.

In the case of failure of initial therapy, or if microbiological results are not yet available, or as initial therapy in the case of clinically severe infection, treatment should be switched to an antibiotic with a broader spectrum that is also active against *Pseudomonas*, such as a fluoroquinolone (if not used for initial therapy), an acylaminopenicillin (piperacillin) plus a BLI, a Group 3b cephalosporin, or a carbapenem, eventually in combination with an aminoglycoside. Similarly, many experts concur that empirical therapy for the institutionalised or hospitalised patients with a serious UTI should include an intravenous antipseudomonal agent because of an increased risk of urosepsis (19).

Patients can generally be treated as outpatients. In more severe cases (e.g. hospitalised patients), antibiotics have to be given parenterally. A combination of an aminoglycoside with a BLI or a fluoroquinolone is widely used for empirical therapy. After a few days of parenteral therapy and clinical improvement, patients can be switched to oral treatment. Therapy has to be reconsidered when the infective strains have been identified and their susceptibilities are known.

The successful treatment of a complicated UTI always combines effective antimicrobial therapy, optimal management of the underlying urological abnormalities or other diseases, and sufficient life-supporting measures. The antibacterial treatment options are summarised in Table 4.2 and Appendix 16.2 (Recommendations for antimicrobial therapy in urology).

4.4.3 ***Duration of antibiotic therapy***

Treatment for 7-14 days is generally recommended, but the duration should be closely related to the treatment of the underlying abnormality (1). Sometimes, a prolongation for up to 21 days, according to the clinical situation, is necessary (2).

4.4.4 ***Complicated UTIs associated with urinary stones***

If a nidus of a stone or an infection remains, stone growth will occur. Complete removal of the stones and

adequate antimicrobial therapy are both needed. Eradication of the infection will probably eliminate the growth of struvite calculi (20). Long-term antimicrobial therapy should be considered if complete removal of the stone cannot be achieved (21).

*4.4.5 **Complicated UTIs associated with indwelling catheters***

Current data do not support the treatment of asymptomatic bacteriuria, either during short-term catheterisation (< 30 days) or during long-term catheterisation, because it will promote the emergence of resistant strains (22,23). In short-term catheterisation, antibiotics may delay the onset of bacteriuria, but do not reduce complications (24).

A symptomatic complicated UTI associated with an indwelling catheter is treated with an agent with as narrow a spectrum as possible, based on culture and sensitivity results. The optimal duration is not well established. Treatment durations that are too short as well as too long may cause the emergence of resistant strains. A 7-day course could be a reasonable compromise.

*4.4.6 **Complicated UTIs in patients with spinal cord injury***

In case of persistent UTIs and suspicion of urinary retention, a full urodynamic assessment to appraise bladder function is to be carried out. Priority is to ensure proper drainage of the bladder to protect the urinary tract. For further details, see the EAU guidelines on Neurogenic Lower Urinary Tract Dysfunction (25).

It is generally accepted that asymptomatic bacteriuria in patients with spinal cord injury should not be treated (26), even in cases of intermittent catheterisation. For symptomatic episodes of infection in patients with spinal cord injury, only a few studies have investigated the most appropriate agent and duration of therapy. Currently, 7-10 days of therapy is most commonly used. There is no superiority of one agent or class of antimicrobials in this group of patients.

Antimicrobial treatment options are summarised in Table 4.2.

Table 4.2: Antimicrobial treatment options for empirical therapy

Antibiotics recommended for initial empirical treatment
Fluoroquinolones
Aminopenicillin plus a BLI
Cephalosporin (Groups 2 or 3a)
Aminoglycoside
Antibiotics recommended for empirical treatment in case of initial failure, or for severe cases
Fluoroquinolone (if not used for initial therapy)
Ureidopenicillin (piperacillin) plus BLI
Cephalosporin (Group 3b)
Carbapenem
Combination therapy:
- Aminoglycoside + BLI
- Aminoglycoside + fluoroquinolone
Antibiotics not recommended for empirical treatment
Aminopenicillins, e.g. amoxicillin, ampicillin
Trimethoprim-sulphamethoxazole (only if susceptibility of pathogen is known)
Fosfomycin trometamol

BLI = β-lactam inhibitor

*4.4.7 **Follow-up after treatment***

The greater likelihood of the involvement of resistant microorganisms in complicated UTIs is another feature of these infectious diseases. This is not a priori related to the urinary abnormality, but is related more to the fact that patients with a complicated UTI tend to have recurrent infection (7). For these reasons, before and after the completion of the antimicrobial treatment, urine cultures must be obtained for the identification of the microorganisms and the evaluation of susceptibility testing.

5. SEPSIS SYNDROME IN UROLOGY (UROSEPSIS)

5.1 Summary and recommendations

Patients with urosepsis should be diagnosed at an early stage, especially in the case of a complicated UTI. The systemic inflammatory response syndrome, known as SIRS (fever or hypothermia, hyperleukocytosis or leukopenia, tachycardia, tachypnoea), is recognised as the first event in a cascade to multi-organ failure. Mortality is considerably increased when severe sepsis or septic shock are present, although the prognosis of urosepsis is globally better than that of sepsis from other infectious sites.

The treatment of urosepsis calls for the combination of adequate life-supporting care, appropriate and prompt antibiotic therapy, adjunctive measures (e.g. sympathomimetic amines, hydrocortisone, blood glucose control) and the optimal management of urinary tract disorders (LE: 1a, GR: A). The drainage of any obstruction in the urinary tract is essential as first-line treatment (LE: 1b, GR: A). Urologists are recommended to treat patients in collaboration with intensive care and infectious diseases specialists (LE; 2a, GR: B).

Urosepsis is seen in both community-acquired and healthcare associated infections. Most nosocomial urosepsis can be avoided by measures used to prevent nosocomial infection, e.g. reduction of hospital stay, early removal of indwelling urethral catheters, avoidance of unnecessary urethral catheterisation, correct use of closed catheter systems, and attention to simple daily asepsis techniques to avoid cross-infection (LE: 2a, GR: B).

5.2 Background

Urinary tract infections can manifest as bacteriuria with limited clinical symptoms, sepsis or severe sepsis, depending on localised or systemic extension. Sepsis is diagnosed when clinical evidence of infection is accompanied by signs of systemic inflammation (fever or hypothermia, tachycardia, tachypnoea, leukocyturia or leukopenia). Severe sepsis is defined by the presence of symptoms of organ dysfunction, and septic shock by the presence of persistent hypotension associated with tissue anoxia.

Severe sepsis is a severe situation with a reported mortality rate of 20-42% (1). Most severe sepsis

reported in the literature is related to pulmonary (50%) or abdominal (24%) infections, with UTIs accounting for only 5% (2). Sepsis is more common in men than in women (3). In recent years, the incidence of sepsis has increased by 8.7% per year (1), but the associated mortality has decreased, which suggests improved management of patients (total in-hospital mortality rate fell from 27.8% to 17.9% during 1995-2000) (4). Globally (this is not true for urosepsis), the rate of sepsis due to fungal organisms has increased while Gram-positive bacteria have become the predominant pathogen in sepsis, even if Gram-negative bacteria remain predominant in urosepsis.

In urosepsis, as in other types of sepsis, the severity depends mostly upon the host response. Patients who are more likely to develop urosepsis include: elderly patients; diabetics; immunosuppressed patients, such as transplant recipients; patients receiving cancer chemotherapy or corticosteroids; and patients with AIDS. Urosepsis also depends on local factors, such as urinary tract calculi, obstruction at any level in the urinary tract, congenital uropathy, neurogenic bladder disorders, or endoscopic manoeuvres. However, all patients can be affected by bacterial species that are capable of inducing inflammation within the urinary tract. Moreover, it is now recognised that SIRS may be present without infection (e.g. pancreatitis, burns, or non-septic shock) (5).

For therapeutic purposes, the diagnostic criteria of sepsis should identify patients at an early stage of the syndrome, which should prompt urologists and intensive care specialists to search for and treat infection, apply appropriate therapy, and monitor for organ failure and other complications.

5.3 Definition and clinical manifestation of sepsis in urology

The clinical evidence of UTI is based on symptoms, physical examination, sonographic and radiological features, and laboratory data, such as bacteriuria and leukocyturia. The following definitions apply (Table 5.1):

- Sepsis is a systemic response to infection. The symptoms of SIRS which were initially considered to be 'mandatory' for the diagnosis of sepsis (5), are now considered to be alerting symptoms (6). Many other clinical or biological symptoms must be considered.
- Severe sepsis is sepsis associated with organ dysfunction.
- Septic shock is persistence of hypoperfusion or hypotension despite fluid resuscitation.
- Refractory septic shock is defined by an absence of response to therapy.

Table 5.1: Clinical diagnostic criteria of sepsis and septic shock (5,6)

Disorder	Definition
Infection	Presence of organisms in a normally sterile site that is usually, but not necessarily, accompanied by an inflammatory host response.
Bacteraemia	Bacteria present in blood as confirmed by culture. May be transient.
Systematic inflammatory response syndrome (SIRS)	Response to a wide variety of clinical insults, which can be infectious, as in sepsis but may be non-infectious in aetiology (e.g. burns, or pancreatitis). This systemic response is manifested by two or more of the following conditions: - Temperature > 38°C or < 36°C - Heart rate > 90 bpm - Respiratory rate > 20 breaths/min or PaCO2 < 32 mmHg (< 4.3 kPa) - WBC > 12,000 cells/mm3 or < 4,000 cells/mm^3 or > 10% immature (band) forms
Sepsis	Activation of the inflammatory process due to infection.
Hypotension	Systolic blood pressure < 90 mmHg or a reduction of > 40 mmHg from baseline in the absence of other causes of hypotension.
Severe sepsis	Sepsis associated with organ dysfunction, hypoperfusion or hypotension. Hypoperfusion and perfusion abnormalities may include but are not limited to lactic acidosis, oliguria or acute alteration of mental status.

Septic shock	Sepsis with hypotension despite adequate fluid resuscitation along with the presence of perfusion abnormalities that may include, but are not limited to lactic acidosis, oliguria, or acute alteration in mental status. Patients who are on inotropic or vasopressor agents may not be hypotensive at the time that perfusion abnormalities are measured.
Refractory septic shock	Septic shock that lasts for > 1 h and does not respond to fluid administration or pharmacological intervention.

5.4 Physiology and biochemical markers

Microorganisms reach the urinary tract by way of the ascending, haematogenous, or lymphatic routes. For urosepsis to be established, the pathogens have to reach the bloodstream. The risk of bacteraemia is increased in severe UTIs, such as pyelonephritis and acute bacterial prostatitis, and is facilitated by obstruction of the urinary tract. *E. coli* remains the most prevalent microorganism. In several countries, some bacterial strains can be resistant to quinolones or third-generation cephalosporins. Some microorganisms are multi-resistant, such as methicillin-resistant *Staphylococcus aureus* (MRSA), *P. aeruginosa* and *Serratia* sp. and therefore difficult to treat. Most commonly, the condition develops in compromised patients (e.g. those with diabetes or immunosuppression), with typical signs of generalised sepsis associated with local signs of infection. A fatal outcome is described in 20-40% of all patients.

*5.4.1 **Cytokines as markers of the septic response***

Cytokines are involved in the pathogenesis of sepsis syndrome. They are peptides that regulate the amplitude and duration of the host inflammatory response. They are released from various cells including monocytes, macrophages and endothelial cells, in response to various infectious stimuli. When they become bound to specific receptors on other cells, cytokines change their behaviour in the inflammatory response. The complex balance between pro- and anti-inflammatory responses is modified in severe sepsis. An immunosuppressive phase follows the initial pro-inflammatory mechanism. Other cytokines are involved such as interleukins (ILs). Tumour necrosis factor (TNF)-α, IL-1, IL-6 and IL-8 are cytokines that are associated with sepsis. Sepsis may indicate an immune system that is severely compromised and unable to eradicate pathogens or a non-regulated and excessive activation of inflammation, or both. Genetic predisposition is a probable explanation of sepsis in several patients. Mechanisms of organ failure and death in patients with sepsis remain only partially understood (2).

*5.4.2 **Procalcitonin is a potential marker of sepsis***

Procalcitonin is the propeptide of calcitonin, but is devoid of hormonal activity. Normally, levels are undetectable in healthy humans. During severe generalised infections (bacterial, parasitic and fungal) with systemic manifestations, procalcitonin levels may rise to > 100 ng/mL. In contrast, during severe viral infections or inflammatory reactions of non-infectious origin, procalcitonin levels show only a moderate or no increase. The exact site of procalcitonin production during sepsis is not known. Procalcitonin monitoring may be useful in patients likely to develop a SIRS of infectious origin. High procalcitonin levels, or an abrupt increase in levels in these patients, should prompt a search for the source of infection. Procalcitonin may be useful in differentiating between infectious and non-infectious causes of severe inflammatory status (7,8).

5.5 Prevention

Septic shock is the most frequent cause of death for patients hospitalised for community-acquired and nosocomial infection (20-40%). Sepsis initiates the cascade that progresses to severe sepsis and then septic shock in a clinical continuum. Urosepsis treatment calls for a combination of treatment of the cause (obstruction of the urinary tract), adequate life-supporting care, and appropriate antibiotic therapy (2). In such a situation, it is recommended that urologists collaborate with intensive care and infectious disease specialists for the best management of the patient.

*5.5.1 **Preventive measures of proven or probable efficacy (9,10)***

The most effective methods to prevent nosocomial urosepsis are the same as those used to prevent other nosocomial infections:

- Isolation of all patients infected with multi-resistant organisms to avoid cross-infection.
- Prudent use of antimicrobial agents for prophylaxis and treatment of established infections, to avoid selection of resistant strains. Antibiotic agents should be chosen according to the predominant pathogens at a given site of infection in the hospital environment.
- Reduction in hospital stay. It is well known that long inpatient periods before surgery lead to a greater

incidence of nosocomial infections.

- Early removal of indwelling urethral catheters, as soon as allowed by the patient's condition. Nosocomial UTIs are promoted by bladder catheterisation as well as by ureteral stenting (11). Antibiotic prophylaxis does not prevent stent colonisation, which appears in 100% of patients with a permanent ureteral stent and in 70% of those temporarily stented.
- Use of closed catheter drainage and minimisation of breaks in the integrity of the system, e.g. for urine sampling or bladder wash-out.
- Use of least-invasive methods to release urinary tract obstruction until the patient is stabilised.
- Attention to simple everyday techniques to assure asepsis, including the routine use of protective, disposable gloves, frequent hand disinfection, and using infectious disease control measures to prevent cross-infections.

*5.5.2 **Appropriate perioperative antimicrobial prophylaxis***

For appropriate perioperative antimicrobial prophylaxis, see Section 15. The potential side effects of antibiotics must be considered before their administration in a prophylactic regimen.

*5.5.3 **Preventive measures of debatable efficacy***

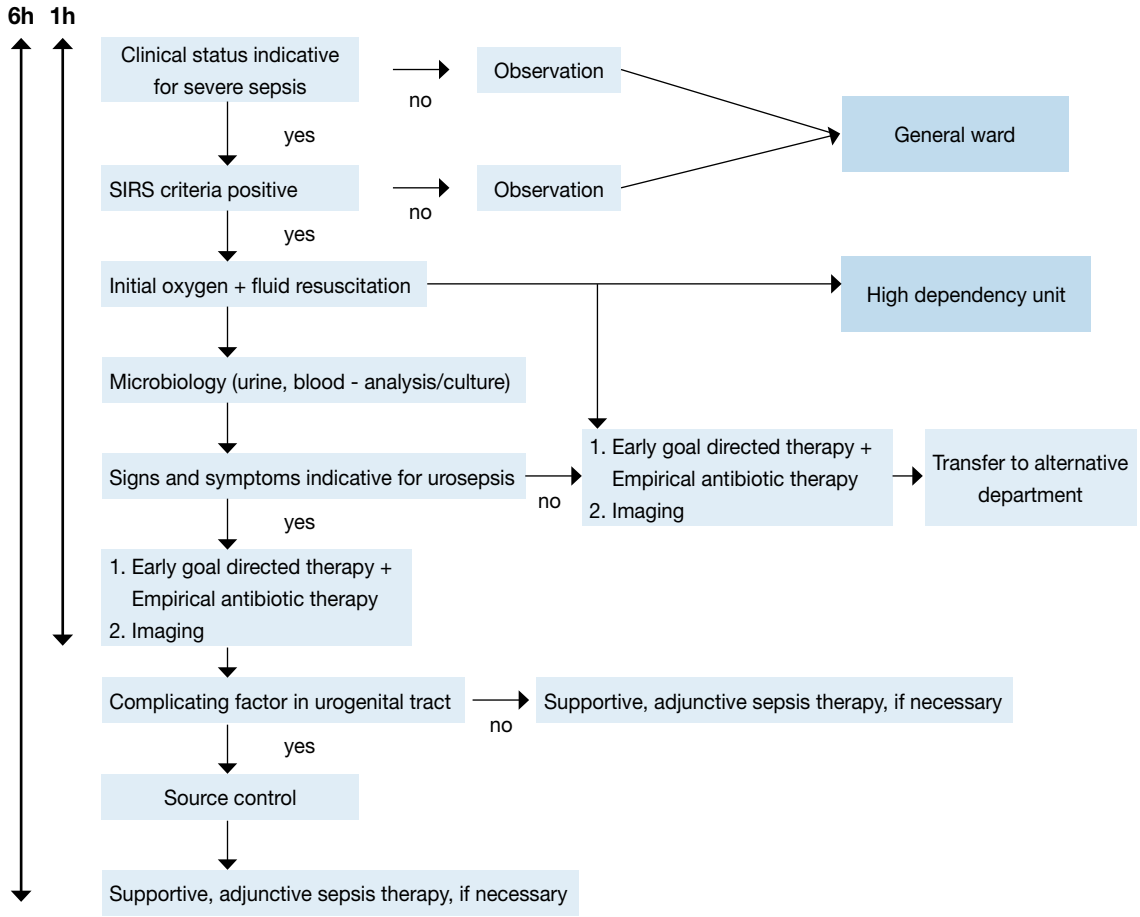
- Instillation of antibiotic or antiseptic drugs into catheters and drainage bags.
- Use of urinary catheters coated with antibiotics or silver.

*5.5.4 **Ineffective or counterproductive measures***

- Continuous or intermittent bladder irrigations with antibiotics or urinary antiseptics that increase the risk of infection with resistant bacteria (9,12).
- Routine administration of antimicrobial drugs to catheterised patients, which reduces the incidence of bacteriuria only for a few days and increases the risk of infection with multi-resistant bacteria (9,12). Its use may be reserved for immunosuppressed patients.

5.6 Algorithm for the management of urosepsis

Figure 5.1: Clinical algorithm for the management of urosepsis



5.7 Treatment

*5.7.1 **Clinical algorithm for management of urosepsis***

Table 5.2: Early goal directed therapy

Early goal directed therapy	
Central venous pressure (CVP)	8-12 mmHg
Mean arterial pressure (MAP)	65-90 mmHg
Central venous oxygen (CVO2)	≥ 70%
Haematocrit (HKT)	> 30 %
Urine output	> 40 mL/h

Table 5.3: Levels of therapy in sepsis

Levels of therapy in sepsis	
Causal therapy	1. Antimicrobial treatment 2. Source control
Supportive therapy	1. Haemodynamic stabilisation 2. Airways, respiration
Adjunctive therapy	1. Glucocorticosteroids 2. Intensified insulin therapy

*5.7.2 **Relief of obstruction***

Drainage of any obstruction in the urinary tract and removal of foreign bodies, such as urinary catheters or stones, should lead to resolution of symptoms and recovery. These are key components of the strategy. This condition is an absolute emergency.

*5.7.3 **Antimicrobial therapy***

Empirical initial treatment should provide broad antimicrobial coverage and should later be adapted on the basis of culture results. The dosage of the antibiotic substances is of paramount importance in patients with sepsis syndrome and should generally be high, with the exception of patients in renal failure. Antimicrobials must be administered not later than 1 h after clinical assumption of sepsis (see algorithm). The antibacterial treatment options are summarised in Appendix 16.1 and 16.2.

*5.7.4 **Adjunctive measures (12,13)***

The management of fluid and electrolyte balance is a crucial aspect of patient care in sepsis syndrome; particularly when the clinical course is complicated by shock. The use of human albumin is debatable. Early goal-directed therapy has been shown to reduce mortality (14). Volaemic expansion and vasopressor therapy have a considerable impact on the outcome. Early intervention with appropriate measures to maintain adequate tissue perfusion and oxygen delivery by prompt institution of fluid therapy, stabilisation of arterial pressure, and providing sufficient oxygen transport capacity are highly effective.

Hydrocortisone (with a debate on dosage) is useful in patients with relative insufficiency in the pituitary gland-adrenal cortex axis (adrenocorticotropin test) (15).

Tight blood glucose control by administration of insulin doses up to 50 U/h is associated with a reduction in mortality (16).

Current evidence does not support the use of human recombinant activated protein C in adults and children with severe sepsis and septic shock (17).

The best strategy has been summarised and graded according to a careful evidence-based methodology in the recently published ‘Surviving Sepsis Guidelines’ (18).

5.8 Conclusion

Sepsis syndrome in urology remains a severe situation with a mortality rate as high as 20-40%. A recent campaign, ‘Surviving Sepsis Guidelines’, aimed at reducing mortality by 25% in the next few years has been published recently (18). Early recognition of the symptoms may decrease the mortality by timely treatment of urinary tract disorders, e.g. obstruction, or urolithiasis. Adequate life-support measures and appropriate antibiotic treatment provide the best conditions for improving patient survival. The prevention of sepsis syndrome is dependent on good practice to avoid nosocomial infections and using antibiotic prophylaxis and

therapy in a prudent and well-accepted manner.

6. CATHETER-ASSOCIATED UTIs

Based on the EAU guidelines published in 2007 (ISBN-13:978-90-70244-59-0), the following text presents the findings of a comprehensive update produced as a collaborative effort by the ESIU (a full EAU section office), the Urological Association of Asia, the Asian Association of UTI/STD, the Western Pacific Society for Chemotherapy, the Federation of European Societies for Chemotherapy and Infection, and the International Society of Chemotherapy for Infection and Cancer. This text was recently published as "The European and Asian guidelines on management and prevention of catheter-associated urinary tract infections" (1). Since the complete document is available online, only the abstract and a summary of the recommendations are presented here.

6.1 Abstract

We surveyed the extensive literature regarding the development, therapy and prevention of catheter-associated UTIs (CAUTIs). We systematically searched for meta-analyses of randomised controlled trials available in Medline, and gave preference to the Cochrane Central Register of Controlled Trials, and also considered other relevant publications, rating them on the basis of their quality. Studies were identified through a PubMed search. The recommendations of the studies, rated according to a modification of the US Department of Health and Human Services (1992), give a close-to-evidence-based guideline for all medical disciplines, with special emphasis on urology, in which catheter care is an important issue.

The survey found that the urinary tract is the commonest source of nosocomial infection, particularly when the bladder is catheterised (LE: 2a). Most CAUTIs are derived from the patient's own colonic flora (LE: 2b) and the catheter predisposes to UTI in several ways. The most important risk factor for the development of catheter-associated bacteriuria is the duration of catheterisation (LE: 2a). Most episodes of short-term catheter-associated bacteriuria are asymptomatic and are caused by a single organism (LE: 2a). Further organisms tend to be acquired by patients who are catheterised for > 30 days.

The clinician should be aware of two priorities: the catheter system should remain closed and the duration of catheterisation should be minimal (GR: A). The use of nurse-based or electronic reminder systems to remove unnecessary catheters can decrease the duration of catheterisation and the risk of CAUTI (LE: 2a). The drainage bag should be always kept below the level of the bladder and the connecting tube (GR: B). In case of short-term catheterisation, routine prophylaxis with systemic antibiotics is not recommended (GR: B). There are sparse data about antibiotic prophylaxis in patients on long-term catheterisation, therefore, no recommendation can be made (GR: C). For patients using intermittent catheterisation, routine antibiotic prophylaxis is not recommended (GR: B). Antibiotic irrigation of the catheter and bladder is of no advantage (GR: A). Healthcare workers should be constantly aware of the risk of cross-infection between catheterised patients. They should observe protocols on hand washing and the need to use disposable gloves (GR: A). A minority of patients can be managed with the use of the non-return (flip) valve catheters, thus avoiding the closed drainage bag. Such patients may exchange the convenience of on-demand drainage with an increased risk of infection. Patients with urethral catheters in place for ≥ 10 years should be screened annually for bladder cancer (GR: C). Clinicians should always consider alternatives to indwelling urethral catheters that are less prone to causing symptomatic infection. In appropriate patients, suprapubic catheters, condom drainage systems and intermittent catheterisation are each preferable to indwelling urethral catheterisation (GR: B). While the catheter is in place, systemic antimicrobial treatment of asymptomatic catheter-associated bacteriuria is not recommended (GR: A), except for some special cases. Routine urine culture in an asymptomatic catheterised patient is also not recommended (GR: C) because treatment is in general not necessary. Antibiotic treatment is recommended only for symptomatic infection (GR: B). After initiation of empirical treatment, usually with broad-spectrum antibiotics based on local susceptibility patterns (GR: C), the choice of antibiotics might need to be adjusted according to urine culture results (GR: B). Long-term antibiotic suppressive therapy is not effective (GR: A).

6.2 Summary of recommendations

Recommendation		GR
General aspects		
1.	Written catheter care protocols are necessary.	B
2.	Health care workers should observe protocols on hand hygiene and the need to use disposable gloves between catheterised patients.	A
Catheter insertion and choice of catheter		
3.	An indwelling catheter should be introduced under antiseptic conditions.	B
4.	Urethral trauma should be minimised by the use of adequate lubricant and the smallest possible catheter calibre.	B
5.	Antibiotic-impregnated catheters may decrease the frequency of asymptomatic bacteriuria within 1 week. There is, however, no evidence that they decrease symptomatic infection. Therefore, they cannot be recommended routinely.	B
6.	Silver alloy catheters significantly reduce the incidence of asymptomatic bacteriuria, but only for < 1 week. There was some evidence of reduced risk for symptomatic UTI. Therefore, they may be useful in some settings.	B
Prevention		
7.	The catheter system should remain closed.	A
8.	The duration of catheterisation should be minimal.	A
9.	Topical antiseptics or antibiotics applied to the catheter, urethra or meatus are not recommended.	A
10.	Benefits from prophylactic antibiotics and antiseptic substances have never been established, therefore, they are not recommended.	A
11.	Removal of the indwelling catheter after non-urological operation before midnight might be beneficial.	B
12.	Long-term indwelling catheters should be changed at intervals adapted to the individual patient, but must be changed before blockage is likely to occur, however, there is no evidence for the exact intervals of changing catheters.	B
13.	Chronic antibiotic suppressive therapy is generally not recommended.	A
14.	The drainage bag should always be kept below the level of the bladder and the connecting tube.	B
Diagnostics		
15.	Routine urine culture in asymptomatic catheterised patients is not recommended.	B
16.	Urine, and in septic patients, also blood for culture must be taken before any antimicrobial therapy is started.	C
17.	Febrile episodes are only found in < 10% of catheterised patients living in a long-term facility. It is therefore extremely important to rule out other sources of fever.	A
Treatment		
18.	While the catheter is in place, systemic antimicrobial treatment of asymptomatic catheter-associated bacteriuria is not recommended, except in certain circumstances, especially before traumatic urinary tract interventions.	A
19.	In case of asymptomatic candiduria, neither systemic nor local antifungal therapy is indicated, but removal of the catheter or stent should be considered.	A/C
20.	Antimicrobial treatment is recommended only for symptomatic infection.	B
21.	In case of symptomatic CAUTI, it might be reasonable to replace or remove the catheter before starting antimicrobial therapy if the indwelling catheter has been in place for > 7 days.	B
22.	For empirical therapy, broad-spectrum antibiotics should be given based on local susceptibility patterns.	C
23.	After culture results are available, antibiotic therapy should be adjusted according to pathogen sensitivity.	B

24.	In case of candiduria associated with urinary symptoms, or if candiduria is the sign of systemic infection, systemic therapy with antifungals is indicated.	B
25.	Elderly female patients may need treatment if bacteriuria does not resolve spontaneously after catheter removal.	C
Alternative drainage systems		
26.	There is limited evidence that postoperative intermittent catheterisation reduces the risk of bacteriuria compared with indwelling catheters. No recommendation can be made.	C
27.	In appropriate patients, a suprapubic, condom drainage system or intermittent catheter is preferable to an indwelling urethral catheter.	B
28.	There is little evidence to suggest that antibiotic prophylaxis decreases bacteriuria in patients using intermittent catheterisation, therefore, it is not recommended.	B
Long-term follow up		
29.	Patients with urethral catheters in place for ≥ 10 years should be screened for bladder cancer.	C

7. UTIs IN CHILDREN

7.1 Summary and recommendations

Urinary tract infection in children is a frequent health problem, with the incidence only a little lower than that of upper respiratory and digestive infections.

The incidence of UTI varies depending on age and sex. In the first year of life, mostly the first 3 months, UTI is more common in boys (3.7%) than in girls (2%), after which the incidence changes, being 3% in girls and 1.1% in boys. Paediatric UTI is the most common cause of fever of unknown origin in boys aged < 3 years. The clinical presentation of UTI in infants and young children can vary from fever to gastrointestinal and lower or upper urinary tract symptoms.

Investigation should be undertaken after two episodes of UTI in girls and one in boys (GR: B). The objective is to rule out the unusual occurrence of obstruction, vesicoureteric reflux (VUR) and dysfunctional voiding, e.g. as caused by a neuropathic disorder.

Chronic pyelonephritic renal scarring develops very early in life due to the combination of a UTI, intrarenal reflux and VUR. It sometimes arises *in utero* due to dysplasia. Although rare, renal scarring may lead to severe long-term complications such as hypertension and chronic renal failure.

VUR is treated with long-term prophylactic antibiotics (GR: B). Surgical re-implantation or endoscopic treatment is reserved for the small number of children with breakthrough infection (GR: B).

For treatment of UTI in children, short courses are not advised and therefore treatment is continued for 5-7 days and longer (GR: A). If the child is severely ill with vomiting and dehydration, hospital admission is required and parenteral antibiotics are given initially (GR: A).

7.2 Background

The urinary tract is a common source of infection in children and infants. It represents the most common bacterial infection in children < 2 years of age (1) (LE: 2a). The outcome of a UTI is usually benign, but in early infancy, it can progress to renal scarring, especially when associated with congenital anomalies of the urinary tract. Delayed sequelae related to renal scarring include hypertension, proteinuria, renal damage and even chronic renal failure, which requires dialysis treatment in a significant number of adults (2) (LE: 2a).

The risk of UTI during the first decade of life is 1% in males and 3% in females (3). It has been suggested that 5% of schoolgirls and up to 0.5% of schoolboys undergo at least one episode of UTI during their school life. The incidence is different for children < 3 months of age, when it is more common in boys. The incidence of asymptomatic bacteriuria is 0.7-3.4% in neonates, 0.7-1.3% in infants < 3 months of age, and 0.2-0.8% in preschool boys and girls (3). The incidence of symptomatic bacteriuria is 0.14% in neonates, with a further increase to 0.7% in boys and 2.8% in girls aged < 6 months. The overall recurrence rate for the neonatal period has been reported to be 25% (3,4).

7.3 Aetiology

The common pathogenic sources are Gram-negative, mainly enteric, bacteria. Of these, *E. coli* is responsible for 90% of UTI episodes (5). Gram-positive bacteria (particularly enterococci and staphylococci) represent 5-7% of cases. Hospital-acquired infections show a wider pattern of aggressive bacteria, such as *Klebsiella, Serratia* and *Pseudomonas* sp. Groups A and B streptococci are relatively common in new-born infants (6). There is an increasing trend towards the isolation of *S. saprophyticus* in UTIs in children, although the role of this bacterium is still debatable (7).

7.4 Pathogenesis and risk factors

The urinary tract is a sterile space with an impermeable lining. Retrograde ascent is the most common mechanism of infection. Nosocomial infection and involvement as part of a systemic infection are less common (8).

Obstruction and dysfunction are among the most common causes of urinary infection. Phimosis predisposes to UTI (9,10) (LE: 2a). Enterobacteria derived from intestinal flora colonise the preputial sac, glandular surface and the distal urethra. Among these bacteria are strains of *E. coli* that express P fimbriae, which adhere to the inner layer of the preputial skin and to uroepithelial cells (11).

A wide variety of congenital urinary tract abnormalities can cause UTIs through obstruction, e.g. urethral valves, ureteropelvic junction obstruction or non-obstructive urinary stasis (e.g. prune belly syndrome, or VUR). More mundane but significant causes of UTIs include labial adhesion and chronic constipation (7).

Dysfunctional voiding in an otherwise normal child may result in infrequent bladder emptying aided by delaying manoeuvres, e.g. crossing legs, sitting on heels (12). Neuropathic bladder dysfunction (e.g. spina bifida, or sphincter dyssynergia) may lead to post-void residual urine and secondary VUR (4).

The link between renal damage and UTIs is controversial. The mechanism in obstructive nephropathy is self-evident, but more subtle changes occur when there is VUR. Almost certainly, the necessary components include VUR, intrarenal reflux and UTI. These must all work together in early childhood when the growing kidney is likely to be susceptible to parenchymal infection. Later on in childhood, the presence of bacteriuria seems irrelevant to the progression of existing scars or the very unusual formation of new scars. Another confounding factor is that many so-called scars are dysplastic renal tissue which develop in utero (13).

7.5 Signs and symptoms

Symptoms are non-specific, and vary with the age of the child and the severity of the disease. Epididymo-orchitis is extremely unusual. With scrotal pain and inflammation, testicular torsion has to be considered.

A UTI in neonates may be non-specific and with no localisation. In small children, a UTI may present with gastrointestinal signs, such as vomiting and diarrhoea. In the first weeks of life, 13.6% of patients with fever have a UTI (14). Rarely, septic shock is the presentation. Signs of UTI may be vague in small children, but later on, when they are older than 2 years, frequent voiding, dysuria and suprapubic, abdominal or lumbar pain may appear with or without fever.

7.6 Classification

UTIs may be classified as a first episode or recurrent, or according to severity (simple or severe).
Recurrent UTI may be subclassified into three groups (8):

- *Unresolved infection*: subtherapeutic level of antimicrobial, non-compliance with treatment, malabsorption, resistant pathogens.
- *Bacterial persistence*: may be due to a nidus for persistent infection in the urinary tract. Surgical correction or medical treatment for urinary dysfunction may be needed.
- *Reinfection*: each episode is a new infection acquired from periurethral, perineal or rectal flora. From the clinical point of view, severe and simple forms of UTIs should be differentiated because to some extent the severity of symptoms dictates the degree of urgency with which investigation and treatment are to be undertaken (Table 7.1).

Table 7.1: Clinical classification of UTIs in children

Severe UTI	Simple UTI
Fever ≥ 39°C	Mild pyrexia
Persistent vomiting	Good fluid intake
Serious dehydration	Slight dehydration
Poor treatment compliance	Good treatment compliance

7.6.1 ***Severe UTI***

Severe UTI is related to the presence of fever of ≥ 39°C, the feeling of being ill, persistent vomiting, and moderate or severe dehydration.

7.6.2 ***Simple UTI***

A child with a simple UTI may have only mild pyrexia, but is able to take fluids and oral medication. The child is only slightly or not dehydrated and has a good expected level of compliance. When a low level of compliance is expected, such a child should be managed as one with a severe UTI.

7.7 Diagnosis

7.7.1 ***Physical examination***

It is mandatory to look for phimosis, labial adhesion, signs of pyelonephritis, epididymo-orchitis, and stigmata of spina bifida, e.g. hairy patch on the sacral skin. The absence of fever does not exclude the presence of an infective process.

7.7.2 ***Laboratory tests***

The definitive diagnosis of infection in children requires a positive urine culture (8,15). Urine must be obtained under bacteriologically reliable conditions when undertaking a urine specimen culture (16). A positive urine culture is defined as the presence of > 100,000 cfu/mL of one pathogen. The urine specimen may be difficult to obtain in a child < 4 years old, and different methods are advised because there is a high risk of contamination (17,18).

7.7.2.1 Collection of the urine

7.7.2.1.1 Suprapubic bladder aspiration

Suprapubic bladder aspiration is the most sensitive method, even though urine may be obtained in 23-99% of cases (8,18).

7.7.2.1.2 Bladder catheterisation

Bladder catheterisation is also a very sensitive method, even though there is the risk of introduction of nosocomial pathogens (8,19).

7.7.2.1.3 Plastic bag attached to the genitalia

Prospective studies have shown a high incidence of false-positive results, ranging from 85 to 99% (8,18). It is helpful when the culture is negative (8,18) and has a positive predictive value of 15% (16). To obtain a urine sample in the best condition in children < 2 years of age (girls and uncircumcised boys without sphincteric control), it is better to use suprapubic bladder aspiration or bladder catheterisation. In older children with sphincteric control, MSU collection is possible and reliable (18).

7.7.2.2 Quantification of bacteriuria

The final concentration of bacteria in urine is directly related to the method of collection, diuresis, and method of storage and transport of the specimen (15). The classical definition of significant bacteriuria of > 10^5 cfu/mL is still used and depends on the clinical environment (15,17).

The presence of pyuria (> 5 leukocytes per field) and bacteriuria in a fresh urine sample reinforce the clinical diagnosis of UTI (17).

In boys, when the urine is obtained by bladder catheterisation, the urine culture is considered positive with > 10^4 cfu/mL. Even though Hoberman (20) has identified a microorganism in 65% of cases with colony counts between 10,000 and 50,000 cfu/mL, there was a mixed growth pattern suggesting contamination. In these cases, it is better to repeat the culture or to evaluate the presence of other signs, such as pyuria, nitrites or other biochemical markers (15). The collection of MSU or in a collecting bag of ≥10^5 cfu/mL is considered positive (16) (Table 7.2).

Table 7.2: Criteria for UTI in children

Urine specimen from suprapubic bladder puncture	Urine specimen from bladder catheterisation	Urine specimen from midstream void
Any number of cfu/mL (at least 10 identical colonies)	≥ 1,000-50,000 cfu/mL	≥ 10^4 cfu/mL with symptoms ≥10^5 cfu/mL without symptoms

7.7.2.3 Other biochemical markers

The presence of other biochemical markers in a urine sample are useful to establish the diagnosis of UTI (8).

The most frequent markers are nitrite and leukocyte esterase usually combined in a dipstick test.

7.7.2.3.1 Nitrite

Nitrite is the degradation product of nitrate in bacterial metabolism, particularly in Gram-negative bacteria. When an infection is caused by Gram-positive bacteria, the test may be negative (8,16). Limitations of the nitrite test include:

- not all uropathogens reduce nitrate to nitrite, e.g. *P. aeruginosa*, or enterococci;
- even nitrite-producing pathogens may show a negative test result, due to the short transit time in the bladder in cases of high diuresis and urine dilution, e.g. neonates;
- the nitrite test has a sensitivity of only 45-60%, but a very good specificity of 85-98% (8,17,21).

7.7.2.3.2 Leukocyte esterase

Leukocyte esterase is produced by the activity of leukocytes. The test for leukocyte esterase has a sensitivity of 48-86% and a specificity of 17-93% (8,17,20,21).

A combination of nitrite and leukocyte esterase testing improves sensitivity and specificity, but carries the risk of false-positive results (21).

The dipstick test has become useful to exclude rapidly and reliably the presence of a UTI, provided both nitrite and leukocyte esterase tests are negative. If the tests are positive, it is better to confirm the results in combination with the clinical symptoms and other tests (17,21).

Bacteriuria without pyuria may be found:

- in bacterial contamination;
- in colonisation (asymptomatic bacteriuria);
- when collecting a specimen before the onset of an inflammatory reaction.

In such cases, it is advisable to repeat the urinalysis after 24 h to clarify the situation. Even in febrile children with a positive urine culture, the absence of pyuria may cast doubt on the diagnosis of UTI. Instead, asymptomatic bacteriuria with a concomitant septic focus responsible for the febrile syndrome has to be considered.

Bacteriuria without pyuria is found in 0.5% of specimens. This figure corresponds well with the estimated rate of asymptomatic bacteriuria in childhood (20,22) (LE: 2a).

Pyuria without bacteriuria may be due to:

- incomplete antimicrobial treatment of UTI;
- urolithiasis and foreign bodies;
- infections caused by *M. tuberculosis* and other fastidious bacteria, e.g. Chlamydia trachomatis.

Thus, either bacteriuria or pyuria may not be considered reliable parameters to diagnose or exclude UTI. Their assessment can be influenced by other factors, such as the degree of hydration, method of specimen collection, mode of centrifugation, volume in which sediment is resuspended and subjective interpretation of results (23). However, according to Landau et al. (24), pyuria in febrile children is indicative of acute pyelonephritis.

For all of these reasons, in neonates and children < 6 months of age, either pyuria, bacteriuria or the nitrite test, separately, have minimal predictive value for UTI (25,26) (LE: 3). In contrast, the positive predictive value of significant Gram staining with pyuria is 85% (20) (LE: 2b). In older children, pyuria with a positive nitrite test is more reliable for the diagnosis of UTI, with a positive predictive value of 98%.

Combining bacteriuria and pyuria in febrile children, the findings of ≥ 10 WBC/mm^3 and ≥ 50,000 cfu/mL in a specimen collected by catheterisation are significant for a UTI, and discriminate between infection and contamination (20,25).

7.7.2.3.3 C-reactive protein

Although non-specific in febrile children with bacteriuria, C-reactive protein seems to be useful in distinguishing between acute pyelonephritis and other causes of bacteriuria. It is considered significant at a concentration > 20 µg/mL.

7.7.2.3.4 Urinary N-acetyl-β-glucosaminidase

Urinary N-acetyl-β-glucosaminidase is a marker of tubular damage. It is increased in febrile UTI and may become a reliable diagnostic marker for UTIs, although it is also elevated in VUR (27).

7.7.2.3.5 IL-6

The clinical use of urinary concentrations of IL-6 in UTIs (28) is still at the research stage.

7.7.3 ***Imaging of the urinary tract***

A gold standard imaging technique has to be cost-effective, painless, safe, and have minimal or no radiation, as well as have the ability to detect any significant structural anomaly. Current techniques do not fulfil all such requirements.

7.7.3.1 Ultrasonography

Ultrasonography (US) has become very useful in children because of its safety, speed and high accuracy in identifying the anatomy and size of the renal parenchyma and collecting system (29). It is subjective and therefore operator-dependent, and gives no information on renal function. However, scars can be identified, although not as well as with Tc-99m DMSA scanning (29,30) (LE: 2a). This technique has been shown to be very sensitive and excretory urography must be reserved only for when images need to be morphologically clarified (31) (LE: 2a).

7.7.3.2 Radionuclide studies

Tc-99m DMSA is a radiopharmaceutical that is bound to the basement membrane of proximal renal tubular cells; half of the dose remains in the renal cortex after 6 h. This technique is helpful in determining functional renal mass and ensures an accurate diagnosis of cortical scarring by showing areas of hypoactivity, which indicates lack of function. A UTI interferes with the uptake of this radiotracer by the proximal renal tubular cells, and may show areas of focal defect in the renal parenchyma. A star-shaped defect in the renal parenchyma may indicate an acute episode of pyelonephritis. A focal defect in the renal cortex usually indicates a chronic lesion or a renal scar (32-34) (LE: 2a).

Focal scarring or a smooth uniform loss of renal substance as demonstrated by Tc-99m DMSA is generally regarded as being associated with VUR (reflux nephropathy) (35,36). However, Rushton et al. (37) have stated that significant renal scarring may develop, regardless of the existence or absence of VUR. Ransley and Risdon (38) have reported that Tc-99m DMSA shows a specificity of 100% and sensitivity of 80% for renal scarring.

The use of Tc-99m DMSA scanning can be helpful in the early diagnosis of acute pyelonephritis. About 50-85% of children show positive findings in the first week. Minimal parenchymal defects, when characterised by a slight area of hypoactivity, can resolve with antimicrobial therapy (39,40). However, defects lasting > 5 months are considered to be renal scarring (41) (LE: 2a).

Tc-99m DMSA scans are considered more sensitive than excretory urography and US in the detection of renal scars (42-45). It remains questionable whether radionuclide scans can substitute for echography as a first-line diagnostic approach in children with a UTI (46,47).

7.7.3.3 Cystourethrography

7.7.3.3.1 Conventional voiding cystourethrography

Voiding cystourethrography (VCU) is the most widely used radiological exploration for the study of the lower urinary tract and especially of VUR. It is considered mandatory in the evaluation of UTIs in children < 1 year of age. Its main drawbacks are the risk of infection, the need for retrogrades filling of the bladder, and the possible deleterious effect of radiation on children (48). In recent years, tailored low-dose fluoroscopic VCU has been used for the evaluation of VUR in girls to minimise radiological exposure (49). VCU is mandatory in the assessment of febrile childhood UTI, even in the presence of normal US. Up to 23% of these patients may reveal VUR (50).

7.7.3.3.2 Radionuclide cystography (indirect)

This investigation is performed by prolonging the period of scanning after the injection of Tc-99m diethylene triamine pentaacetate (DTPA) or mercaptoacetyltriglycine (MAG-3) as part of dynamic renography. It represents an attractive alternative to conventional cystography, especially when following patients with reflux, because of its lower dose of radiation. Disadvantages are poor image resolution and difficulty in detecting lower urinary tract abnormalities (51,52).

7.7.3.3.3 Cystosonography

Contrast-material-enhanced voiding ultrasonography has been introduced for the diagnoses of VUR without irradiation (47,52). Further studies are necessary to determine the role of this new imaging modality in UTI.

7.7.3.4 Additional imaging

Excretory urography remains a valuable tool in the evaluation of the urinary tract in children, but its use in UTIs is debatable unless preliminary imaging has demonstrated abnormalities that require further investigation. The major disadvantages in infants are the risks of side effects from exposure to contrast media and radiation (53). However, the role of excretory urography is declining with the increasing technical superiority of CT (54) and

MRI. However, the indications for their use is still limited in UTI.

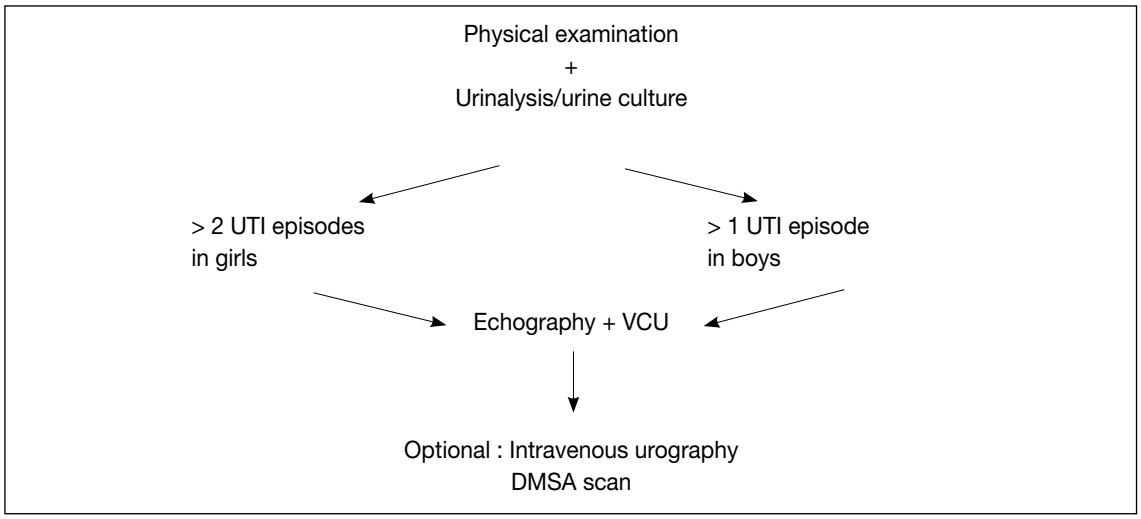
7.7.3.5 Urodynamic evaluation

When voiding dysfunction is suspected, e.g. incontinence, residual urine, increased bladder wall thickness, urodynamic evaluation with uroflowmetry, (video) cystometry, including pressure flow studies, and electromyography should be considered.

7.8 Schedule of investigation

Screening of infants for asymptomatic bacteriuria is unlikely to prevent pyelonephritic scar formation, as these usually develop very early in infancy. Only a minority of children with a UTI have an underlying urological disorder, but when present, such a disorder can cause considerable morbidity. Thus, after a maximum of two UTI episodes in a girl and one in a boy, investigations should be undertaken (Figure 7.1), but not in the case of asymptomatic bacteriuria (51-58). The need for DTPA/MAG-3 scanning is determined by the ultrasound findings, particularly if there is suspicion of an obstructive lesion.

Figure 7.1: Schedule of investigation of a UTI in a child



DMSA = dimercaptosuccinic acid; UTI = urinary tract infection; VCU = voiding cystourethrography.

7.9 Treatment

Treatment has four main goals:

1. elimination of symptoms and eradication of bacteriuria in the acute episode;
2. prevention of renal scarring;
3. prevention of a recurrent UTI;
4. correction of associated urological lesions.

7.9.1 ***Severe UTIs***

A severe UTI requires adequate parenteral fluid replacement and appropriate antimicrobial treatment, preferably with cephalosporins (third generation). If a Gram-positive UTI is suspected by Gram stain, it is useful to administer aminoglycosides in combination with ampicillin or amoxycillin/clavulanate (59) (LE: 2a). Antimicrobial treatment has to be initiated on an empirical basis, but should be adjusted according to culture results as soon as possible. In patients with an allergy to cephalosporins, aztreonam or gentamicin may be used. When aminoglycosides are necessary, serum levels should be monitored for dose adjustment.
Chloramphenicol, sulphonamides, tetracyclines, rifampicin, amphotericin B and quinolones should be avoided. The use of ceftriaxone must also be avoided due to its undesired side effect of jaundice.

A wide variety of antimicrobials can be used in older children, with the exception of tetracyclines (because of tooth staining). Fluorinated quinolones may produce cartilage toxicity (58), but if necessary, may be used as second-line therapy in the treatment of serious infections, because musculoskeletal adverse events are of moderate intensity and transient (60,61). For a safety period of 24-36 h, parenteral therapy should be administered. When the child becomes afebrile and is able to take fluids, he/she may be given an oral agent to complete the 10-14 days of treatment, which may be continued on an outpatient basis. This provides some advantages, such as less psychological impact on the child and more comfort for the whole family.
It is also less expensive, well tolerated and eventually prevents opportunistic infections (20). The preferred oral antimicrobials are: trimethoprim (TMP), co-trimoxazole (TMP plus sulphamethoxazole), an oral cephalosporin,

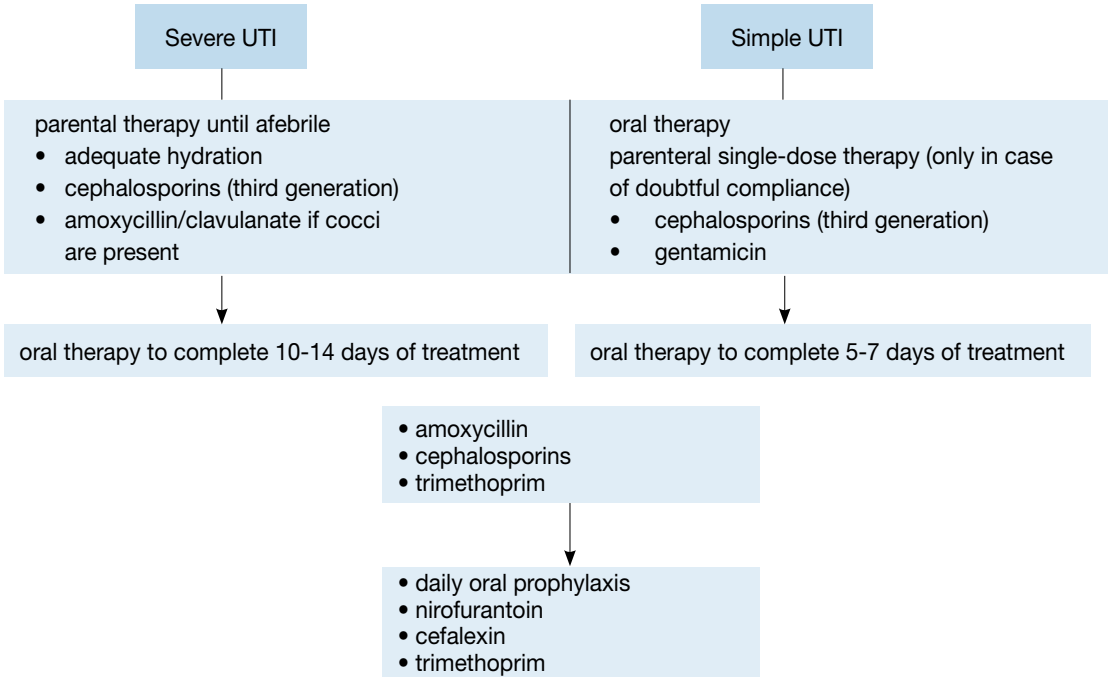
or amoxycillin/clavulanate. However, the indications for TMP are declining in areas with increasing resistance.

In children < 3 years of age, who have difficulty taking oral medications, parenteral treatment for 7-10 days seems advisable, with similar results to those with oral treatment (62).

If there are significant abnormalities in the urinary tract (e.g. VUR, or obstruction), appropriate urological intervention should be considered. If renal scarring is detected, the patient will need careful follow-up by a paediatrician in anticipation of sequelae such as hypertension, renal function impairment, and recurrent UTI.

An overview of the treatment of febrile UTIs in children is given in Figure 7.2 and the dosing of antimicrobial agents is outlined in Table 7.3 (63).

Figure 7.2: Treatment of febrile UTIs in children



*7.9.2 **Simple UTIs***

A simple UTI is considered to be a low-risk infection in children. Oral empirical treatment with TMP, an oral cephalosporin or amoxycillin/clavulanate is recommended, according to the local resistance pattern. The duration of treatment in uncomplicated UTIs treated orally should be 5-7 days (64,65) (LE: 1b). A single parenteral dose may be used in cases of doubtful compliance and with a normal urinary tract (66) (LE: 2a). If the response is poor or complications develop, the child must be admitted to hospital for parenteral treatment (67).

*7.9.3 **Prophylaxis***

If there is an increased risk of pyelonephritis, e.g. VUR, and recurrent UTI, low-dose antibiotic prophylaxis is recommended (68,69) (LE; 2a). It may also be used after an acute episode of UTI until the diagnostic work-up is completed. The most effective antimicrobial agents are: nitrofurantoin, TMP, cephalexin and cefaclor (68).

8. UTIs IN RENAL INSUFFICIENCY, TRANSPLANT RECIPIENTS, DIABETES MELLITUS AND IMMUNOSUPPRESSION

8.1 Summary and recommendations

8.1.1 Acute effects of UTI on the kidney

In acute pyelonephritis, very dramatic changes can occur with focal reduction in perfusion on imaging and corresponding renal tubular dysfunction. However, if in the adult the kidney is normal beforehand, chronic renal damage is unlikely. There is no evidence that prolonged or intensive antibiotic treatment of acute pyelonephritis shortens the episode or prevents complications.

In diabetes mellitus, overwhelming infection can predispose to pyogenic infection with intrarenal perinephric abscess formation, emphysematous pyelonephritis, and rarely, a specific form of infective interstitial nephropathy. Papillary necrosis is a common consequence of pyelonephritis in patients with diabetes. Women are more prone to asymptomatic bacteriuria than men with diabetes, but in both sexes, progression to clinical pyelonephritis is more likely than in normal individuals. The risk factors for developing asymptomatic bacteriuria differ between type 1 and type 2 diabetes.

It is arguable that diabetic patients are susceptible to rapid progression of parenchymal infection. However, the clearance of asymptomatic bacteriuria should not be attempted if the intention is to prevent complications, notably acute pyelonephritis (GR: A).

8.1.2 Chronic renal disease and UTI

There are several factors of general potential importance that predispose to infection in uraemia, including the loss of several urinary defence mechanisms and a degree of immunosuppression. Typically, adult polycystic kidney disease (APCKD), gross VUR and end-stage obstructive uropathy harbour infective foci or promote ascending infection, but not invariably so. Clearly, severe UTI with accompanying bacteraemia can hasten progression of renal failure, but there is little evidence that vigorous treatment of lesser degrees of infection or prophylaxis will slow renal functional impairment once it is established (GR: C).

In patients with VUR and UTI in end-stage chronic renal failure, bilateral nephroureterectomy should only be undertaken as a last resort (GR: B).

8.1.2.1 APCKD

In patients with acute pyelonephritis and infected cysts (presenting as recurrent bacteraemia or local sepsis), treatment requires a long course of high-dose systemic fluoroquinolones, followed by prophylaxis. Bilateral nephrectomy should be utilised as a last resort (GR: B).

8.1.2.2 Calculi and UTI

Management is similar to that for patients without renal impairment, i.e. to clear the stones if possible and to minimise antibiotic treatment if the calculus cannot be removed. Nephrectomy should be performed as a last resort, but even residual renal function may be of vital importance (GR: B).

8.1.2.3 Obstruction of the urinary tract and UTI

As in all other situations, the combination of obstruction and infection is dangerous and should be treated vigorously. Obstruction may be covert and require specific diagnostic tests, e.g. video-urodynamics, or upper urinary tract pressure flow studies.

*8.1.3 **UTI in renal transplantation and immunosuppression***

The need to correct uropathy or to remove a potential focus of infection in an end-stage disease kidney is more pressing in patients enlisted for renal transplantation. Even so, the results of nephrectomy for a scarred or hydronephrotic kidney may be disappointing.

Immunosuppression is of secondary importance, although if this is extreme, immunosuppression can promote persistent bacteriuria, which may become symptomatic. In the context of renal transplantation, UTI is very common, but immunosuppression is only one of many factors that are mainly classified as 'surgical'.

HIV infection is associated with acute and chronic renal disease, possibly through the mechanisms of thrombotic microangiopathy and immune-mediated glomerulonephritis. Steroids, angiotensin-converting enzyme (ACE) inhibitors and highly active retroviral therapy appear to reduce progression to end-stage renal disease.

*8.1.4 **Antibiotic treatment for UTI in renal insufficiency and after renal transplantation***

The principles of antibiotic treatment for UTI in the presence of renal impairment, during dialysis treatment and after renal transplantation are discussed in the text and summarised in Tables 8.1-8.4.

8.2 Background

Whenever UTI is present in patients with renal insufficiency, problems arise in both the treatment of infection and the management of renal disease. There are also important scientific issues to be considered concerning the cause, special susceptibilities, effects and complications of renal parenchymal infection, particularly in the immunosuppressed patient.

This part of the guidelines can be subdivided into four sections.

1. What are the acute effects of UTI on the kidney and do the lesions become chronic?
2. Does chronic renal disease progress more quickly as a result of infection, and do particular renal diseases predispose to UTI?
3. Are immunosuppressed patients prone to UTI, particularly in the context of renal transplantation? Is UTI a significant cause of graft failure?
4. Which problems arise in antibiotic therapy in patients with renal insufficiency and after renal transplantation?

8.3 Acute effects of UTI on the kidney

Some authors regard acute pyelonephritis as complicated because, in their view, it may cause renal scarring in a previously normal kidney (1,2) (LE: 2a). Pathologically, a similar process may occur in such fundamentally different situations as obstructive and reflux nephropathy, although the distribution and extent of the lesions may be different (3-5) (LE: 2a).

*8.3.1 **VUR and intrarenal reflux***

The effects of VUR and intrarenal reflux on the renal parenchyma, and the contribution of ascending infection are still unresolved. Renal scarring can certainly be acquired as a result of these three factors, although, in almost all cases, this usually occurs very early in life. In this narrow age range, developmental renal dysplasia must be a major consideration in the pathogenesis of chronic pyelonephritis.

Although acute infection is important in the early stages of this disease, the status of either recurrent acute UTI or asymptomatic bacteriuria specifically in the progression of scar formation is tenuous. Prophylactic antibiotics therefore offer little benefit in preserving renal tissue in reflux nephropathy in older children and adults, even if the reflux has not already been successfully treated (6) (GR: A). However, further discussion of reflux nephropathy is beyond the scope of these guidelines.

*8.3.2 **Obstructive neuropathy***

Obstruction occurring through a voiding disorder or supravesically causes renal tubular dysfunction and ultimately renal damage, mainly through the process of apoptosis. Infection enhances the process of

parenchymal loss. In extreme cases, pyonephrosis, perinephric abscess and widespread systemic sepsis develop. Obstruction has to be cleared if infection is to be eradicated (7) (GR: A).

A detailed discussion of obstructive nephropathy is not appropriate here, but the kidney that is permanently damaged by any cause has less reserve to withstand the effects of reflux, obstruction and infection. In any circumstances, the combination of obstruction and infection is a surgical emergency and both must be relieved without delay. It is sometimes difficult to exclude an element of obstruction when discussing the pathogenesis of putative infective renal damage in the alleged normal kidney. Urinary calculi and pregnancy can cause urinary stasis and an intermittent increase in pressure in the upper urinary tract, which can cause subtle and persistent damage.

8.3.3 ***Renal effects of severe UTI***

Severe infection can lead to renal functional impairment through sepsis, endotoxaemia, hypotension and poor renal perfusion, as part of the process of multiorgan failure. The presence of renal calculi and diabetes mellitus further reduces host defences (8).

8.3.4 ***Acute effects of UTI on the normal kidney***

The acute effects of UTI on the normal kidney are complex. They are worth reviewing because they may provide a lead in deciding how chronic changes can occur and therefore a basis for the development of guidelines on the prevention of renal damage.

E. coli is the most common of the Gram-negative bacteria that are isolated in the majority of patients with acute pyelonephritis. The proportion of infections caused by *E. coli* is lower in adults than children (69% vs. 80%) (9) (LE: 2b).

Virulent microorganisms cause direct cellular injury, usually after colonising the renal pelvis. Damage can also occur indirectly from the effects of inflammatory mediators. Metastatic infection rarely causes renal infection, which presents as cortical abscesses, and usually only in susceptible individuals (see the sections below on Diabetes mellitus and Immunosuppression) (10).

Bacterial infection in the urinary tract can induce fever and elevate acute phase reactants, such as C-reactive protein, and erythrocyte sedimentation rate (ESR). Bacterial infection also elicits immunoglobulin A and cytokine responses (11) (LE: 2b). In particular, serum levels of IL-6 and IL-8 are elevated (12,13) (LE: 2b). Tissue damage is reflected by urinary secretion of tubular proteins and enzymes, such as α2-macroglobulin, β2-microglobulin and N-acetyl-β-D-glucosaminidase. In functional terms, there may be a loss of concentrating power that can persist in the long term (14,15) (LE: 2b). The fact that there is a serological immune response and bacteria become coated with antibodies to various antigenic components of the microorganism is regarded as evidence of an immune response, and therefore, of exposure to microorganisms that are potentially damaging to the renal parenchyma (16) (LE: 2b).

There are many identifiable factors relating to virulence of the bacterial cell and to its ability to adhere to the mucosa as a preliminary to invasion (17). For example, type 1 pili or fimbriae combine with mannose receptors on the uromucoid, which is part of the protective mucopolysaccharide layer found on uroepithelial cells lining the urinary tract. Type 2 or P fimbriae bind to glycolipids of the blood group substances that are secreted by the host urothelium. In practical terms, *E. coli*, which is pathological to the kidney, appears to express P (or pyelonephritis-associated) or type 2 fimbriae, at least in children in whom 90% of individuals with acute pyelonephritis express these bacteria, compared with a much smaller proportion of those who have had cystitis or asymptomatic bacteriuria (18) (LE; 2b).

Bacterial adhesion may be of variable benefit to the bacterium, because its attachment may mean that it is easier for host defence mechanisms to localise and abolish it (19). The cellular and humoral inflammatory host response is also a crucial part of host defences. Various cytokines (e.g. IL-6 and IL-8) are responsible for inducing leukocyte migration, and may be intrinsically deficient in converting asymptomatic bacterial colonisation to clinical infection.

Paradoxically, reduced adhesiveness can facilitate silent penetration into the renal parenchyma. In a Swedish study, a group of 160 patients who had recently suffered acute UTI all developed reduced concentrating power, even though a significant proportion (40%) did not develop a febrile illness. In the majority of these patients, the infiltrating bacteria had reduced adhesive characteristics, perhaps facilitating their penetration into the renal parenchyma and promoting more permanent structural and functional damage (15) (LE: 2b).

8.3.5 ***Renal scarring***

The possible development of scarring, as a result of UTI in the absence of reflux, obstruction or calculi, is controversial (20) (LE: 2a). It is agreed that dramatic reduction in renal perfusion and excretion can occur acutely and so-called ‘lobar nephronia’ has been demonstrated with the newer methods of imaging, such as CT or DMSA scanning, but not with standard intravenous urography (IVU).

A study has shown that 55% of patients with no pre-existing lesions developed acute parenchymal lesions during an episode of acute pyelonephritis (2) (LE: 2a). These lesions were found to have persisted after 3-6 months follow-up in 77% of patients (9) (LE: 3).

An earlier study by Alwall (21) has described 29 women who were followed for 20-30 years, with evidence of increasing renal damage and chronic pyelonephritis upon biopsy (LE: 3). That study would have used cruder diagnostic techniques, which might not have identified pre-existing disease, therefore, patients may have had renal damage initially. Over such a long period, it was impossible to exclude other causes of renal impairment and interstitial nephropathy, e.g. analgesic abuse. This important issue is clarified by a recent more critical study of DMSA scanning during the acute phase of acute pyelonephritis. In the study, 37 of 81 patients had one or more perfusion defects, of which, the majority resolved within 3 months. In lesions that persisted, further imaging invariably showed evidence of reflux or obstructive nephropathy that must have predated the acute infective episode (22) (LE: 2a).

In summary, small parenchymal scars demonstrated by modern imaging may develop as a result of acute non-obstructive pyelonephritis. However, such patients do not develop chronic renal failure and the scar is a very different lesion from the typical scar of reflux nephropathy. This is reflected in clinical experience. Thus, in acute pyelonephritis, IVU or DMSA scanning during an acute urinary infection can have alarming and dramatic results, but in practical terms the observed changes mostly resolve.

The poor correlation between the severity of the symptoms in an episode of acute pyelonephritis and the risk of permanent damage, which is very small, should discourage the clinician from prescribing excessive antibiotic treatment beyond that needed to suppress the acute inflammatory reaction (GR: A).

In future, the rare occurrence of renal damage apparently arising from acute or recurrent uncomplicated UTI may be prevented by targeting long-term treatment at selected patients. These patients will have been identified as having an intrinsic genetic defect in the host response of cytokine release to infection. Such a genetic defect would be even more important if a patient also had structural abnormalities that cause complicated UTI.

8.3.6 ***Specific conditions in which an acute UTI causes renal damage***

There are several specific conditions in which acute UTI can cause renal damage:

8.3.6.1 Diabetes mellitus

Asymptomatic bacteriuria is common in diabetic women. In a prospective study of non-pregnant women with diabetes mellitus, 26% had significant bacteriuria ($\geq 10^5$ cfu/mL) compared with 6% of controls. Women with type 1 diabetes are particularly at risk if they have had diabetes for a long time or complications have developed, particularly peripheral neuropathy and proteinuria. Risk factors in patients with type 2 diabetes were old age, proteinuria, a low body mass index and a past history of recurrent UTIs (23) (LE: 2a).

Diabetes mellitus increases the risk of acute pyelonephritis from infection by Enterobacteriaceae That originate in the lower urogenital tract. *Klebsiella* infection is particularly common (25% compared with 12% in non-diabetics).

Asymptomatic bacteriuria is common in women with diabetes (though not in men). If left untreated, it may lead to renal functional impairment (24). The mechanism is ill-understood and, as in uncomplicated acute pyelonephritis, a direct causal link is dubious. Other subtle factors may be present, such as underlying diabetic nephropathy (25) and autonomic neuropathy that causes voiding dysfunction. Impaired host resistance is thought to predispose to persistence of nephropathogenic organisms, but specific evidence is lacking for the development of renal complications. Glycosuria inhibits phagocytosis and perhaps cellular immunity, and encourages bacterial adherence. However, diabetic women with asymptomatic bacteriuria can have good glycaemic control, but still show reduced urinary cytokine and leukocyte concentrations (although polymorph function is normal). Poor glycaemic control has not been shown to increase the risk of bacteriuria (26).

It has always been recognised that diabetic patients are particularly susceptible to rapid progression of renal parenchymal infection and ensuing complications. Until recently, there was no consensus on the questions of pre-emptive screening, treatment and prophylaxis of asymptomatic bacteriuria. However, these issues have been addressed in a placebo-controlled, double-blind randomised trial (27) (LE: 1b), which has concluded that treatment does not reduce complications, and diabetes should not therefore be regarded as an indication for screening or treatment of asymptomatic bacteriuria. The findings from this trial have been subsequently recognised in the guidelines published by the Infectious Diseases Society of America (IDSA) on the diagnosis and treatment of asymptomatic bacteriuria in general (28).

Diabetic patients are also prone to an under-reported and probably unusual form of infective interstitial nephritis, which sometimes includes infection by gas-forming organisms, with a high mortality (emphysematous pyelonephritis) (29). This is characterised histologically by acute pyogenic infiltration with micro-abscesses and the development of acute renal failure. The origin of the organisms may be haematogenous. Even in the absence of obstruction, acute parenchymal infection may progress insidiously to form an intrarenal abscess

that ruptures, which leads to a perinephric collection and a psoas abscess. The presentation can occasionally be indolent.

Papillary necrosis is common in diabetics, particularly in association with acute pyelonephritis. It is certainly associated with permanent renal parenchymal scarring, although it is difficult to exclude obstruction by the sloughed papillae as the cause of the nephropathy. Antibiotic prophylaxis for the treatment of asymptomatic bacteriuria is probably required (GR: C).

8.3.6.2 Tuberculosis

Tuberculosis can cause acute and chronic renal damage through bilateral renal infiltration. Rarely, this can lead to end-stage renal failure. However, a more subtle form of interstitial granulomatous disease can occur, which is sufficient to cause renal failure in the absence of fibrosis, calcification or obstruction (30,31) (LE: 3).

Tuberculosis and leprosy can cause renal damage through the development of amyloid and a form of proliferative glomerulonephritis (32,33). (LE: 2b). For more details see the EAU guidelines on genitourinary tuberculosis (34).

8.4 Chronic renal disease and UTI

There are good reasons why all uraemic patients should be prone to UTI, and why UTI should increase the rate of deterioration of renal function. The antibacterial properties of normal urine, due to urea or low pH and high osmolality, may be lost (35). Uraemic patients are also mildly immunosuppressed and the formation of protective uroepithelial mucus may be inhibited (36-38) (LE: 2b).

However, apart from a few exceptions, there is little evidence for a causal relationship between pre-existing chronic renal disease and persistent UTI (7). The results of removing a scarred or hydronephrotic kidney in the hope of curing infection are often disappointing.

The few exceptions include the following.

8.4.1 ***Adult dominant polycystic kidney disease (ADPKD)***

UTI is a prominent complication of ADPKD, with symptomatic UTI being the presenting feature in 23-42% of patients, who are usually female (39). It may be difficult to obtain a positive culture on standard laboratory media, but pyuria is common, particularly in the later stages of disease progression. Acute pyelonephritis is common and may originate from pyogenic infection in the cysts (40) (LE: 3).

The efficacy of antibiotic treatment may depend on whether cysts are derived from proximal (active secretion) or distal tubules (passive diffusion) and on the lipid solubility of the agent used. Cephalosporins, gentamicin and ampicillin, which are standard treatments of acute pyelonephritis and require active transport, are often ineffective (41) (LE; 2b). Fluoroquinolones are generally the most effective (GR: A).

After transplantation, overall graft and patient survival rates do not differ between ADPKD and control groups (42) (LE: 2a). However, despite close monitoring of patients, UTI and septicaemic episodes are still a significant cause of morbidity, such that bilateral nephrectomy may be the only option.

Polycystic disease is not to be confused with acquired renal cystic disease of the end-stage kidney, which has no predisposition to UTI.

The issue of whether urological complications including UTI affect the progression of renal failure in polycystic disease or in any other renal pathology is controversial. Severe symptomatic UTIs may indicate an adverse prognosis, particularly in men with ADPKD.

8.4.2 ***Renal calculi***

Nephrolithiasis, particularly from infective struvite stones, obstructive uropathy and gross reflux, clearly does promote infection, although not always. However, it is doubtful whether vigorous treatment of asymptomatic bacteriuria or even mild clinical UTI makes any difference to the progression of renal disease (43) (LE; 3).

It is disappointing that, as yet, few studies have provided long-term serial data that identify renal damage and its causal relationship with infection. In this respect, it is of some interest that a study of 100 patients who underwent reflux prevention surgery at least 20 years before has recently been published (44). It was concluded that even patients whose reflux prevention surgery had been successful were prone to recurrent UTI, hypertension and complications, which even occasionally included progressive renal scarring. Such consequences should at least inform the patient's decision in deciding between surgical and medical treatment of VUR.

8.5 UTI in renal transplantation

UTI is common after renal transplantation. Bacteriuria is present in 35-80% of patients, although the risk has been reduced by improvements in donation surgery, which have lowered the dose of immunosuppressive therapy and prophylactic antibiotics (45).

8.5.1 ***Donor organ infection***

Early factors predisposing to UTI include infection in the transplanted kidney. Clearly, the organ donor should be screened for a variety of viral and bacterial infections. Detailed discussion of this process is beyond the limits of these guidelines. However, it must be acknowledged that the urinary tract of the cadaver donor is rarely investigated, even if the mid-stream urine (MSU) culture is positive. Antibiotics are given empirically, but usually the first suspicion of occurrence of a renal tract abnormality is raised during the organ donation operation. Under these circumstances, only the most obvious renal or ureteric abnormality will be detected. Very occasionally, organ donation will be abandoned at this late stage.

After the kidney is removed from its storage box, the effluent from the renal vein and surrounding fluid in the sterile plastic bags that contain the excised kidney should ideally be cultured because microorganisms are likely to have been introduced during the donation process. Bladder catheters and ureteric stents promote the loss of the glycosoaminoglycan layer from the uroepithelium, as well as providing a source of microorganisms within the mucous biofilm that covers the foreign body. Infection in the native kidneys may worsen considerably as a result of maximum immunosuppression.

In renal transplant recipients, the following problems are most troublesome: papillary necrosis, particularly in diabetes mellitus (46), massive infective VUR, polycystic disease, and infective calculi. There is also concern about the increasing number of children with congenital uropathy, often associated with neuropathic bladder dysfunction and the sinister combination of intravesical obstruction, poor bladder compliance, residual urine, and VUR. A full urodynamic assessment, establishing a routine of intermittent self-catheterisation and any necessary bladder surgery must be completed well in advance of renal transplantation.

Urinary diversions and bladder augmentation and substitution have also been successfully completed in patients on dialysis treatment and after transplantation, although bacteriuria is common and may require antibiotic treatment (47).

In the first 3 months, UTI is more likely to be symptomatic with a high rate of relapse. Later on, there is a lower rate of pyelonephritis and bacteraemia, and a better response to antibiotics unless there are urological complications (e.g. fistula, or obstruction of the urinary tract). Infarction, either of the whole kidney or of a segment due to arterial damage, can promote UTI through bacterial colonisation of dead tissue. This often occurs by commensal or fastidious pathogens. The infection may be impossible to eradicate until the kidney or at least the dead segment is removed.

8.5.2 ***Graft failure***

There are several potential mechanisms by which severe UTI can cause graft failure. There was an early suggestion that reflux into the graft could lead to pyelonephritis and parenchymal scarring. However, these findings have not been confirmed and most surgeons do not make a special effort to perform an antireflux anastomosis.

Infection can theoretically induce graft failure by three other mechanisms, such as by the direct effect of cytokines, growth factors (e.g. tumour necrosis factor [TNF]) and free radicals as part of the inflammation cascade (45). UTIs can also reactivate cytomegalovirus infection, which can lead to acute transplant rejection. Sometimes it can be very difficult to distinguish rejection from infection (48) (LE: 2b).

For many years, the polyomavirus type BK has been listed as a possible candidate for causing transplant ureteric stenosis. Improved detection of so-called ‘decoy cells’ in urine and of virus DNA by polymerase chain reaction has confirmed the causal relationship between infection and obstruction, but also with interstitial nephropathy progressing to graft loss in possibly 5% of recipients. The virus is susceptible to treatment with the antiviral agent cidofovir (49) (LE: 2a).

8.5.3 ***Kidney and whole-organ pancreas transplantation***

Simultaneous kidney and whole-organ pancreas transplantation can present specific urological complications when the bladder is chosen for drainage of exocrine secretions. These may include recurrent UTI, chemical urethritis and bladder calculi of sufficient severity to warrant cystoenteric conversion. The risk of such complications is minimised if urodynamic abnormalities, e.g. obstruction, are identified and corrected well in advance of the transplant procedure (50) (LE: 3).

8.6 Antibiotic therapy in renal failure and transplant recipients

Much of the detailed information on antibiotic prescribing in renal failure is summarised in Tables 8.1-8.5 and Appendix 16.3. It is important to note that peritoneal dialysis and haemodialysis clear certain antibiotics, which should either be avoided or given at much higher doses. Also, there are important interactions to consider between immunosuppressive agents and antibiotics.

Table 8.1: Use of antibiotics for UTI with renal impairment

Most antibiotics have a wide therapeutic index. No adjustment of dose is necessary until GFR < 20 mL/min, except antibiotics with nephrotoxic potential, e.g. aminoglycoside.
Drugs removed by dialysis should be administered after dialysis treatment.
Combination of loop diuretics (e.g. furosemide) and a cephalosporin is nephrotoxic.
Nitrofurantoin and tetracyclines are contraindicated, but not doxycycline.

GFR = glomerular filtration rate.

Table 8.2: Clearance of antibiotics at haemodialysis

Dialysed	Slightly dialysed	Not dialysed
Amoxycillin/ampicillin	Fluoroquinolones*	Amphotericin
Carbenicillin	Co-trimoxazole	Methicillin
Cephalosporins*	Erythromycin	Teicoplanin
Aminoglycosides*	Vancomycin	
Trimethoprim		
Metronidazole		
Aztreonam*		
Fluconazole*		

** Drugs cleared by peritoneal dialysis.*

Table 8.3: Treatment of tuberculosis in renal failure

Rifampicin and isoniazid (INH) not cleared by dialysis. Give pyridoxine.
Ethambutol not dialysed. Reduce dose if GFR < 30 mL/min.
Avoid rifampicin with cyclosporin.

Table 8.4: Recommendations for prevention and treatment of UTI in renal transplanation

Treat infection in recipient before transplantation.
Culture donor tissue sample and perfusate.
Perioperative antibiotic prophylaxis.
6 months low-dose TMP-SMX (co-trimoxazole) (LE: 1b, GR: A).
Empirical treatment of overt infection (quinolone, TMP-SMX for 10-14 days).

TMX = trimethoprim-sulphamethoxazole.

Table 8.5: Drug interactions with cyclosporin and tacrolimus

Rifampicin
Erythromycin
Aminoglycosides
TMP-SMX
Amphotericin B

TMP-SMX = trimethoprim-sulphamethoxazole.

8.6.1 Treatment of UTI in renal transplant recipients

The treatment of a symptomatic UTI is similar to treatment given to non-transplant patients. However, a short course of treatment has yet to be established, and in most cases a 10-14-day course of treatment is given.

The choice of antibiotic is dictated by the special need for penetration into the renal parenchyma rather than for merely a 'mucosal' antibiotic. Fluoroquinolones seem to be particularly effective.

There is good evidence for the beneficial effects of treating asymptomatic bacteriuria in the first 6 months after renal transplantation (51) (LE: 2a). Patients must be investigated for surgical complications.

In most units, the combination of trimethoprim and sulphamethoxazole (co-trimoxazole) is effective in preventing UTI (52) (LE: 1b). It will also prevent *Pneumocystis carinii* pneumonia (PCP) and infection with other rare fastidious organisms. Low-dose antibiotic prophylaxis with co-trimoxazole has been recommended for 6 months after transplantation. This will cover the high-risk period when infection is more likely to be symptomatic and associated with acute graft impairment. At a low dose, adverse interactions with cyclosporin do not occur, although the higher dose advocated by some units results in synergistic nephrotoxicity with trimethoprim.

A number of other drug interactions need to be considered, e.g. gentamicin, co-trimoxazole and amphotericin B promote cyclosporin and tacrolimus toxicity. Rifampicin and erythromycin also interact with calcineurin inhibitors by increasing cytochrome p450 synthetase and inhibiting hepatic cyclosporin A metabolism.

In any patients with relapsing or recurrent infection, an anatomical cause, such as a urological complication in the transplant kidney or recipient bladder dysfunction, must be considered and treated vigorously.

*8.6.2 **Fungal infections***

Candidal infections can occur in any immunosuppressed patient, but are more common in diabetic patients and those with chronic residual urine and in whom there is an indwelling catheter or stent. It is wise to treat all patients with antifungal agents (fluconazole, amphotericin B plus flucytosine) even when they are asymptomatic. Removal of the catheter or stents is usually necessary (GR: B).

*8.6.3 **Schistosomiasis***

Schistosomiasis is a familiar problem for patients treated for end-stage renal failure from locations where the disease is endemic. Renal transplantation is possible, even when live donors and recipients have active lesions, provided they are treated. Combined medication (praziquantil and oxaminoquine) is recommended for 1 month. In a trial that compared infected patients with those free of schistosomiasis, there was no difference between the incidence of acute and chronic rejection. However, UTI and urological complications occurred in the infected group and a higher cyclosporin dose was required. Despite this, however, it was concluded that active schistosomiasis did not preclude transplantation (53) (LE: 3). For further details on schistosomiasis in genitourinary tract infections see Bichler et al. (54).

8.7 Immunosuppression

It is well known that viral and fungal infections are common in immunosuppressed patients.

*8.7.1 **Human immunodeficiencey virus (HIV) infection***

HIV infection can lead to acute renal failure through non-specific severe systemic illness, and to chronic renal failure through a variety of nephropathies. These include HIV-induced thrombotic microangiopathy, immune-mediated glomerulonephritis and nephropathy due to virus-induced cellular damage, primarily to the glomerular epithelial cell. Combination therapy using corticosteroids, ACE inhibitors and highly active antiretroviral therapy seems to delay and prevent progression of nephropathy, although evidence from randomised trials is not available (55). HIV infection is therefore no longer a contraindication to renal replacement therapy.

The place of immunosuppression per se in the development of UTI remains unresolved (56). Patients with end-stage renal failure are generally not particularly susceptible to the usual Gram-negative urinary pathogens, although they may acquire unusual and granulomatous infections. Patients have evidence of reduced cellular and humoral immunity.

However, the situation is a little clearer in male patients with HIV and AIDS, in whom there is a close relationship between CD4 counts and the risk of bacteriuria, particularly in patients whose counts are < 200 cells/mL (57). About 40% of patients with bacteriuria are asymptomatic. In these patients, PCP prophylaxis of the type used in transplant patients may not reduce the rate of bacteriuria, perhaps due to the previous development of resistant organisms.

*8.7.2 **Viral and fungal infections***

Viral and fungal infections are relatively common in immunosuppressed patients.

9. URETHRITIS

9.1 Epidemiology

From a therapeutic and clinical point of view, gonorrhoeal urethritis has to be differentiated from non-specific urethritis. In Central Europe, non-specific urethritis is much more frequent than gonorrhoeal urethritis. There is a correlation between promiscuity and low socioeconomic status and the frequency of infections due to *Neisseria gonorrhoeae* and *C. trachomatis*. Infection is spread by sexual contact.

9.2 Pathogens

Pathogens include *N. gonorrhoeae, C. trachomatis, Mycoplasma genitalium* and *Trichomonas vaginalis*. The frequency of the different species varies between patient populations (1-5). *Mycoplasma hominis* probably does not cause urethritis, and *Ureaplasma urealyticum* is an infrequent cause. In most cases, clinical evidence of *Mycoplasma* or *Ureaplasma* is caused by asymptomatic colonisation of the urogenital tract.

9.3 Route of infection and pathogenesis

Causative agents either remain extracellularly on the epithelial layer or penetrate into the epithelium (*N. gonorrhoeae* and *C. trachomatis*) and cause pyogenic infection. Although arising from urethritis, chlamydiae and gonococci can spread further through the urogenital tract to cause epididymitis in men or cervicitis, endometritis and salpingitis in women. Recent evidence has suggested that *Myc. genitalium* can also cause cervicitis and pelvic inflammatory disease in women (6) (LE: 3)

9.4 Clinical course

Mucopurulent or purulent discharge, alguria, dysuria and urethral pruritus are symptoms of urethritis. However, many infections of the urethra are asymptomatic.

9.5 Diagnosis

A Gram stain of a urethral discharge or a urethral smear that shows more than five leukocytes per high power field (× 1,000) and eventually, gonococci located intracellularly as Gram-negative diplococci, indicate pyogenic urethritis (7) (LE: 3, GR: B). The Gram stain is the preferred rapid diagnostic test for evaluating urethritis. It is highly sensitive and specific for documenting urethritis and the presence or absence of gonococcal infection. A positive leukocyte esterase test or > 10 leucocytes per high power field (× 400) in the first voiding urine specimen is diagnostic. In all patients with urethritis, and when sexual transmission is suspected, the aim should be to identify the pathogenic organisms. If an amplification system is used for identifying the pathogens, the first voiding urine specimen can be taken instead of a urethral smear. *Trichomonas* sp. can usually be identified microscopically.

9.6 Therapy

*9.6.1 **Treatment of gonorrhoeal urethritis***

The following guidelines for therapy comply with the recommendations of the US Centers for Disease Control and Prevention (8-10). The following antimicrobials can be recommended for the treatment of gonorrhoea:

As first-choice treatment

- cefixime, 400 mg orally as a single dose, or 400 mg by suspension (200 mg/5 mL)
- ceftriaxone, 1 g intramuscularly (with local anaesthetic) as a single dose

Alternative regimens

- ciprofloxacin, 500 mg orally as single dose
- ofloxacin, 400 mg orally as single dose
- levofloxacin, 250 mg orally as single dose.

Note that fluoroquinolones are contraindicated in adolescents (< 18 years) and pregnant women. As a result of the continuous spread of fluoroquinolone-resistant N. gonorrhoeae, this class of antibiotics is no longer recommended for the treatment of gonorrhoea in the United States. In Europe, knowledge of local susceptibility patterns is mandatory for the correct treatment of gonorrhoeal urethritis.

Because gonorrhoeae is frequently accompanied by chlamydial infection, an active antichlamydial therapy should be added.

*9.6.2 **Treatment of non-gonorrhoeal urethritis***

The following treatment has been successfully applied to non-gonorrhoeal urethritis:

As first choice of treatment:	**LE**	**GR**
azithromycin, 1 g orally as single dose	1b	A
doxycycline, 100 mg orally twice daily for 7 days	1b	A
As second choice of treatment:		
erythromycin base, 500 mg orally four times daily for 14 days	1b	A
erythromycin ethylsuccinate, 800 mg orally four times daily for 7 days		
ofloxacin, 300 mg orally twice daily for 7 days	1b	A
levofloxacin, 500 mg orally once daily for 7 days		

Doxycycline and azithromycin are considered to be equally effective in the treatment of chlamydial infections, however, infections with *Myc. genitalium* may respond better to azithromycin (11). Erythromycin is less effective and causes more side effects. In pregnant women, fluoroquinolones and doxycycline are contraindicated, therefore, besides erythromycin and azithromycin, a regimen with amoxicillin 500 mg three times daily for 7 days is also recommended.

If therapy fails, one should consider treating infections by *T. vaginalis* and/or *Mycoplasma* with a combination of metronidazole (2 g orally as single dose) and erythromycin (500 mg orally four times daily for 7 days). As in other STDs, the treatment of sexual partners is necessary.

9.7 Follow-up and prevention

Patients should return for evaluation if symptoms persist or recur after completion of therapy. Patients should be instructed to abstain from sexual intercourse until 7 days after therapy is initiated, provided their symptoms have resolved and their sexual partners have been adequately treated. Persons who have been diagnosed with a new STD should receive testing for other STDs, including syphilis and HIV.

10. PROSTATITIS AND CHRONIC PELVIC PAIN SYNDROME

10.1 Summary and recommendations

Bacterial prostatitis is a disease entity diagnosed clinically and by evidence of inflammation and infection localised to the prostate. According to the duration of symptoms, bacterial prostatitis is described as either acute or chronic, when symptoms persist for at least 3 months. It is recommended that European urologists use the classification suggested by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) of the National Institutes of Health (NIH), in which bacterial prostatitis with confirmed or suspected infection is distinguished from chronic pelvic pain syndrome (CPPS).

Acute bacterial prostatitis can be a serious infection. Parenteral administration of high doses of a bactericidal antibiotic is usually required, which may include a broad-spectrum penicillin, a third-generation cephalosporin, or a fluoroquinolone. All of these agents can be combined with an aminoglycoside for initial therapy. Treatment is required until there is defervescence and normalisation of infection parameters (LE: 3, GR: B). In less severe cases, a fluoroquinolone may be given orally for 10 days (LE: 3, GR: B).

In chronic bacterial prostatitis, and if infection is strongly suspected in CPPS, a fluoroquinolone or trimethoprim should be given orally for 2 weeks after the initial diagnosis. The patient should then be reassessed and antibiotics only continued if pre-treatment cultures are positive and/or the patient has reported positive effects from the treatment. A total treatment period of 4-6 weeks is recommended (LE: 3, GR: B).

Patients with CPPS are treated empirically with numerous medical and physical modalities. Despite the existence of some scientifically valid studies, no specific recommendations have been made until now. This has been because patients with CPPS probably represent a heterogeneous group of diseases and therapeutic outcome is always uncertain.

10.2 Introduction and definition

Traditionally, the term prostatitis has included both acute and chronic bacterial prostatitis, in which an infective origin is accepted, and the term prostatitis syndrome or, more recently, CPPS, in which no infective agent can be found and whose origin is multifactorial and in most cases obscure.

Prostatitis and CPPS are diagnosed by symptoms and evidence of inflammation and infection localised to the prostate (1). A causative pathogen, however, is detected by routine methods in only 5-10% of cases (2), and for whom antimicrobial therapy therefore has a rational basis. The remainder of patients are treated empirically with numerous medical and physical modalities. However, recent improvement in classification and application of modern methods, including molecular biology, should allow proper

systematisation of treatment (3-5).

This chapter reviews documented or suspected bacterial infections of the prostate.

10.3 Diagnosis

10.3.1 ***History and symptoms***

According to the duration of symptoms, bacterial prostatitis is described as either acute or chronic, the latter being defined by symptoms that persist for at least 3 months (3-5). The predominant symptoms are pain at various locations and LUTSs (Tables 10.1 and 10.2) (6-8). Chronic bacterial prostatitis is the most frequent cause of recurrent UTI in men (9).

Table 10.1: Localisation of pain in prostatitis and CPPS*

Site of pain	Percentage of patients
Prostate/perineum	46%
Scrotum and/or testes	39%
Penis	6%
Urinary bladder	6%
Lower back	2%

**Adapted from Zermann et al. (6).*

Table 10.2: LUTSs in prostatitis and CPPS*

Frequent need to urinate
Difficulty urinating, e.g. weak stream and straining
Pain on urination, or that increases with urination

**Adapted from Alexander et al. (8).*

10.3.1.1 Symptom questionnaires

Symptoms appear to have the strongest basis for use as a classification parameter in bacterial prostatitis as well as in CPPS (10). Prostatitis symptom questionnaires have therefore been developed for the quantification of symptoms (10,11). They include the Chronic Prostatitis Symptom Index (CPSI), which was recently developed by the International Prostatitis Collaborative Network (IPCN), initiated by the NIH (USA) (12). Although the CPSI has been validated, to date, its benefit in clinical studies is still uncertain. The questionnaire contains four questions regarding pain or discomfort, two regarding urination, and three related to quality of life (see Appendix 16.5).

10.3.2 ***Clinical findings***

In acute prostatitis, the prostate may be swollen and tender on digital rectal examination (DRE). Prostatic massage is contraindicated. Otherwise, the prostate is usually normal on palpation. An essential consideration in the clinical evaluation is to exclude differential diagnoses, such as other diseases in the urogenital organs and anorectal disorders. Clinical examination should include evaluation of the pelvic floor musculature.

10.3.3 ***Urine cultures and expressed prostatic secretion***

The most important investigations in the evaluation of the patient with prostatitis are quantitative bacteriological localisation cultures and microscopy of the segmented urine and of expressed prostatic secretion (EPS), as described by Meares and Stamey (1) (see Appendix 16.6).

According to the classification developed by the NIDDK/NIH (Table 10.3), the presence of leukocytes in post-massage urine and ejaculate are also included in the definition of inflammatory chronic prostatitis or CPPS (group IIIA) (3). The inclusion of leukocytes in the ejaculate as part of the new consensus CPPS concept allows almost twice as many patients to be reclassified into group IIIA as were formerly included in the category abacterial prostatitis using the earlier Drach's classification (13).

Table 10.3: Classification of prostatitis and CPPS according to NIDDK/NIH (3-5)

Type	Name and description
I	Acute bacterial prostatitis
II	Chronic bacterial prostatitis
III	Chronic abacterial prostatitis - CPPS A. Inflammatory CPPS (white cells in semen/EPS/VB3) B. Non-inflammatory CPPS (no white cells in semen/EPS/VB3)
IV	Asymptomatic inflammatory prostatitis (histological prostatitis)

CPPS = chronic pelvic pain syndrome; EPS = expressed prostatic secretion; VB3 = voided bladder urine 3 (urine following prostatic massage).

The Enterobacteriaceae, especially *E. coli*, are the predominant pathogens in bacterial prostatitis (Table 10.4) (14). The significance of intracellular bacteria, such as *C. trachomatis*, is uncertain (15). In patients with immune deficiency or HIV infection, prostatitis may be caused by fastidious pathogens, such as *M. tuberculosis*, *Candida* sp. and rare pathogens, such as *Coccidioides immitis, Blastomyces dermatitidis* and *Histoplasma capsulatum* (16).

Table 10.4: Most common pathogens in prostatitis

Aetiologically recognised pathogens*
E. coli
Klebsiella sp.
Prot. mirabilis
Enterococcus faecalis
P. aeruginosa
Organisms of debatable significance
Staphylococci
Streptococci
Corynebacterium sp.
C. trachomatis
U. urealyticum
Myc. hominis

**Adapted from Weidner et al. (2) and Schneider et al. (14).*

There is no correlation between leukocyte and bacterial counts and the severity of symptoms in men with chronic prostatitis/CPPS (17). It has also been shown that culture, leukocyte and antibody status does not predict antibiotic response in this group of prostatitis patients (18). In both studies, however, patients with clearly defined chronic bacterial prostatitis were excluded.

*10.3.4 **Perineal biopsy***

Perineal biopsies may be taken to help in the detection of difficult-to-culture microorganisms, but perineal biopsy should be reserved for research purposes, and cannot be recommended as part of the routine work-up. Bacteria have been cultured from perineal prostate biopsies in 36% of men with CPPS, but these results do not differ from the findings in asymptomatic controls (19).

*10.3.5 **Other tests***

The main parameter for diagnosis of inflammation in the male urogenital tract is increased leukocyte counts in the prostatic fluid, post-prostate massage urine, and seminal fluid.

Prostatic biopsy is not indicated in the routine management of prostatitis/CPPS. However, histological prostatitis is frequently diagnosed in biopsies taken for suspected prostate cancer. If such patients are asymptomatic, they are classified in the new category of asymptomatic prostatitis (type IV) (Table 10.3).

Other inflammatory markers include elevated pH, lactate dehydrogenase (LDH) and immunoglobulins

(20). The cytokines, IL-1β and TNF-α, may be identified in EPS (20) and complement C3, coeruloplasmin or polymorphonuclear (PMN) elastase in the ejaculate. These tests, however, cannot be considered to be part of routine diagnostic work-up (21).

Transrectal ultrasound (TRUS) may reveal intraprostatic abscesses, calcification in the prostate, and dilatation in the seminal vesicles. However, TRUS is not an important classification parameter in prostatitis (22), because it is unreliable for diagnosis.

*10.3.6 **Classification systems***

The purpose of the culture technique described by Meares and Stamey in 1968 was to decide whether bacteriuria originated from the urethra, prostate or bladder. Ten years later, Drach et al. (23) suggested a classification of prostatitis based on the work of Meares and Stamey, in which various types of prostatitis were differentiated according to the number of leukocytes, and positive cultures in EPS and in segmented urine samples, i.e. first voided bladder urine-1 (VB1), mid-stream urine (second voided bladder urine-2, VB2) and urine following prostatic massage (third voided bladder urine-3, VB3). This has been the most widely used classification of prostatitis for almost three decades (Table 10.5), and is still included in the latest WHO classification of diseases (ICD 10) (24).

Table 10.5: Classification of prostatitis according to Drach et al. (23)

Classification	Clinical and laboratory findings
Acute bacterial prostatitis	Clinically significant infection of the prostate
Chronic bacterial prostatitis	Significant inflammation of the prostate Isolation of an aetiologically recognised organism from the prostatic fluid/urine
Chronic abacterial prostatitis	Significant prostatic inflammation Failure to isolate an organism from the prostatic fluid/urine, or isolation of an organism whose aetiological significance is debatable
Prostatodynia	No significant prostatic inflammation Failure to isolate an organism from the prostatic fluid/urine

In 1995, the NIDDK of the NIH (USA) convened a workshop to 'develop a plan which would enable clinicians and research investigators to effectively diagnose, treat, and eventually prevent the prostatitis syndrome' (4). The NIDDK recommended a new classification of the prostatitis syndrome, which has been accepted by the IPCN. The terms abacterial prostatitis and prostatodynia were exchanged for CPPS, with or without inflammation, respectively. Seminal secretion was added to segmented urine and EPS as an additional parameter. A new category (type IV) of asymptomatic prostatitis (histological prostatitis) was added (Table 10.3). This classification is now used as a logical basis for choice of treatment.

*10.3.7 **Diagnostic evaluation***

The content and order of procedures in the diagnostic evaluation of a patient with suspected prostatitis depends on previous examinations undertaken by GPs, the established routines in different hospitals and countries, and the distance from the patient's home to the urologist. A suggested algorithm for diagnostic evaluation is presented in Table 10.6.

Table 10.6: Algorithm for diagnostic urological work-up in prostatitis

Clinical evaluation
Urinalysis and urine culture
Exclude STDs
Micturition chart, uroflowmetry and residual urine
Four-glass test according to Meares and Stamey
Microscopy
Culture
Try antibiotics if signs of inflammation

*10.3.8 **Additional investigations***

The EAU working group believes that guidelines on prostatitis should not contain a set of minimum differential diagnostic examinations. An experienced urologist should decide which investigations are relevant for each

individual patient. Bladder outflow and urethral obstruction should always be considered and ruled out by uroflowmetry, retrograde urethrography, or endoscopy. If suspected, bladder cancer must be excluded by urine cytology and cystoscopy. Ureteric calculus is ruled out by unenhanced spiral CT or intravenous pyelography. Interstitial cystitis is diagnosed by means of a micturition chart, cystoscopy and biopsy. Anorectal examination is carried out whenever indicated.

Microscopic examination of ejaculate is inferior to microscopy of EPS. It is difficult to differentiate between spermatocytes and leukocytes, unless specific methods are applied, e.g. peroxidase staining (25), and the detection rate for positive cultures is significantly reduced (26).

Video-urodynamics and advanced urodynamic examination with measurement of urethral closing pressure are not justified in the routine evaluation of patients with prostatitis, although intriguing results have been obtained in some studies (27).

The measurement of cytokines and biofilms in EPS has research interest only (6,28). Prostate-specific antigen values may be elevated in both symptomatic and asymptomatic prostatitis (29). If a patient has elevated PSA and evidence of prostatic inflammation, serum PSA will normalise after antimicrobial treatment for 4 weeks in about 50% of patients (30). A delay of at least 3 months should be allowed before it can be assumed that a stable level of PSA has been reached. Measurement of free and total PSA adds no practical diagnostic information in prostatitis (31).

10.4 Treatment

10.4.1 ***Antibiotics***

Antibiotics are life-saving in acute bacterial prostatitis, recommended in chronic bacterial prostatitis, and may be tried in inflammatory CPPS.

Acute bacterial prostatitis can be a serious infection with fever, intense local pain, and general symptoms. Parenteral administration of high doses of bactericidal antibiotics, such as a broad-spectrum penicillin, a third-generation cephalosporin or a fluoroquinolone, may be administered. For initial therapy, these regimens may be combined with an aminoglycoside. After defervescence and normalisation of infection parameters, oral therapy can be substituted and continued for a total of 2-4 weeks (32). In less severe cases, a fluoroquinolone may be given orally for 10 days (5) (IVC).

The recommended antibiotics in chronic bacterial prostatitis and inflammatory CPPS (NIH type IIIA), together with their advantages and disadvantages, are listed in Table 10.7 (33). Fluoroquinolones, such as ciprofloxacin and levofloxacin, are considered drugs of choice because of their favourable pharmacokinetic properties (33) (LE: 2b, GR: B), their generally good safety profile, and antibacterial activity against Gram-negative pathogens, including *P. aeruginosa*. In addition, levofloxacin is active against Gram-positive and atypical pathogens, such as *C. trachomatis* and genital mycoplasmas (LE: 2b, GR: B).

The duration of antibiotic treatment is based on experience and expert opinion and is supported by many clinical studies (34). In chronic bacterial prostatitis and in inflammatory CPPS, antibiotics should be given for 2 weeks after initial diagnosis. The patient should then be reassessed and antibiotics continued only if cultures are positive or the patient reports positive effects from the treatment. A total treatment period of 4-6 weeks is recommended. Relatively high doses are needed and oral therapy is preferred (33,34) (LE: 3, GR: B).

The reason for administration of antibiotics in inflammatory CPPS is that there may be a bacterial infection, even though bacteria have not been detected by routine methods (35,36). Furthermore, many clinical studies report a beneficial effect of antibiotics in inflammatory CPPS (37,38) (LE: 2a, GR: B). If intracellular bacteria have been detected or are suspected, tetracyclines or erythromycin should be given (33,38) (LE: 2b, GR: B).

10.4.2 ***Antibiotics and β-blockers in combination therapy***

Urodynamic studies have shown increased urethral closing pressure in patients with chronic prostatitis (5). A combination treatment of β-blockers and antibiotics is reported to have a higher cure rate than antibiotics alone in inflammatory CPPS (Type IIIA+B) (39) (LE: 1b, GR: B). This is a treatment option that is favoured by many urologists.

However, in a recent randomised, double-blind, placebo-controlled multicentre study, it was shown that neither ciprofloxacin, tamsulozin, nor the combination of ciprofloxacin and tamsulozin was superior to placebo in reducing symptoms in men with moderate to severe symptoms (40) (LE: 1b, GR: B). However, in this study, many patients were included who had already been heavily pre-treated with different drug regimens.

Table 10.7: Antibiotics in chronic bacterial prostatitis*

Antibiotic	Advantages	Disadvantages	Recommendation
Fluoroquinolones	Favourable pharmacokinetics	Depending on the substance:	Recommend
	Excellent penetration into the prostate	Drug interactions	
	Good bioavailability	Phototoxicity	
	Equivalent oral and parenteral pharmacokinetics (depending on the substance)	Central nervous system adverse events	
	Good activity against typical and atypical pathogens and *P. aeruginosa*		
	In general, good safety profile		
Trimethoprim	Good penetration into prostate	No activity against *Pseudomonas*, some enterococci and some Enterobacteriaceae	Consider
	Oral and parenteral forms available		
	Relatively cheap		
	Monitoring unnecessary		
	Active against most relevant pathogens		
Tetracyclines	Cheap	No activity against P. Aeruginosa	Reserve for special indications
	Oral and parenteral forms available	Unreliable activity against coagulase-negative staphylococci, *E. coli*, other Enterobacteriaceae, and enterococci	
	Good activity against *Chlamydia and Mycoplasma*	Contraindicated in renal and liver failure	
		Risk of skin sensitisation	
Macrolides	Reasonably active against Gram-positive bacteria	Minimal supporting data from clinical trials	Reserve for special indications
	Active against Chlamydia	Unreliable activity against Gram-negative bacteria	
	Good penetration into prostate		
	Relatively non-toxic		

**Adapted from Bjerklund Johansen et al. (33).*

10.4.3 ***Other oral medication***

The β-blocker terazosin has been found to be superior to placebo in reducing symptoms for patients with CPPS (41) (LE: 1b, GR: B). Pentosan polysulphate sodium may reduce symptoms and improve quality of life in patients with CPPS (42) (LE: 2a, GR: B). Finasteride will provide some improvement for patients with category IIIA prostatitis (43) (LE: 1b, GR: B).

10.4.4 ***Intraprostatic injection of antibiotics***

This treatment has not been evaluated in controlled trials and should be considered only if oral treatment fails to eradicate the infection (44,45).

10.4.5 ***Surgery***

In acute prostatitis, some patients need bladder drainage, preferably with a suprapubic catheter. A positive effect of TURP and transurethral needle ablation has been observed in patients with severe discomfort (46,47) (LE: 2a, GR: B). Even radical prostatovesiculectomy has been carried out to relieve the pain of chronic prostatitis; the results of which are dubious (48). In general, surgery should be avoided in the treatment of prostatitis patients, except for drainage of prostatic abscesses.

10.4.6 ***Other treatment forms***

Microwave energy delivered from Prostatron 2.0 has an *in vitro* bactericidal effect on laboratory-cultured *E. coli* and *Enterobacter cloacae* (49), and transurethral microwave thermotherapy (TUMT) in inflammatory CPPS has been proven to be superior to sham-treated controls (50) (LE: 1b, GR: B). However, TUMT is still considered an experimental treatment option in patients with a suspected infection.

A number of other medical and physical treatment modalities have been suggested in non-inflammatory CPPS. In this condition, there is no evidence of an infection, therefore, full coverage of this topic lies beyond the scope of this review, and the reader is referred to other publications. It should be recalled, however, that symptoms resolve within 1 year in about 30% of men with CPPS (51) (2).

11. EPIDIDYMITIS AND ORCHITIS

11.1 Summary and recommendations

Orchitis and epididymitis are classified as acute or chronic processes according to the onset and clinical course. The most common type of orchitis, mumps orchitis, develops in 20-30% of post-pubertal patients with mumps virus infection. If mumps orchitis is suspected, a history of parotitis and evidence of IgM antibodies in

the serum supports the diagnosis.

Epididymitis is almost always unilateral and relatively acute in onset. In young males it is associated with sexual activity and infection of the consort (LE: 3). The majority of cases in sexually active males aged < 35 years are due to sexually transmitted organisms, whereas in elderly patients, it is usually due to common urinary pathogens (LE: 3). Epididymitis causes pain and swelling, which begins in the tail of the epididymis, and may spread to involve the rest of the epididymis and testicular tissue. The spermatic cord is usually tender and swollen. It is imperative for the physician to differentiate between epididymitis and spermatic cord torsion as soon as possible using all available information. The microbial aetiology of epididymitis can usually be determined by examination of a Gram stain of a urethral smear and/or an MSU for the detection of Gram-negative bacteriuria (LE: 3). A urethral swab and MSU should be obtained for microbiological investigation before antimicrobial therapy (GR: C). Antimicrobials should be selected on the empirical basis that in young, sexually active men, *C. trachomatis* is usually causative, and that in older men, the most common uropathogens are involved. Fluoroquinolones with activity against *C. trachomatis* (e.g. ofloxacin and levofloxacin), should be the drugs of first choice. If *C. trachomatis* has been detected, treatment could also be continued with doxycycline, 200 mg/day, for a total of at least 2 weeks. Macrolides may be used as alternative agents (GR: C). Supportive therapy includes bed rest, up positioning of the testes and anti-inflammatory therapy. In case of *C. trachomatis* epididymitis, the sexual partner should also be treated (GR: C). Abscess-forming epididymitis or orchitis needs surgical treatment. Chronic epididymitis can sometimes be the first clinical manifestation of urogenital tuberculosis.

11.2 Definition and classification

Epididymitis, inflammation of the epididymis, causes pain and swelling which is almost always unilateral and relatively acute in onset. In some cases, the testes are involved in the inflammatory process (epididymo-orchitis). On the other hand, inflammatory processes of the testicle, especially virally induced orchitis, often involve the epididymis.

Orchitis and epididymitis are classified as acute or chronic processes according to the onset and clinical course. Chronic disease with induration develops in 15% of acute epididymitis cases. In the case of testicular involvement, chronic inflammation may result in testicular atrophy and the destruction of spermatogenesis (1,2).

11.3 Incidence and prevalence

There are no new data available concerning the incidence and prevalence of epididymitis. According to older data, acute epididymitis has been a major cause for admission to hospitals of military personnel (2) (LE: 3). Acute epididymitis in young men is associated with sexual activity and infection of the consort (3) (LE: 3).

The most common type of orchitis, mumps orchitis, develops in 20-30% of post-pubertal patients with mumps virus infection. The incidence depends upon the vaccination status of the population (4). Primary chronic orchitis is a granulomatous disease, and a rare condition with uncertain aetiology that has been reported in about 100 cases in the literature (5).

11.4 Morbidity

Complications in epididymo-orchitis include abscess formation, testicular infarction, testicular atrophy, development of chronic epididymal induration and infertility (2).

Epididymitis caused by sexually transmitted organisms occurs mainly in sexually active males aged < 35 years (2,6) (LE: 3). The majority of cases of epididymitis are due to common urinary pathogens, which are also the most common cause of bacteriuria (2,6) (LE: 3). Bladder outlet obstruction and urogenital malformations are risk factors for this type of infection.

11.5 Pathogenesis and pathology

Typically, in epididymitis due to common bacteria and sexually transmitted organisms, the infection is spread from the urethra or bladder. In non-specific granulomatous orchitis, autoimmune phenomena are assumed to trigger chronic inflammation (5,7). Paediatric orchitis and mumps orchitis are of haematogenous origin (7).

Epididymo-orchitis is also seen in systemic infections such as tuberculosis, lues, brucellosis and cryptococcus disease.

11.6 Diagnosis

In acute epididymitis, the inflammation and swelling usually begin in the tail of the epididymis, and may spread to involve the rest of the epididymis and testicular tissue. The spermatic cord is usually tender and swollen. All men with epididymitis that is caused by sexually transmitted organisms have a history of sexual exposure, and the organisms can lie dormant for months before the onset of symptoms. If the patient is examined immediately after undergoing urinalysis, urethritis and urethral discharge may be missed because WBC and

bacteria have been washed out of the urethra during urination.

The microbial aetiology of epididymitis can usually be determined by examination of a Gram stain of a urethral smear and/or an MSU for the detection of Gram-negative bacteriuria. The presence of intracellular Gram-negative diplococci on the smear correlates with infection with *N. gonorrhoeae*. The presence of only WBC on a urethral smear indicates the presence of non-gonorrhoeal urethritis. *C. trachomatis* is isolated in approximately two-thirds of these patients (2,6) (LE; 3).

Ejaculate analysis according to WHO criteria including leukocyte analysis indicates persistent inflammatory activity. In many cases, transient decreased sperm counts and forward motility can be found. Azoospermia due to complete obstruction of both epididymides is a rare complication (8). If mumps orchitis is suspected, a history of parotitis and evidence of IgM antibodies in the serum supports the diagnosis. In about 20% of mumps orchitis cases, the disease occurs bilaterally in post-pubertal men with a risk of testicular atrophy and azoospermia (3) (LE: 3).

11.6.1 ***Differential diagnosis***

It is imperative for the physician to differentiate between epididymitis and spermatic cord torsion as soon as possible using all available information, including the age of the patient, history of urethritis, clinical evaluation and Doppler (duplex) scanning of testicular blood flow.

11.7 Treatment

Only a few studies have measured the penetration of antimicrobial agents into the epididymis and testes in humans. Of these, the fluoroquinolones have shown favourable properties (9) (LE: 2a).

Antimicrobials should be selected on the empirical basis that in young, sexually active men, *C. trachomatis* is usually causative, and that in older men, with BPH or other micturition disturbances, the most common uropathogens are involved. Studies that have compared microbiological results from puncture of the epididymis and from urethral swabs as well as urine have shown very good correlation. Therefore, before antimicrobial therapy, a urethral swab and MSU should be obtained for microbiological investigation (GR: C).

Again, fluoroquinolones, preferably those with activity against *C. trachomatis* (e.g. ofloxacin and levofloxacin), should be the drugs of first choice, because of their broad antibacterial spectra and their favourable penetration into the tissues of the urogenital tract. If *C. trachomatis* has been detected as an aetiological agent, treatment could also be continued with doxycycline, 200 mg/day, for a total period of at least 2 weeks. Macrolides may be used as alternative agents (GR: C).

Supportive therapy includes bed rest, up-positioning of the testes and antiphlogistic therapy. In young men, epididymitis can lead to permanent occlusion of the epididymal ducts and thus to infertility, therefore, one should consider antiphlogistic therapy with methylprednisolone, 40 mg/day, and reduce the dose by half every second day (GR: C).

In case of *C. trachomatis* epididymitis, the sexual partner should also be treated (GR: C). If uropathogens are found as causative agents, a thorough search for micturition disturbances should be carried out to prevent relapse (GR: C). Abscess-forming epididymitis or orchitis also needs surgical treatment. Chronic epididymitis can sometimes be the first clinical manifestation of urogenital tuberculosis.

12. SEXUALLY TRANSMITTED INFECTIONS

The classical bacteria that cause venereal diseases, e.g. gonorrhoea, syphilis, chancroid and inguinal granuloma, only account for a small proportion of all known sexually transmitted deceases (STDs) today. Other bacteria and viruses as well as yeasts, protozoa and epizoa must also be regarded as causative organisms of STD. Taken together, all STDs are caused by > 30 relevant pathogens. However, not all pathogens that can be sexually transmitted manifest genital diseases, and not all genital infections are exclusively sexually transmitted. Concise information and tables that summarise the diagnostic and therapeutic management of STDs in the field of urology allow a synoptic overview and are in agreement with recent international guidelines of other specialities.

Special considerations (i.e. HIV infection, pregnancy, infants, and allergy) and recommended regimens may be looked up here.

13. FOURNIER'S GANGRENE

13.1 Summary of recommendations

1. Full, repeated surgical debridement should commence within 24 h of presentation (LE: 3; GR: B).
2. Treatment with broad-spectrum antibiotics should be started on presentation, with subsequently refinement according to culture and clinical response (LE: 3; GR: B).
3. Adjunctive treatment such as pooled immunoglobulin and hyperbaric oxygen are not recommended, except in the context of clinical trials (LE: 3; GR: C).

13.2 Background

Fournier's gangrene describes an aggressive and frequently fatal polymicrobial soft tissue infection of the perineum, perianal region, and external genitalia. It is an anatomical sub-category of necrotising fasciitis with which it shares a common aetiology and management pathway. Evidence regarding investigation and treatment is predominantly from case series and expert opinion (LE: 3/4).

13.3 Clinical presentation

Fournier's gangrene remains rare but its incidence is increasing with an ageing population and higher prevalence of diabetes, together with emergence of multi-resistant pathogens. Typically there is painful swelling of the scrotum or perineum associated with signs of severe sepsis. Examination shows a small necrotic bulla with surrounding erythema and oedema. Crepitus on palpation and a foul-smelling exudate occurs with more advanced disease. Risk factors include immuno-compromised patients, most commonly diabetes or malnutrition, or a recent history of catheterisation, instrumentation or perineal surgery. In up to 40% of cases, the onset is more insidious with undiagnosed pain often resulting in delayed treatment. A high index of suspicion and careful examination, particularly of obese patients, is required.

13.4 Microbiology

Fournier's gangrene is typically a type 1 necrotising fasciitis that is polymicrobial in origin, including *S. aureus, Streptococcus sp., Klebsiella sp.*, *E. coli* and anaerobic bacteria; involvement of Clostridium sp. is

now less common. These organisms secrete a variety of endotoxins that cause tissue necrosis and severe cardiovascular impairment. Subsequent inflammatory reaction by the host contributes to multi-organ failure and death if untreated.

13.5 Management

It is essential, first, to appreciate that the degree of internal necrosis is much greater than suggested by the external signs, and second, that adequate, repeated surgical debridement is necessary to save the patient's life (LE: 3, GR: B). Recently, severity scoring systems have been devised based on laboratory parameters to aid management, and cross-sectional imaging using CT or MRI can help define para-rectal involvement, which suggests the need for colostomy (LE: 3, GR: C). Consensus from case series suggests that surgical debridement should be early (< 24 h) and complete, because delayed and/or inadequate surgery results in higher mortality (LE: 3/4, GR: B). Concurrent parenteral antibiotic treatment should be given that covers all causative organisms and can penetrate inflammatory tissue (LE: 3, GR: B). This can then be refined following surgical cultures. The benefit of pooled immunoglobulin therapy and hyperbaric oxygen remains uncertain (LE: 3, not recommended grade C). With aggressive early surgical management, survival rates are > 70% depending upon patient group and availability of critical care (LE: 3). Following resolution, reconstruction using skin grafts is required.

14. SPECIFIC INFECTIONS

Urogenital tuberculosis and bilharziasis are two infections that may affect the urogenital tract. Although not endemic in Europe, cases of urogenital tuberculosis are occasionally diagnosed in all communities. In a world of globalisation, travellers are regularly confronted with situations in which they may be infected. Guidelines on the diagnosis and management of these two infections have been published elsewhere. Following the abstract printed here, there is a direct link to these published guidelines, which can be consulted for free.

14.1 Urogenital tuberculosis

Nearly one third of the world's population is estimated to be infected with *M. tuberculosis*. Moreover, tuberculosis is the most common opportunistic infection in AIDS patients. Urogenital tuberculosis is not very common but it is considered as a severe form of extra-pulmonary tuberculosis. The diagnosis of urogenital tuberculosis is made based on culture studies by isolation of the causative organism; however, biopsy material on conventional solid media may occasionally be required. Drugs are the first-line therapy in urogenital tuberculosis. Treatment regimens of 6 months are effective in most patients. Although chemotherapy is the mainstay of treatment, surgery in the form of ablation or reconstruction may be unavoidable. Both radical and reconstructive surgery should be carried out in the first 2 months of intensive chemotherapy.

http://www.ncbi.nlm.nih.gov/pubmed/15982799

14.2 Urogenital schistosomiasis

More than 100 million people worldwide are affected by bilharziasis, which is caused by Schistosoma heamatobium. For travellers, precautions are most important. For the population in endemic areas, an integrated approach including health education is necessary. Effective pharmacological treatment is available.

15. PERIOPERATIVE ANTIBACTERIAL PROPHYLAXIS IN UROLOGY

15.1 Summary and recommendations

The aim of antimicrobial prophylaxis in urological surgery is to prevent infective complications that result from diagnostic and therapeutic procedures. However, evidence for the best choice of antibiotics and prophylactic regimens is limited (Table 15.1).

Before surgery, it is essential to categorise the patients in relation to (1):

- general health status according to American Society of Anesthesiology (ASA) score P1-P5;
- presence of general risk factors such as older age, diabetes mellitus, impaired immune system, malnutrition, extreme weight;
- presence of specific endogenous or exogenous risk factors such as a history of UTI or urogenital

infection, indwelling catheters, bacterial burden, previous instrumentation, genetic factors;
- type of surgery and surgical field contamination burden;
- expected level of surgical invasiveness, duration and technical aspects.

Only transrectal core prostate biopsy (LE: 1b, GR: A) and TURP (LE: 1a, GR: A) are well documented. There is no evidence for any benefits of antibiotic prophylaxis in standard non-complicated endoscopic procedures and shockwave lithotripsy (SWL), although it is recommended in complicated procedures and patients with identified risk factors.

For open and laparoscopic surgery, the same rules as in abdominal and gynaecological surgery can be applied. No antibiotic prophylaxis is recommended for clean operations, whereas a single or 1-day dose is recommended in clean-contaminated/contaminated operations. Opening of the urinary tract is considered as clean-contaminated surgery.

A single dose or a short course of antimicrobials can be given parenterally or orally. The administration route depends on the type of intervention and patient characteristics. Oral administration requires drugs that have good bioavailability. In a case of continuous close urinary drainage, prolongation of perioperative antibiotic prophylaxis is not recommended.

Many antibiotics are suitable for perioperative antibacterial prophylaxis, e.g. co-trimoxazole, second-generation cephalosporins, fluoroquinolones, aminopenicillins plus a beta-lactam inhibitor, and aminoglycosides. Broader-spectrum antibiotics including fluoroquinolones should be used cautiously and reserved for treatment. This applies also to the use of vancomycin.

The use of antimicrobials should be based on knowledge of the local pathogen profile and antibiotic susceptibility pattern. Best practice includes surveillance and an audit of infectious complications.

Table 15.1: Level of evidence and grade of recommendation for standard urological procedures
(The consequences in terms of antibiotic prophylaxis are given in Table 15.5)

Procedure	LE	GR	Remarks
Diagnostic procedures			
Cystoscopy	1b	A	Low frequency of infections Contradictory findings
Urodynamic study	1a	A	Low frequency of infections Contradictory findings
Transrectal core biopsy of prostate	1b	A	High risk of infection Assess carefully risk factors
Diagnostic ureteroscopy	4	C	No available studies
Therapeutic procedures			
TURB	2b	C	Poor data. No concern given to burden of tumor, i.e. size, multiplicity, necrosis
TURP	1a	A	Good documentation
SWL (standard, no risk factors such as the presence of a stent or nephrostomy tube)	1a/1b	A	Low frequency of infections Contradictory findings
Ureteroscopy stone	2b	B	Literature does not distinguish between severity of stone management
Percutaneous stone management	2b	B	High risk of infection
Open and laparoscopic surgery			
Clean operations (no opening of urinary tract)			
Nephrectomy	3	C	SSI poorly documented Catheter-related UTI
Scrotal surgery	3	C	Review studies contradictory
Prosthetic implants	3	B	Limited documentation Regimen not well defined
Clean-contaminated (opening of urinary tract)			
Nephroureterectomy	3	B	Poor documentation
Ureteropelvic junction repair	4	C	No studies detected

Total (radical) prostatectomy	2a	B	No RCT, poor documentation
Partial bladder resection	3	C	No specific RCT studies
Clean-contaminated/contaminated (opening of bowel, urine deviation)			
Cystectomy with urine deviation	2a	B	Limited documentation

SWL = extracorporeal shockwave lithotripsy; TURB = transurethral resection of the bladder; SSI = surgical site infection; TURP = transurethral resection of the prostate; RCT= randomised controlled trials.

15.2 Introduction

Antibiotic prophylaxis in urology has been controversial for many years. Most studies in the past have been poorly designed and have lacked statistical power. There has been inconsistency concerning definitions and assessment of risk factors. Urological practice has changed particularly in the last decade and older studies are no longer relevant. Several surveys among urologists in Europe have revealed wide differences in regimens and choice of antibiotics for prophylaxis. Clearly, there is a need for evidence-based guidelines (2-6).
The present section aims to clarify the current state of knowledge and to propose practical recommendations based on clinical studies, expert opinion and professional consensus. The section also considers the recommendations of societies, such as the Paul Ehrlich Society for Chemotherapy, the corresponding working groups of the German Society of Urology (7), French Association of Urology (8) and of an international consensus working group (1).

One systematic review of antibiotic prophylaxis in urological surgery has been published (9). The results of the review strengthen the underlying documentation for the present recommendations.

A recent pan-European survey was carried out by the EAU Section for Infection in Urology (ESIU) in a large number of European countries, including > 200 urological services or units. The survey found that 9.7% of patients had a healthcare-associated UTI (10). The survey illustrated the need for a stringent antibiotic policy throughout Europe, and that recommendations for antibiotic prophylaxis should be included in the general antibiotic policy of each hospital.

The microbial development of resistance presents a challenge to the urological community for both treatment and prophylaxis. It is essential that the urologist is aware of the microbial pattern and resistance profile in his/her community and can assess the risk of each individual patient of harbouring resistant strains (see section 1.2).

15.3 Goals of perioperative antibacterial prophylaxis

Antibiotic prophylaxis and therapy are two different issues. Antibiotic prophylaxis aims to prevent healthcare-associated infections that result from diagnostic and therapeutic procedures. Antibiotic prophylaxis is only one of several measures to prevent infections and can never compensate for poor hygiene and operative technique. In contrast, antibiotic therapy is the treatment of a clinically suspected or microbiologically proven infection.

There are some clinical situations, however, that are not easily classified as either prophylaxis or therapy, e.g. patients with long-term indwelling catheters and bacteriuria. These patients must receive antibiotics at the time of surgery, regardless of how they are classified.

There is also a dilemma regarding the definition of infections. The US Centers for Disease Control and Prevention (CDC) have presented definitions that are currently the most comprehensive, and are recommended for the evaluation of infectious complications (11). These definitions have also been used in the recent pan-European study on nosocomial UTI (10). Revision of definitions and recommendations are ongoing in some countries (12). Table 15.2 illustrates the different types of infectious complications encountered in urological surgery.

Table 15.2: Main types of healthcare-associated infections encountered in urological practice

Site of infection	Minor	Major
Surgical wound Incision/surgical site infection (SSI)	Superficial wound infection	Deep wound infection Wound rupture (abdominal dehiscence) Deep abdominal or surgical site abscess
UTI or organ-specific infection	Asymptomatic bacteriuria (bacterial colonisation) Symptomatic lower UTI	Febrile UTI Pyelonephritis Renal abscess

Blood stream	Bacteremia without signs of systemic response	SIRS or sepsis with signs of systemic response
Septic embolism Other urogenital sites	Epididymitis (Orchitis)	Acute bacterial prostatitis (type I)
Other sites		Pneumonia

Surgical site infections are seen after open surgery and to some extent after laparoscopic surgery. Febrile and complicated UTIs are mainly complications of endoscopic surgery and the use of indwelling catheters and stents. They can also occur following open surgery of the urinary tract. Sepsis can be seen with all types of procedures.

The endpoints of perioperative prophylaxis in urology are debatable. It is generally agreed that its main aim is to prevent symptomatic, febrile urogenital infections such as acute pyelonephritis, prostatitis, epididymitis and urosepsis, as well as serious wound infections directly related to surgery (Table 15.2). This might be extended to asymptomatic bacteriuria and even minor wound infections, which could easily be treated on an outpatient basis. In some circumstances, even minor wound infections can have serious consequences, as in implant surgery. However, asymptomatic bacteriuria after TURP or other endourological procedures can disappear spontaneously and is usually of no clinical significance. Another question is whether perioperative prophylaxis should also be concerned with the prevention of non-urological infections, e.g. endocarditis and postoperative pneumonia. Perioperative antibacterial prophylaxis in urology must go beyond the traditional aim of prophylaxis in surgery, which is the prevention of wound infections.

15.4 Risk factors

Risk factors (Table 15.3) are underestimated in most trials. However, they are important in the preoperative assessment of the patient. They are related to:

- general health of the patient as defined by ASA score P1-P5;
- presence of general risk factors such as older age, diabetes mellitus, impaired immune system, malnutrition, extreme weight;
- presence of specific endogenous or exogenous risk factors such as a history of UTI or urogenital infection, indwelling catheters, bacterial burden, previous instrumentation, genetic factors;
- type of surgery and surgical field contamination;
- expected level of surgical invasiveness, duration and technical aspects.

The traditional classification of surgical procedures according to Cruse and Foord (13) into clean, clean-contaminated, contaminated, and dirty operations applies to open surgery but not to endourological interventions. It is still debated whether opening of the urinary tract (i.e. bladder surgery, radical prostatectomy, or surgery of the renal pelvis and ureter) should be classified as clean or clean-contaminated surgery in cases of negative urine culture. The same applies to endoscopic and transurethral surgery. However, members of the EAU Expert Group consider these procedures as clean-contaminated because urine culture is not always a predictor of bacterial presence, and the lower genitourinary tract is colonised by microflora, even in the presence of sterile urine (6,14,15).

Table 15.3: Generally accepted risk factors for infectious complications

General risk factors	Special risk factors associated with an increased bacterial load
Older age	Long preoperative hospital stay or recent hospitalisation
Deficient nutritional status	History of recurrent urogenital infections
Impaired immune response	Surgery involving bowel segment
Diabetes mellitus	Colonisation with microorganisms
Smoking	Long-term drainage
Extreme weight	Urinary obstruction
Coexisting infection at a remote site	Urinary stone
Lack of control of risk factors	

The pan-European study on nosocomial UTI (10) has identified the three most important risk factors for infectious complications as:

- an indwelling catheter;

- previous urogenital infection;
- long preoperative hospital stay.

The risk of infection varies with the type of intervention. The wide spectrum of interventions further complicates the provision of clearcut recommendations. Furthermore, the bacterial load, the duration and difficulty of the operation, the surgeon's skill, and perioperative bleeding may also influence the risk of infection (6).

15.5 Principles of antibiotic prophylaxis

Antibiotic prophylaxis aims at protecting the patient but not at the expense of promoting resistance. However, there is good evidence that intelligent use of prophylaxis can lower the overall consumption of antibiotics (15,16). It is essential to individualise the choice of antibiotic prophylaxis according to each patient's cumulative risk factors (17). Urine culture prior to surgery is strongly recommended. Antibiotics cannot replace other basic measures to reduce infection (18-20).

Unfortunately, the benefit of antibiotic prophylaxis for most modern urological procedures has not yet been established by well-designed interventional studies.

*15.5.1 **Timing***

There is a given time-frame during which antibiotic prophylaxis should be administered. Although the following guidelines are based on research into skin wounds and clean-contaminated and contaminated bowel surgery, there is good reason to believe that the same findings apply to urological surgery. The optimal time for antibiotic prophylaxis is from 2 h before but not later than 3 h after the start of an intervention (21-23). For practical purposes, oral antibiotic prophylaxis should be given approximately 1 h before the intervention. Intravenous antibiotic prophylaxis should be given at the induction of anaesthesia. These timings allow antibiotic prophylaxis to reach a peak concentration at the time of highest risk during the procedure, and an effective concentration shortly afterwards (24). It is worth noting that a bloodstream infection can develop in less than an hour (21).

*15.5.2 **Route of administration***

Oral administration is as effective as the intravenous route for antibiotics with sufficient bioavailability. This is recommended for most interventions when the patient can easily take the drug between 1 and 2 h before intervention. Administration of the drug several hours before surgery is probably less effective. In other cases, intravenous administration is recommended. Local irrigation of the operating field with antibiotics is not recommended.

*15.5.3 **Duration of the regimen***

For most procedures, duration of antibiotic prophylaxis has not yet been adequately addressed and rarely can a defined regimen be recommended. In principle, the duration of perioperative prophylaxis should be minimised; ideally to a single preoperative antibiotic dose. Perioperative prophylaxis should be prolonged only where there are significant risk factors (see Section 15.4).

*15.5.4 **Choice of antibiotics***

No clear-cut recommendations can be given, as there are considerable variations in Europe regarding both bacterial spectra and susceptibility to different antibiotics. Antimicrobial resistance is usually higher in Mediterranean compared with Northern European countries; resistance is correlated with an up to fourfold difference in sales of antibiotics (25). Thus, knowledge of the local pathogen profile, susceptibility and virulence is mandatory in establishing local antibiotic guidelines. It is also essential to define the predominant pathogens for each type of procedure. When choosing an antimicrobial agent, it is necessary to consider the procedure-specific risk factors, contamination load, target organ, and the role of local inflammation.

In general, many antibiotics are suitable for perioperative antibacterial prophylaxis, e.g. co-trimoxazole, second-generation cephalosporins, aminopenicillins plus a BLI, aminoglycosides and fluoroquinolones. Broader-spectrum antibiotics should be used sparingly and reserved for treatment. Fluoroquinolones should be avoided as far as possible for prophylaxis. This applies also to the use of vancomycin.

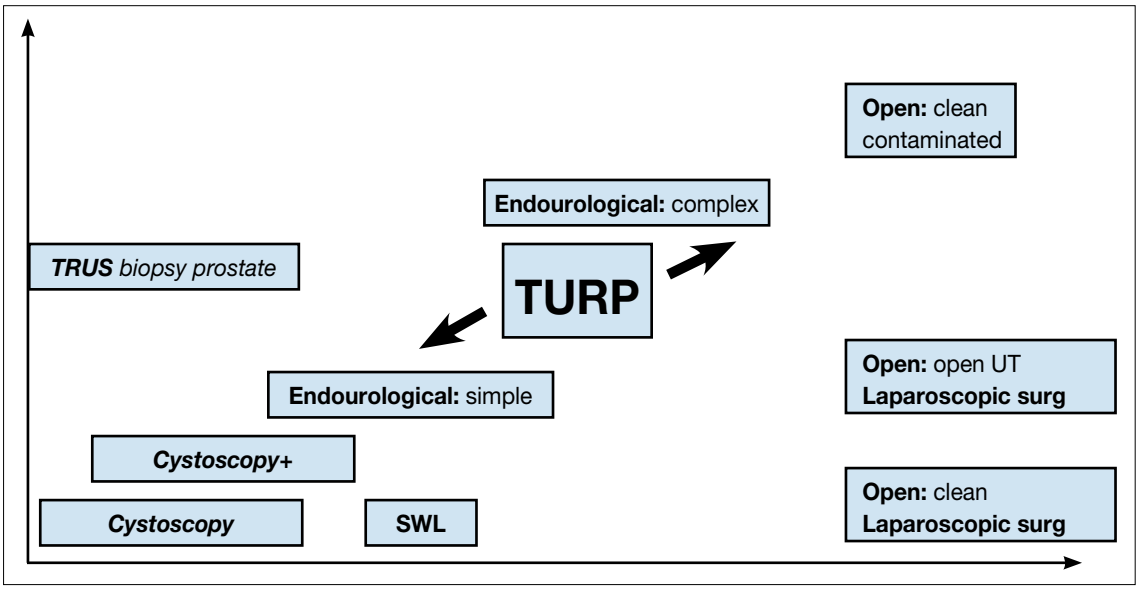
15.6 Prophylactic regimens in defined procedures

The list of major urological diagnostic and therapeutic procedures is given in Table 15.4 and the empirical relationship between the level of invasiveness and risk for infective complications is illustrated in Figure 15.1. Moreover, a tentative classification of the urological procedures in relation to the surgical field contamination level is given in Table 15.6.a and 15.6.b.

Table 15.4: List of urological interventions

Diagnostic procedures
• Fine-needle biopsy of the prostate
• Core-needle biopsy of the prostate
Cystoscopy
• Urodynamic examination
• Radiological diagnostic intervention of the urinary tract
• Ureteroscopy
Deviation procedures
• Insertion of indwelling catheter
• Insertion of suprapubic catheter
• Insertion of nephrostomy tube
• Insertion of ureteric stent
Endourological operations
• Resection of bladder tumour
• Resection of prostate
• Minimal invasive prostatic operation, i.e. microwave thermotherapy
• Ureteroscopy for stone or tumour fulguration
• Percutaneous stone or tumour surgery
SWL
Laparoscopic surgery
• Radical prostatectomy
• Pyeloplasty
• Nephrectomy and nephron-sparing surgery of the kidney
• Other major laparoscopic surgery, including bowel surgery
Open surgery
• Open surgery of the prostate, i.e. enucleation of prostatic adenoma
• Open stone surgery
• Pyeloplasty
• Nephrectomy and nephron-sparing surgery of the kidney
• Nephro-ureterectomy, including bladder resection
• Bladder resection
• Urethroplasty
• Implantation of prosthetic devices
• Urinary diversion procedures using intestinal segments

Figure 15.1: Level of invasiveness and risk of infection in urological procedures (empirical scheme) (5)



The recommendations for antibiotic prophylaxis in standard urological surgery are summarised in Table 15.5 and Appendix 16.4.

15.6.1 ***Diagnostic procedures***

Antimicrobial prophylaxis in core biopsy of the prostate is generally recommended (GR: A). However, the choice of regimens remains debatable. Most regimens used are effective, and recent studies have suggested that 1-day and even single doses are sufficient in low-risk patients (26-41) (LE: 1b, GR: A).

The frequency of infectious complications after cystoscopy, urodynamic studies and diagnostic simple ureteroscopy is low. The use of antibiotic prophylaxis is still debated and the results are controversial. In view of the very large number of cystoscopic examinations and the potential adverse effect on bacterial sensitivity, antibiotic prophylaxis is not recommended in standard cases. However, bacteriuria, indwelling catheters, and a history of urogenital infection are risk factors that must be considered (42-56) (LE: 1b, GR: A).

15.6.2 ***Endourological treatment procedures (urinary tract entered)***

There is little evidence for any benefit of antibiotic prophylaxis in TURB. However, antibiotic prophylaxis should be considered in patients with large tumours with a prolonged resection time, large necrotic tumours, and with risk factors (43,57,58) (LE: 2b, GR: C).

TURP is the best-studied urological intervention. A meta-analysis of 32 prospective, randomised and controlled studies, including > 4,000 patients, showed a benefit of antibiotic prophylaxis with a relative risk reduction of 65% and 77% for bacteriuria and septicaemia, respectively (15,59-61) (LE: 1a, GR: A). There is a difference between smaller resections in healthy patients and large resections in at-risk patients (Figure 15.1).

There have been few studies that have defined the risk of infection following ureteroscopy and percutaneous stone removal, and no clear-cut evidence exists (62). It is reasonable, however, to distinguish low-risk procedures, such as simple diagnostic and distal stone treatment, from higher-risk procedures, such as treatment of proximal impacted stones and intrarenal interventions (Figure 15.1) (5). Other risk factors (i.e. size, length, bleeding, and surgeon's experience) also need to be considered in the choice of regimen (63-70) (LE: 2b, GR: B).

SWL is one of the most commonly performed procedures in urology. No standard prophylaxis is recommended. However, prophylaxis is recommended in cases of internal stent and treatment, due to the increased bacterial burden (e.g. indwelling catheter, nephrostomy tube, or infectious stones) (71-79) (LE: 1a-1b, GR: A).

Most antibiotic groups have been evaluated, such as fluoroquinolones, BLIs, including cephalosporins, and co-trimoxazole, but comparative studies are limited.

15.6.3 ***Laparoscopic surgery***

There has been a lack of sufficiently powered studies in laparoscopic urological surgery. However, it seems reasonable to manage laparoscopic surgical procedures in the same manner as the corresponding open procedures (LE: 4, GR: C).

15.6.4 ***Open or laparoscopic urological operations without opening of the urinary tract (clean procedures)***

No standard antibiotic prophylaxis is recommended in clean operations (80-84) (LE: 3, GR: C).

15.6.5 ***Open or laparoscopic urological operations with open urinary tract (clean-contaminated procedures)***

In cases of opening the urinary tract, a single perioperative parenteral dose of antibiotics is recommended (LE: 3, GR: C). This is valuable for standard procedures such as total (radical) prostatectomy (85-88). In open enucleation of prostatic adenoma, the risk of postoperative infection is particularly high (89) (LE: 2b, GR: B).

15.6.6 ***Open urological operations with bowel segment (clean-contaminated or contaminated procedures)***

Antibiotic prophylaxis is recommended, as for clean-contaminated operations in general surgery. Single or 1-day dosage is recommended, although prolonged operation and other morbidity risk factors might support the use of a prolonged regimen, which should be < 72 h. The choice of antibiotic should focus on aerobic and anaerobic pathogens. Evidence is based on colorectal surgery (LE: 1a, GR: A), but experience is limited as for specific urological interventions (90-93) (LE: 2a, GR: B).

15.6.7 ***Postoperative drainage of the urinary tract***

When continuous urinary drainage is left in place after surgery, prolongation of perioperative antibacterial prophylaxis is not recommended, unless a complicated infection that requires treatment is suspected. Asymptomatic bacteriuria (bacterial colonisation) should only to be treated before surgery or after removal of the drainage tube (LE: 3, GR: B).

15.6.8 ***Implantation of prosthetic devices***

When infectious complications occur in implant surgery, they are usually problematic and often result in removal of the prosthetic device. Diabetes mellitus is considered a specific risk factor for infection. Skin-related staphylococci are responsible for most infections. The antibiotics used must be chosen to target these strains (94-97) (LE: 2a, GR: B).

15.5 Recommendations for perioperative antibiotic prophylaxis in urology

Procedure	Pathogens (expected)	Prophylaxis	Antibiotics	Remarks
Diagnostic procedures				
Transrectal biopsy of the prostate	Enterobacteriaceae Anaerobes?	All patients	Fluoroquinolones TMP ± SMX Metronidazole?[1]	Single dose effective in low-risk patients. Consider prolonged course in high-risk patients
Cystoscopy Urodynamic examination	Enterobacteriaceae Enterococci Staphylococci	No	TMP ± SMX Cephalosporin 2nd Generation	Consider in high-risk patients
Ureteroscopy	Enterobacteriaceae Enterococci Staphylococci	No	TMP ± SMX Cephalosporin 2nd generation	Consider in high-risk patients
Endourological surgery and SWL				
SWL	Enterobacteriaceae Enterococci	No	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI[a]	
SWL with stent or nephrostomy tube	Enterobacteriaceae Enterococci	All patients	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI[a]	Risk patients

Ureteroscopy for uncomplicated distal stone	Enterobacteriaceae Enterococci Staphylococci	No	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI Fluoroquinolones	Consider in risk patients
Ureteroscopy of proximal or impacted stone and percutaneous stone extraction	Enterobacteriaceae Enterococci Staphylococci	All patients	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI Fluoroquinolones	Short course Length to be determined Intravenous suggested at operation
TURP	Enterobacteriaceae Enterococci	All patients	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI	Low-risk patients and small-size prostate probably do not require prophylaxis
TUR of bladder tumour	Enterobacteriaceae Enterococci	No	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI	Consider in high-risk patients and large tumours
Open or laparoscopic urological surgery				
Clean operations	Skin-related pathogens, e.g. staphylococci Catheter-associated uropathogens	No		Consider in high-risk patients Short postoperative catheter requires no treatment
Clean-contaminated (opening of urinary tract)	Enterobacteriaceae Enterococci Staphylococci	Recommended	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI	Single perioperative course
Clean-contaminated/ contaminated (use of bowel segments)	Enterobacteriaceae Enterococci Anaerobes Skin-related bacteria	All patients	Cephalosporin 2nd or 3rd generation Metronidazole	As for colonic surgery
Implant of prosthetic devices	Skin-related bacteria, e.g. staphylococci	All patients	Cephalosporin 2nd or 3rd generation Penicillin (penicillinase stable)	

[1]No evidence for metronidazole in core biopsy of the prostate

[a] = Gram-negative bacteria excluding Pseudomonas aeruginosa

Table 15.6.a: Surgical Wound Classes and risk of wound infection modified for urological procedures. Tentative classification of urological instrumentation and procedures in relation to the different classes. The risk of wound infection as expressed in per cent is that of classical wound infection and not bacteriuria or clinical UTI in urological surgery. (Urogenital infections, EAU/ICUD, 2010, p 674-75)

Category of intervention (risk of surgical wound infection)	Description	Open or laparoscopic urological surgery (Examples)	Endoscopic urological instrumentation and surgery (examples)
Clean (1-4%)	Urogenital tract not entered No evidence of inflammation No break in technique Blunt trauma	Simple nephrectomy Planned scrotal surgery Vasectomy Varicocele surgery	Cystoscopy Urodynamic study TURB (minor, fulguration)* SWL*
Clean-contaminated (4-10%)	*Urogenital tract* entered with no or little (controlled) spillage No major break in technique	Pelvio-ureteric junction repair Nephron-sparing tumour resection Total/radical prostatectomy Bladder surgery and partial cystectomy Incl. Vaginal surgery	TURB (major, necrotic)* TURP* Diagnostic URS* Uncomplicated URS* and PCNL stone management SWL*
	Gastrointestinal tract entered with no or little (controlled) spillage No break in technique	Urine diversion (orthotopic bladder replacement; ileal conduit)	
Contaminated (10-15%)	Spillage of Gastrointestinal content Inflammatory tissue Major break in technique Open, fresh accidental wounds	Urine deviation (colon) and small intestine/spillage Trauma surgery Concomitant gastrointestinal disease	Core prostate biopsy* TURP* Impacted proximal stone management Complicated PCNL
Dirty (15-40%)	Pre-existing infection Perforated viscera at surgery Old traumatic wound	Drainage of abscess Large dirty trauma surgery	Infectious stone surgery

**Detailed description in table 15.6.b*

Table 15.6.b: Tentative list of essential criteria for assessment of surgical wound class/surgical field contamination level of common urological procedures: The estimated risk of infectious complication is related to the surgical class or category (Urogenital infections, EAU/ICUD, 2010, p 674-75)

Operation/ Category	TURB	TURP	Endoscopy Stone	SWL	Prostate biopsy
Clean	Small tumours No history UTI Sterile urine (similar cystoscopy)	-	Distal ureteral stone No history UTI Sterile urine No or minor obstruction No other RF	Standard ureteral or kidney stone No history UTI Sterile urine No or mild obstruction	-
Clean-contaminated	Large tumours History UTI Sterile urine	No history UTI/ UGI Sterile urine No catheter	All ureteral stone History UTI Sterile urine Minor/moderate obstruction No stent Other RF	Standard ureteral or kidney stone History UTI Sterile urine Moderate obstruction Other RF	*Transperineal* Sterile urine No history UTI/UGI
Contamin-ated	Large tumours Necrosis Bacteriuria controlled	History UTI/UGI Catheter prior to surgery Bacteriuria controlled	Proximal impacted stone History UTI Sterile urine or Controlled bacteriuria Moderate obstruction Stent/catheter	Complex stone History UTI Obstruction Bacteriuria controlled Stent or nephrostomy tube	*Transperineal* Sterile urine History UTI/ UGI *Transrectal* No- or history UTI/UGI Sterile urine
Dirty	Clinical infected Emergency	Clinical infected Emergency	Clinical infected Drainage only	Clinical infected Drainage only	*Transrectal* Presence of catheter or bacteriuria

**UTI = urinary tract infection; UGI = urogenital infection (i.e. prostatitis); RF = risk factor.*

16. APPENDICES

16.1 Criteria for the diagnosis of UTI, as modified according to IDSA/European Society of Clinical Microbiology and Infectious Diseases guidelines (1-3)

Category	Description	Clinical features	Laboratory investigations
1	Acute uncomplicated UTI in women; acute uncomplicated cystitis in women	Dysuria, urgency, frequency, suprapubic pain, no urinary symptoms in 4 weeks before this episode	> 10 WBC/mm^3 > 10^3 cfu/mL*
2	Acute uncomplicated pyelonephritis	Fever, chills, flank pain; other diagnoses excluded; no history or clinical evidence of urological abnormalities (ultrasonography, radiography)	> 10 WBC/mm^3 > 10^4 cfu/mL*
3	Complicated UTI	Any combination of symptoms from categories 1 and 2 above; one or more factors associated with a complicated UTI (see text)	> 10 WBC/mm^3 > 10^5 cfu/mL* in women > 10^4 cfu/mL* in men, or in straight catheter urine in women
4	Asymptomatic bacteriuria	No urinary symptoms	> 10 WBC/mm^3 > 10^5 cfu/mL* in two consecutive MSU cultures > 24 h apart
5	Recurrent UTI (antimicrobial prophylaxis)	At least three episodes of uncomplicated infection documented by culture in past 12 months: women only; no structural/functional abnormalities	< 10^3 cfu/mL*

All pyuria counts refer to unspun urine.
**Uropathogen in MSU culture.*

16.2 Recommendations for antimicrobial therapy in urology

Diagnosis	Most frequent pathogen/species	Initial, empirical antimicrobial therapy	Therapy duration
Cystitis acute, uncomplicated	• *E. coli* • *Klebsiella* • *Proteus* • Staphylococci	• TMP-SMX[1] • Nitrofurantoin • Fosfomycin trometamol • Pivmecillinam Alternative: • Fluoroquinolone[2,3]	3 days (5-)7 days 1 day (3-)5 days (1-)3 days
Pyelonephritis acute, uncomplicated	• *E. coli* • *Proteus* • *Klebsiella* • Other enterobacteria • Staphylococci	• Fluoroquinolone[2] • Cephalosporin (group 3a) Alternatives: • Aminopenicillin/BLI • Aminoglycoside	7-10 days
UTI with complicating factors	• *E. coli* • Enterococci • *Pseudomonas* • Staphylococci	• Fluoroquinolone[2] • Aminopenicillin/BLI • Cephalosporin (group 2) • Cephalosporin (group 3a) • Aminoglycoside In case of failure of initial therapy within 1-3 days or in clinically cases: Anti-*Pseudomonas* active: • Fluoroquinolone, if not used initially • Acylaminopenicillin/BLI • Cephalosporin (group 3b) • Carbapenem • ± Aminoglycoside In case of Candida: • Fluconazole • Amphotericin B	3-5 days after defervescence or control/elimination of complicating factor
Nosocomial UTI	• *Klebsiella* • *Proteus*		
Pyelonephritis severe acute, complicated	• *Enterobacter* • Other enterobacteria • *(Candida)*		
Prostatitis acute, chronic	• *E. coli* • Other enterobacteria • *Pseudomonas* • Enterococci Chronic: • Staphylococci • *Chlamydia* • *Ureaplasma* • *E. coli* • Other enterobacteria After urological interventions - multi-resistant pathogens: • *Pseudomonas* • *Proteus* • *Serratia* • *Enterobacter*	• Fluoroquinolone[2] Alternative in acute bacterial prostatitis: • Cephalosporin (group 3a/b) In case of *Chlamydia* or *Ureaplasma*: • Doxycycline • Macrolide • Cephalosporin (group 3a/b) • Fluoroquinolone[2] • Anti-*Pseudomonas* active acylaminopenicillin/BLI • Carbapenem • ± Aminoglycoside	Acute: 2-4 weeks Chronic: 4-6 weeks or longer 3-5 days after defervescence or control/elimination of complicating factor
Epididymitis Ureaplasma: Acute			
Urosepsis			

[1]Only in areas with resistance rate < 20% (for E. coli).

[2]Fluoroquinolone with mainly renal excretion (see text).

[3]Avoid Fluoroquinolones in uncomplicated cystitis whenever possible.

16.3 Recommendations for antimicrobial prescription in renal failure

Antibiotic	GFR (mL/min)			Comments
	Mild 50-20	**Moderate** 20-10	**Severe** < 10	
*Aciclovir	normal dose every 12 h	normal dose every 24 h	50% of normal dose every 24 h	Give post-HD
Aciclovir po	normal	Herpes simplex: normal Herpes zoster: 800 mg Total Dissolved Solids tds	Herpes simplex: 200 mg bid Herpes zoster: 800 mg bd	Give post-HD
Amikacin	5-6 mg/kg 12 h	3-4 mg/kg 24 h HD: 5mg/kg post HD and monitor levels	2 mg/kg 24-48 h	Give post-HD Monitor pre- and 1 h post-dose levels after 3rd dose and adjust dose as required
Amoxicillin po	normal	normal	250 mg 8 h (normal)	Give post-HD
Amphotericin	normal	normal	normal	
(Liposonal + lipid complex)	Amphotericin is highly NEPHROTOXIC. Consider using liposomal/lipid complex amphotericin. Daily monitoring of renal function (GFR) essential.			
Ampicillin IV	normal	250-500 mg 6 h	250 mg 6 h (500 mg 6 h)	Give post-HD
Benzylpenicillin	normal	75%	20-50% Max. 3.6 g/day (1.2 g qds)	Give post-HD Refer to microbiology for dosing in SBE
Caspofungin	normal	normal	normal	
Cefotaxime	normal	normal	1 g stat then 50%	Give post-HD
Cefradine	normal	Normal	250 mg 6 h	Give post-HD
Ceftazidime	1 g 12 h	1 g 24 h	500 mg 24 h (1 g 24 h)	Give post-HD
Ceftriaxone	normal	normal	normal Max. 2 g/day	
Cefuroxime IV	normal	750 mg-1.5 g 12 h	750 mg 24 h (750 mg 12 h)	Give post-HD
Ciproflazin IV + po	normal	50%	50%	
Clarithromycin IV + po	normal	normal	50%	Give post-HD
Clindamycin IV + po	normal	normal	normal	
Co-amoxiclav IV (Augmentin)	normal	1.2 stat then 50% 12 h (1.2 g 12 h)	1.2 stat then 50% 24 h (1.2 g stat then 600 mg 12 h)	Give post-HD
Co-amoxiclav po (Augmentin)	normal	375-625 mg 12 h (375 mg 8 h)	375 mg 12 h (375 mg 8 h)	Give post-HD
*Co-trimoxazole IV	normal	Normal for 3/7 then 50%	50%	Give post-HD

Doxycycline	normal	normal	normal	All other tetracyclines contraindicated in renal impairment
Erythromycin IV + po	normal	normal	normal Max. 1.5 g/day (500 mg qds)	
*Ethambutol	normal	24-36 h	48 h	Give post-HD
	Monitor levels if GFR < 30mL/min (contact Mirco)			
Flucloxacillin IV + po	normal	normal	normal Max. 4 g/day	
Fluconazole	normal	normal	50%	Give post-HD No adjustments in single-dose therapy required
*Flucytosine	50 mg/kg 12 h	50 mg/kg 24 h	50 mg/kg stat then dose according to levels	Give post-HD Levels should be monitored predialysis.
Fusidic acid	normal	normal	normal	
1) Gentamicin ONCE DAILY	**GFR 10-40 mL/min** 3 mg/kg stat (max. 300 mg) Check pre-dose levels 18-24 h after first dose Redose only when level < 1 mg/L		**GFR < 10 mL/min** 2 mg/kg (max. 200 mg) redose according to levels	BOTH METHODS Give post-HD Monitor blood levels:
2) Gentamicin CONVENTIONAL	80 mg 12 h	80 mg 48 h	80 mg 24 h HD: 1-2 mg/kg Post-HD: redose according to levels	Once daily: pre only Conventional: pre and 1 h post level required.
Imipenem	500 mg 8-12 h	250-500 mg bid	Risk of convulsions - use Meropenem: *see below*	Give post-HD
Isoniazid	normal	normal	200-300 mg 24 h	Give post-HD
Itraconazole	normal	normal	normal	
Levoflaxacin	500 mg stat then 250 mg bid**	500 mg stat then 125 mg bid**	500 mg stat then 125 mg od	**Applies if full dose is 500 mg bid If full dose is 500 mg od, five reduced doses daily
Linezolid	normal	normal	normal	Give post-HD
Meropenem	12 h	50% 12 h	50% 24 h	Give post-HD
Metronidazole	normal	normal	12 h (normal)	Give post-HD
Nitrofurantoin	Do **NOT** use in renal impairment			
Penicillin V	normal	normal	normal	Give post-HD
Piperacillin/ Tazobactam (Tazocin)	4.5 g 8 h	4.5 g 12 h	4.5 g 12 h	Give post-HD
Pyrazinamide	normal	normal	normal	
Rifampicin	normal	normal	50-100%	

*Teicoplanin	100% 48 h	100% 72 h	100% 72 h	Dose reduction after day 3 of therapy
Tetracycline	See **Doxycycline**			
Trimethoprim	normal	Normal for 3/7 then 50% 18 h	50% 24 h	Give post-HD
Vancomycin	1 g od Check pre-dose level before 3rd dose	1 g 48 h Check pre-dose level before 2nd dose	1 g stat (or 15 mg/kg, up to max. 2 g). Recheck level after 4-5 days ONLY give subsequent dose when level < 12mg/L	Monitor pre-dose levels and adjust dose as required
Vorinconazole	normal	normal	normal	Give post HD

bid = twice daily; HD = haemodialysis; od = once daily; po = by mouth; qid = four times daily; SBE = subacute bacterial endocarditis; tds = total dissolved solids; qds = Quantum Dots.

16.4 Recommendations for perioperative antibiotic prophylaxis in urology

Procedure	Pathogens (expected)	Prophylaxis	Antibiotics	Remarks
Diagnostic procedures				
Transrectal biopsy of the prostate	Enterobacteriaceae Anaerobes?	All patients	Fluoroquinolones TMP ± SMX Metronidazole?[1]	Single dose effective in low-risk patients. Consider prolonged course in high-risk patients
Cystoscopy Urodynamic examination	Enterobacteriaceae Enterococci Staphylococci	No	TMP ± SMX Cephalosporin 2nd Generation	Consider in high-risk patients
Ureteroscopy	Enterobacteriaceae Enterococci Staphylococci	No	TMP ± SMX Cephalosporin 2nd generation	Consider in high-risk patients
Endourological surgery and SWL				
SWL	Enterobacteriaceae Enterococci	No	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI[a]	
SWL with stent or nephrostomy tube	Enterobacteriaceae Enterococci	All patients	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI[a]	Risk patients
Ureteroscopy for uncomplicated distal stone	Enterobacteriaceae Enterococci Staphylococci	No	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI Fluoroquinolones	Consider in risk patients
Ureteroscopy of proximal or impacted stone and percutaneous stone extraction	Enterobacteriaceae Enterococci Staphylococci	All patients	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI Fluoroquinolones	Short course Length to be determined Intravenous suggested at operation

TURP	Enterobacteriaceae Enterococci	All patients	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI	Low-risk patients and small-size prostate probably do not require prophylaxis
TUR of bladder tumour	Enterobacteriaceae Enterococci	No	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI	Consider in high-risk patients and large tumours
Open or laparoscopic urological surgery				
Clean operations	Skin-related pathogens, e.g. staphylococci Catheter-associated uropathogens	No		Consider in high-risk patients Short postoperative catheter requires no treatment
Clean-contaminated (opening of urinary tract)	Enterobacteriaceae Enterococci Staphylococci	Recommended	TMP ± SMX Cephalosporin 2nd or 3rd generation Aminopenicillin/BLI	Single perioperative course
Clean-contaminated/ contaminated (use of bowel segments)	Enterobacteriaceae Enterococci Anaerobes Skin-related bacteria	All patients	Cephalosporin 2nd or 3rd generation Metronidazole	As for colonic surgery
Implant of prosthetic devices	Skin-related bacteria, e.g. staphylococci	All patients	Cephalosporin 2nd or 3rd generation Penicillin (penicillinase stable)	

[1]No evidence for metronidazole in core biopsy of the prostate.

[a] = gram-negative bacteria excluding Pseudomonas aeruginosa.

16.5 CPSI

from: Litwin MS, McNaughton-Collins M, Fowler FJ Jr, Nickel JC, Calhoun MA, Pontari MA, Alexander RB, Farrar JT, O'Leary MP. The National Institute of Health chronic prostatitis symptom index: development and validation of new outcome measure. Chronic Prostatitis Collaborative Research Network. J Urol 1999:162;369-375.

NIH-Chronic Prostatitis Symptom Index (NIH-CPSI)

Pain or Discomfort

1. In the last week, have you experienced any pain or discomfort in the following areas?

	Yes	No
a. Area between rectum and testicles (perineum)	☐ 1	☐ 0
b. Testicles	☐ 1	☐ 0
c. Tip of penis (not related to urination)	☐ 1	☐ 0
d. Below your waist, in your pubic or bladder area	☐ 1	☐ 0

2. In the last week, have you experienced:

	Yes	No
a. Pain or burning during urination?	☐ 1	☐ 0
b. Pain or discomfort during or after sexual climax (ejaculation)?	☐ 1	☐ 0

3. How often have you had pain or discomfort in any of these areas over the last week?

☐ 0 Never
☐ 1 Rarely
☐ 2 Sometimes
☐ 3 Often
☐ 4 Usually
☐ 5 Always

4. Which number best describes your AVERAGE pain or discomfort on the days that you had it, over the last week?

☐ 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐ 6 ☐ 7 ☐ 8 ☐ 9 ☐ 10

NO PAIN — PAIN AS BAD AS YOU CAN IMAGINE

Urination

5. How often have you had a sensation of not emptying your bladder completely after you finished urinating over the last week?
☐ 0 Not at all
☐ 1 Less than 1 time in 5
☐ 2 Less than half the time
☐ 3 About half the time
☐ 4 More than half the time
☐ 5 Almost always

6. How often have you had to urinate again less than two hours after you finished urinating, over the last week?

☐ 0 Not at all
☐ 1 Less than 1 time in 5
☐ 2 Less than half the time
☐ 3 About half the time
☐ 4 More than half the time
☐ 5 Almost always

Impact of Symptoms

7. How much have your symptoms kept you from doing the kinds of things you would usually do over the last week?

☐ 0 None
☐ 1 Only a little
☐ 2 Some
☐ 3 A lot

8. How much did you think about your symptoms, over the last week?

☐ 0 None
☐ 1 Only a little
☐ 2 Some
☐ 3 A lot

Quality of life

9. If you were to spend the rest of your life with your symptoms, just the way they have been during the last week, how would you feel about that?

☐ 0 Delighted
☐ 1 Pleased
☐ 2 Mostly satisfied
☐ 3 Mixed (about equally satisfied and dissatisfied)
☐ 4 Mostly dissatisfied
☐ 5 Unhappy
☐ 6 Terrible

Scoring the NIH-CPSI Prostatitis Symptom Index Domain

Pain:
Total of items 1a,1b,1c,1d,2a,2b,3 and 4 = _____

16.7 Antibacterial agents

Groups	Agents
Trimethoprim-sulphonamide combinations	Trimethoprim, co-trimoxazole, co-tetroxoprime (trimethoprim plus sulfametrol)
Fluoroquinolones[1,2]	
Group 1	Norfloxacin, pefloxacin
Group 2	Enoxacin, fleroxacin, lomefloxacin, ofloxacin, ciprofloxacin
Group 3	Levofloxacin
Group 4	Gatifloxacin, moxifloxacin
Macrolides	Erythromycin, roxithromycin, clarithromycin, azithromycin
Tetracyclines	Doxycycline, minocycline, tetracycline
Fosfomycin	Fosfomycin sodium, fosfomycin trometamol3
Nitrofuran[4]	Nitrofurantoin
Penicillins	
Benzylpenicillin	Penicillin G
Phenoxypenicillins	Penicillin V, propicillin, azidocillin
Isoxazolylpenicillins	Oxacillin, cloxacillin, dicloxacillin, flucloxacillin
Aminobenzylpenicillins[5]	Ampicillin, amoxycillin, bacampicillin
Aminopenicillins/BLI[6]	Ampicillin/sulbactam, amoxycillin/clavulanic acid[7]

Acylaminopenicillins	Mezlocillin, piperacillin
±BLI[6]	Piperacillin/tazobactam, sulbactam[6]
Cephalosporins[1]	
Group 1 (oral)	Cefalexin, cefadroxil, cefaclor
Group 2 (oral)	Loracarbef, cefuroxime axetile
Group 3 (oral)	Cefpodoxime proxetile, cefetamet pivoxil, ceftibuten, cefixime
Group 1 (parenteral)	Cefazolin
Group 2 (parenteral)	Cefamandole, cefuroxime, cefotiam
Group 3a (parenteral)	Cefodizime, cefotaxime, ceftriaxone
Group 3b (parenteral)	Cefoperazone, ceftazidime
Group 4 (parenteral)	Cefepime, cefpirome
Group 5 (parenteral)	Cefoxitin
Monobactams	Aztreonam
Carbapenems	Imipenem, meropenem, ertapenem
Aminoglycosides	Gentamicin, netilmicin, tobramycin, amikacin
Glycopeptides	Vancomycin, teicoplanin
Oxazolidones	Linezolid

[1]Classification according to the Paul Ehrlich Society for Chemotherapy (1-3).
[2]Only in adults, except pregnant and lactating women.
[3]Only in acute, uncomplicated cystitis as a single dose.
[4]Contraindicated in renal failure and in newborns.
[5]In cases of resistance, the pathogen is most likely to be a β-lactamase producer.
[6]BLIs can only be used in combination with β-lactam antibiotics.
[7]In solution, storage instability.

16.7.1 ***Penicillins***

Penicillin G and the oral penicillins, penicillin V, propicillin and azidocillin, have a high intrinsic activity against streptococci and pneumococci. However, the resistance rate of pneumococci may vary considerably between countries. In Germany, penicillin resistance in pneumococci is still < 1%. Because of their narrow spectrum of activity, these penicillins do not have any role in the treatment of urogenital infections.

16.7.1.1 Aminopenicillins

Aminopenicillins, e.g. ampicillin and amoxycillin, have a broader spectrum of activity. Apart from streptococci and pneumococci, they cover enterococci, *Haemophilus influenzae*, *Haemophilus parainfluenzae, Listeria sp*., *E. coli*, *Pr. mirabilis*, and *Salmonella* and *Shigella* sp. However, resistance may occur.

Aminopenicillins are sensitive to β-lactamases. They are therefore not sufficiently active against certain species, such as staphylococci, *Moraxella catarrhalis*, *Bacteroides fragilis* and many enterobacteria. This gap in the spectrum of activity can be closed by the use of a BLI (clavulanic acid, or sulbactam). Amoxycillin/clavulanic acid and ampicillin/sulbactam are available on the market as fixed combinations. Indications for aminopenicillins and their combinations with a BLI are mild respiratory tract infections, UTIs, as well as infections of the skin and soft tissues.

16.7.1.2 Acylaminopenicillins

The acylaminopenicillins include apalcillin, azlocillin, mezlocillin and piperacillin. They are characterised by their high activity against enterococci, enterobacteria and *Pseudomonas* (weaker activity of mezlocillin). Acylaminopenicillins are hydrolyzed by β-lactamases and are therefore active only against β-lactamase-producing strains of staphylococci, *B. fragilis*, and if used in combination with a BLI, some of the enterobacteria. The acylaminopenicillin/BLI combination provides a broad spectrum of activity and may be used for a large number of indications, including complicated UTIs and urosepsis. A selection of free combinations with sulbactam is available, or there is the fixed combination of tazobactam and piperacillin, which has the advantages of being easy to use and a well-documented database drawn from qualified clinical studies.

16.7.1.3 Isoxazolylpenicillins

Isoxazolylpenicillins are available as parenteral drugs with oxacillin and flucloxacillin, and have a narrow

spectrum of activity. Their indications are limited to infections caused by *S. aureus*. Due to their suboptimal pharmacokinetic parameters, isoxazolylpenicillins are preferably used in milder infections of the skin and soft tissues, and of the ear, nose and throat area. They play no role in the treatment of UTIs, but may be used for staphylococcal abscesses in the genital area.

16.7.2 ***Parenteral cephalosporins***

According to the Paul Ehrlich Society for Chemotherapy (1), the parenteral cephalosporins have been classified into five groups, according to their spectrum of activity (Table 16.7.2).

16.7.2.1 Group 1 cephalosporins

Group 1 cephalosporins (cefazolin and cefazedone) are very active against streptococci and staphylococci (including penicillin-G-resistant strains). They have only weak activity against Gram-negative microorganisms. Like all cephalosporins, cefazolin is not active against enterococci and MRSA and methicillin-resistant coagulase-negative staphylococci (MRSE).

16.7.2.2 Group 2 cephalosporins

Compared with Group 1 cephalosporins, Group 2 cephalosporins, e.g. cefuroxime, cefotiame and cefamandole, exhibit markedly improved activity against Gram-negative pathogens and maintain high activity against staphylococci.

16.7.2.3 Group 3a cephalosporins

Group 3a cephalosporins have high activity against Gram-negative bacteria and less activity against staphylococci. They differ mainly in their pharmacokinetic characteristics.

16.7.2.4 Group 3b cephalosporins

Group 3b cephalosporins, e.g. ceftazidime and cefoperazone, have added high anti-pseudomonal activity. However, the activity of cefoperazone against P. aeruginosa is markedly inferior to that of the other substances in this group.

16.7.2.5 Group 4 cephalosporins

Group 4 cephalosporins, e.g. cefepime and cefpirome, have a comparable activity against Gram-negative bacteria, but are more stable against extended-spectrum β-lactamases, and a better activity against Gram-positive bacteria.

16.7.2.6 Group 5 cephalosporins

The Group 5 cephalosporins are characterised by their anti-anaerobic activity. These cephalosporins have superior activity against Gram-negative bacteria compared with Group 1 and 2 cephalosporins, but most of them are weaker than Group 3 drugs. At present, cefoxitin is the only drug of that group available on the market in some countries.

Table 16.7.2: Classification of parenteral cephalosporins (2)

Group	Generic names	Features of the group
Group 1 (1st generation)	Cefazolin Cefazedone	• Active against Gram-positive and partly against Gram-negative bacteria • Stable against staphylococcal penicillinases • Unstable against β-lactamases of Gram-negative bacteria
Group 2 (2nd generation)	Cefuroxime Cefotiame Cefamandole	• Activity against Gram-positive bacteria good, but weaker than Group 1 • Activity against Gram-negative bacteria superior to that of Group 1 • Stable against staphylococcal penicillinases • Limited stability against β-lactamases of Gram-negative bacteria
Group 3a (3rd generation)	Cefotaxime Ceftriaxone Ceftizoxime Cefmenoxime Cefodizime	• Activity against Gram-negative bacteria clearly superior to that of Groups 1 and 2 • Stable against numerous β-lactamases of Gram-negative bacteria • Microbiologically less active against staphylococci
Group 3b (3rd generation)	Ceftazidime	• Spectrum of antibacterial activity similar to that of Group 3a
	Cefoperazone	• Additional activity against P. aeruginosa
Group 4	Cefepime Cefpirome	• Spectrum of antibacterial activity similar to that of Group 3a
Group 5	Cefoxitin	• Additional activity against P. aeruginosa • Higher stability against beta-lactamases than group 3b • With anti-anaerobic activity • Superior activity against Gram-negative bacteria than Group 1 and 2 • Weaker than Group 3

16.7.3 ***Oral cephalosporins***

Oral cephalosporins are classified into three groups, based on their spectrum of activity, according to the recommendations of the Paul Ehrlich Society for Chemotherapy (1) (Table 16.7.3).

Table 16.7.3: Classification of oral cephalosporins (1)

Oral cephalosporins	Drug names
Group 1	Cefalexin Cefadroxil Cefaclor
Group 2	Cefprozil Loracarbef Cefuroxime axetile
Group 3	Cefpodoxime proxetile Cefetamet pivoxile Ceftibuten Cefixime

16.7.3.1 Group 1 oral cephalosporins

Group 1 oral cephalosporins include cefalexin, cefadroxil and cefaclor. They are mainly active against Gram-positive cocci with limited activity against *H. influenzae* (cefaclor). Their main indications are skin and soft tissue infections and, with limitations, respiratory tract infections. Their activity against enterobacteria is limited, therefore, they can only be recommended for the treatment or prophylaxis of uncomplicated UTIs in children or

pregnant women, for whom the use of other antibiotics is limited.

16.7.3.2 Group 2 oral cephalosporins

The activity of cefprozil against *S. aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *H. influenzae* and *Mor. catarrhalis* is somewhat higher than that of cefaclor. However, cefprozil is less active than cefaclor against *E. coli*, *Klebsiella pneumoniae* and *Pr. mirabilis*.

Loracarbef is structurally close to cefaclor. In contrast to cefaclor, it is stable in solution, has better pharmacokinetics and a broader antibacterial spectrum. However, its activity against staphylococci is lower than that of cefaclor. The main indications are respiratory tract, skin and soft-tissue infections and uncomplicated UTIs.

Cefuroxime axetile has a higher β-lactamase stability and thus a broader spectrum than others in this group. It can be used mainly for bacterial infections of the upper (including otitis media) and lower respiratory tract, for skin and soft-tissue infections, and UTIs.

16.7.3.3 Group 3 oral cephalosporins

Group 3 oral cephalosporins have a higher activity and a broader spectrum against enterobacteria than group 2 cephalosporins. In contrast, their activity against Gram-positive bacteria is lower. Against staphylococci, the activity of cefpodoxime proxetil is intermediate, whereas cefetamet pivoxil, ceftibuten and cefixime are inactive.

The main indications for the oral cephalosporins of group 3 are complicated infections of the respiratory tract (provided that staphylococci can be excluded) and infections due to enterobacteria, e.g. UTIs or infections in immunocompromised patients. Group 3 oral cephalosporins are also suitable for oral switch therapy, i.e. when initial parenteral therapy (using a parenteral group 3a cephalosporin) needs to be continued orally. In addition, cefixime is licensed also for treatment of gonorrhoea.

*16.7.4 **Monobactams***

Among the monobactams, only aztreonam is available. It is active only against Gram-negative aerobes. In this respect, its spectrum and activity are similar to those of the parenteral group 3b cephalosporins.

*16.7.5 **Carbapenems***

Carbapenems are broad-spectrum antibiotics with good activity against Gram-positive and Gram-negative bacteria, including anaerobes. They are preferably used in the treatment of mixed infections and in the initial therapy of life-threatening diseases, including urosepsis. Imipenem/cilastatin, meropenem and doripenem are also active against P. aeruginosa. However, ertapenem is not active against P. aeruginosa. Ertapenem has a longer half-life than imipenem/cilastatin and meropenem, and is therefore, suitable for once-daily dosing.

*16.7.6 **Fluoroquinolones***

Non-fluorinated quinolones are no longer recommended because of their poor antibacterial activity. According to the Paul Ehrlich Society for Chemotherapy, the fluoroquinolones are classified into four groups, based on their spectrum of activity, their pharmacokinetics and indications (Table 16.7.4).

Table 16.7.4: Classification of fluoroquinolones, as modified according to the Paul Ehrlich Society for Chemotherapy (3)

Generic name	**Trade name* / features of the group**
Group 1	**Indications essentially limited to UTIs in some countries, e.g. Germany**
	Norfloxacin
	Pefloxacin**
Group 2	**Broad indications for systemic use**
	Enoxacin
	Fleroxacin***
	Lomefloxacin
	Ofloxacin
	Ciprofloxacin

Group 3	Improved activity against Gram-positive and atypical pathogens
	Levofloxacin
Group 4	Improved activity against Gram-positive and atypical pathogens and anaerobes
	Gatifloxacin
	Moxifloxacin

** Listed according to increasing in vitro activity (minimum inhibitory concentration) against indicative pathogens.*
*** In France and other countries, pefloxacin is also available for systemic use.*
**** Investigated in acute exacerbations of chronic bronchitis, UTIs, gonorrhoea and gastrointestinal infections.*

16.7.6.1 Group 1 fluoroquinolones
The indications for group 1 fluoroquinolones are limited to UTIs in some countries, e.g. Germany. In France and some other countries, pefloxacin is also used for systemic oral and parenteral use. Norfloxacin is not available as parenteral antibiotic.

16.7.6.2 Group 2 fluoroquinolones
Group 2 fluoroquinolones includes fluoroquinolones for systemic use with a broad spectrum of indications. These include infections of the urinary tract, respiratory tract, skin and soft tissues, bones and joints, as well as systemic infections and even sepsis. Group 2 fluoroquinolones exhibit good activity against enterobacteria and *H. influenzae*, with less activity against staphylococci, pneumococci, enterococci and atypical pathogens, e.g. *Chlamydia, Legionella* and *Mycoplasma* sp. Their activity against *P. aeruginosa* varies, with ciprofloxacin being most active in vitro. In addition, ciprofloxacin, ofloxacin and fleroxacin are also available for parenteral use.

16.7.6.3 Group 3 fluoroquinolones
The main difference in the spectra of activity of group 3 fluoroquinolones (levofloxacin) and group 4 fluoroquinolones (gatifloxacin and moxifloxacin) is that the former have a higher intrinsic activity against Gram-positive pathogens, such as staphylococci, streptococci, pneumococci and enterococci.

However, group 3 and group 4 fluoroquinolones have comparable activity against Gram-negative pathogens. In addition, they have improved activity against the so-called atypical pathogens, such as *Chlamydia, Mycoplasma* and *Legionella* sp. In addition, group 4 fluoroquinolones have improved anti-anaerobic activity.

The only group 3 fluoroquinolone available for parenteral use is levofloxacin; the left enantiomer of the ofloxacin racemate. The main indications for levofloxacin are respiratory tract infections, and, due to its high renal elimination rate, UTIs, as well as skin and soft-tissue infections.

Among group 4 fluoroquinolones, gatifloxacin (not on the market in Europe), moxifloxacin and trovafloxacin have been licensed. However, in June 1999, trovafloxacin was taken off the market because of severe side effects. Thus, to date, no parenteral fluoroquinolone of this group has been made available.

Apart from respiratory tract infections, these broad-spectrum fluoroquinolones are appropriate for treatment of skin, soft-tissue and intra-abdominal infections, and oral treatment of gynaecological infections. However, final judgement of their position in the treatment of these diseases is not yet possible. Gatifloxacin has the highest renal excretion (about 84%) after oral administration. It is therefore also the most suitable for the treatment of uncomplicated and complicated UTI. Urinary excretion of moxifloxacin after oral administration is only in the range of about 20%.

16.7.7 ***Co-trimoxazole***
The treatment of UTIs is the main indication for trimethoprim alone or in combination with a sulphonamide, e.g. sulphamethoxazole. Trimethoprim with or without sulphamethoxazole can also be used for the prophylaxis of recurrent cystitis. The resistance rate against *E. coli* can vary between countries. It is therefore not recommended for empirical therapy of acute uncomplicated cystitis or pyelonephritis, when the resistance rate in the area is > 10-20% (4). In complicated UTIs, co-trimoxazole should only be used in accordance with sensitivity testing. Trimethoprim, especially in combination with sulphamethoxazole, can lead to severe although rare adverse events, such as Lyell syndrome, Stevens-Johnson syndrome and pancytopenia.

16.7.8 ***Fosfomycin***
Fosfomycin is active against Gram-negative and Gram-positive bacteria. The sodium salt is only for parenteral use. Fosfomycin trometamol is licensed for single-dose (3 g) treatment of uncomplicated cystitis in women.

16.7.9 ***Nitrofurantoin***

The antibacterial activity of nitrofurantoin is limited to the urinary tract because of its low serum concentrations. It is active against *E. coli*, *Citrobacter* and most strains of *Klebsiella* and *Enterobacter*, whereas *Providencia* and *Serratia* are mostly resistant. *Proteus, P. aeruginosa* and *Acinetobacter* are almost always resistant. It is active against Gram-positive cocci, e.g. enterococci and staphylococci.

It is suitable only for the treatment or prophylaxis of uncomplicated UTIs. Short-term therapy for this indication has not been proven in sufficiently large studies. Little development of resistance has been observed over many years. Treatment can lead to severe, though rare adverse events, such as chronic desquamative interstitial pneumonia with fibrosis.

16.7.10 ***Macrolides***

Erythromycin is the only macrolide that is available for both oral and parenteral use. The newer macrolides, roxithromycin, clarithromycin and azithromycin, are better tolerated than erythromycin, but can only be administered orally. The macrolides have good activity against streptococci, pneumococci, *Bordetella pertussis*, and *Chlamydia, Mycoplasma* and *Legionella* sp. The macrolides are not active against Gram-negative rods, therefore, their use in the treatment of UTIs is limited to special indications, such as non-gonococcal urethritis due to *C. trachomatis*.

16.7.11 ***Tetracyclines***

The resistance against doxycycline and tetracycline of pneumococci, streptococci, *H. influenzae* and *E. coli* shows marked regional differences. Tetracyclines are therefore only suitable for initial empirical therapy if the local resistance situation is sufficiently well known and justifies their use. As a result of their high activity against the so-called atypical pathogens (*Legionella, Chlamydia* and *Mycoplasma* sp.), they may be used as alternative antibiotics in infections caused by these microorganisms, e.g. in non-gonococcal urethritis due to *C. trachomatis*.

16.7.12 ***Aminoglycosides***

Aminoglycosides are for parenteral use only. These drugs have a narrow therapeutic window. Their effective levels of activity are close to toxic borderline concentrations, making a strict therapeutic indication mandatory. With few exceptions (e.g. treatment of UTIs), aminoglycosides should only be used in combination with another appropriate antibiotic. Ideal partners are β-lactam antibiotics, because this combination has a marked synergistic effect against certain bacterial species. Streptomycin is one of the older aminoglycosides and is used only for the treatment of tuberculosis.

Newer aminoglycosides include netilmicin, gentamicin, tobramycin and amikacin. They have good activity against enterobacteria and *Pseudomonas* (especially tobramycin). Their activity against streptococci, anaerobes and *H. influenzae* is not satisfactory. Resistance data for tobramycin, gentamicin and netilmicin are almost identical, whereas the resistance situation is more favourable for amikacin against many enterobacteria.

16.7.13 ***Glycopeptides***

The glycopeptides vancomycin and teicoplanin are active against Gram-positive pathogens, i.e. staphylococci (including oxacillin-resistant strains), streptococci, enterococci, *Clostridium difficile*, diphtheria bacteria and Gram-positive aerobes. They are inactive against Gram-negative pathogens. Their use is indicated:

- In infections caused by the above-mentioned pathogens in case of allergy against all other suitable antibiotics.
- In infections caused by ampicillin-resistant enterococci or oxacillin-resistant staphylococci, or multi-resistant corynebacteria.
- As an alternative, in oral form, to metronidazole for the treatment of pseudomembranous colitis. Due to the risk of selection of glycopeptide-resistant enterococci and staphylococci, the use of glycopeptides should be highly restricted. Similar to the aminoglycosides, glycopeptides have a narrow therapeutic window.

16.7.14 ***Oxazolidinones***

The only substance of this group is linezolid, which can be administered parenterally and orally. It has good activity against Gram-positive cocci, such as staphylococci, including methicillin (oxacillin)-resistant strains, enterococci, including vancomycin-resistant strains, and streptococci.

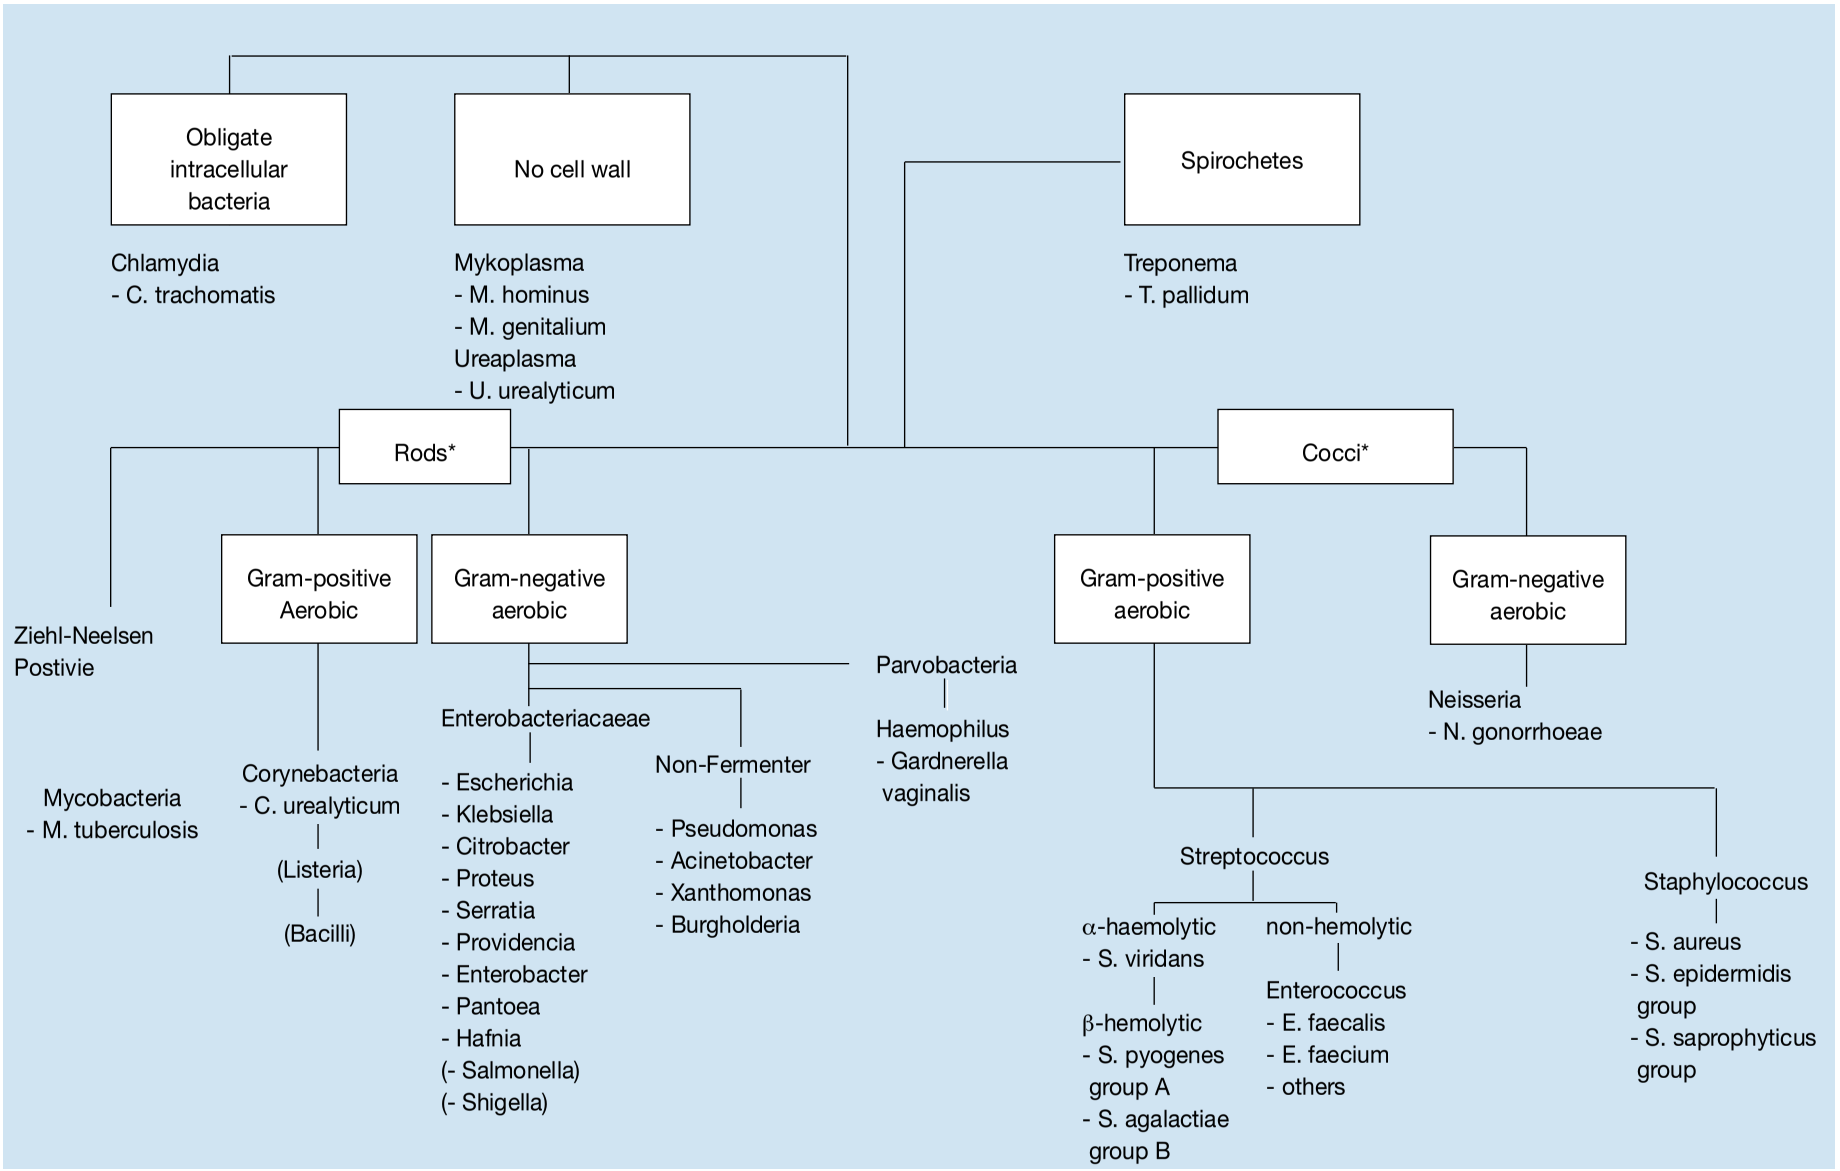
16.8 Relevant bacteria for urological infections



**Anaerobic bacteria not considered.*

17. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations.

ABU	asymptomatic bacteriuria
ACE	angiotensin-converting enzyme
ADPKD	adult dominant polycystic disease
APCKD	adult polycystic kidney disease
BLI	β-lactamase inhibitor
BPH	benign prostatic hyperplasia
CPPS	chronic pelvic pain syndrome
CPSI	Chronic Prostatitis Symptom Index
CT	computed tomography
CAUTIs	catheter-associated urinary tract infections
DMSA	dimercaptosuccinic acid
DTPA	diethylenetriamine pentaacetate
EPS	expressed prostatic secretion
EUCAST	European Committee for Antimicrobial Susceptibility Testing
G6PD	glucose-6-phosphate dehydrogenase
GFR	glomerular filtration rate
IDSA	Infectious Diseases Society of America
IL	interleukin
IPCN	International Prostatitis Collaborative Network
IVU	intravenous urography
LUTS	lower urinary tract symptom
MAG-3	mercaptoacethylglycine
MRI	magnetic resonance imaging
MRSA	methicillin-resistant Staphylococcus aureus
MSU	mid-stream sample of urine
NCCLS	National Committee for Clinical Laboratory Standards
NIDDK	National Institute of Diabetes and Digestive and Kidney Diseases
NIH	National Institutes of Health
PCP	Pneumocystis carinii pneumonia
PSA	prostate-specific antigen
SIRS	systemic inflammatory response syndrome
SMX	sulphamethoxazole
SSI	surgical site infection
STD	sexually transmitted disease
SWL	shockwave lithotripsy
TMP	trimethoprim
TNF	tumour necrosis factor
TRUS	transrectual ultrasound
TURP	transurethral resection of the prostate
US	ultrasonography
UTI	urinary tract infection
VB1	first-voided urine
VB2	mid-stream urine
VB3	voided bladder urine-3
VCU	voiding cysto-urethography
VUR	vesicoureteric reflux
WBC	white blood cells

Conflict of interest

All members of the Urological Infections guidelines working group have provided disclosure statements of all relationships which they have and which may be perceived as a potential source of conflict of interest. This information is kept on file in the EAU Central Office database. This guidelines document was developed with the financial support of the EAU. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on Urinary Incontinence

European Association of Urology

TABLE OF CONTENTS PAGE

1. INTRODUCTION

Urinary incontinence (UI) is an extremely common complaint in every part of the world. It causes a great deal of distress and embarrassment, as well as significant costs, to both individuals and societies. Estimates of prevalence vary according to the definition of incontinence being used and the populations being studied. However, there is universal agreement about the importance of the problem, both in terms of human suffering and economic costs.

These new Guidelines from the European Association of Urology (EAU) Working Panel on Urinary Incontinence are written by urologists for urologists, and aim to provide sensible and practical guidance on the clinical problems of UI rather than an exhaustive narrative review. Such a review is already available elsewhere, as provided by the International Consultation on Incontinence (1), and so these Guidelines do not mention topics such as the causation, basic science, epidemiology and psychology of UI. The focus of these Guidelines is entirely on assessment and treatment reflecting clinical practice. The Guidelines also do not consider patients with UI caused by neurological disease, as this is covered by complementary EAU Guidelines (2).

The EAU Panel knew that they would find only a little evidence for some issues and a lot of evidence for others. This difference largely reflects the much greater research funding needed to produce the high-quality evidence required for regulatory submissions by the regulated (pharmaceutical) industries and their marketing strategies. The situation regarding published evidence for surgical devices is different, with much more surgical experimentation. However, despite the higher potential for harm, there are far fewer high-quality studies from which to derive clear evidence. There is a high potential for bias in this situation, and so the Panel has deliberately adjusted its expectation for quality evidence, depending on the domain of management being considered, and tried to reflect this in the text.

1.1 Methodology

The Panel decided to rewrite the existing EAU Guidelines on UI using a new methodological approach and to present them in a format that most closely reflected the approach to management of UI. The current Guidelines provide:

- A clear clinical pathway (algorithm) for common clinical problems. This can provide the basis for thinking through a patient's management and also for planning and designing clinical services.
- A brief but reliable summary of the current state of evidence on clinical topics, complete with references to the original text.
- Clear guidance on what to do or not to do, in most clinical circumstances. This should be particularly helpful in those areas of practice for which there is little or no published evidence.

*1.1.1 **PICO questions***

The 'PICO' (Population, Intervention, Comparison, Outcome) framework was used to develop a series of clinical questions that would provide the basis of presentation of the guidelines (3,4). There are four elements to each clinical question:

- population;
- intervention;
- comparison;
- outcome.

The wording is important because it directs the subsequent literature research. For each element, the Panel listed every possible wording variation.

In these Guidelines, four traditional domains of urological practice are presented as separate chapters, namely assessment and diagnosis, conservative management, drug therapy and surgical treatments.

In this first edition of these new EAU Guidelines for Urinary Incontinence, the Panel has focused largely on the management of a 'standard' patient. The Panel has referred in places to patients with 'complicated incontinence', by which we mean patients with associated morbidity, a history of previous pelvic surgery, surgery for UI, radiotherapy and women with associated genitourinary prolapse. This first edition does not review the prevention of UI, the management of fistula, or the special problems of the frail elderly, but these issues will be fully addressed in future editions.

*1.1.2 **Search strategies***

A number of significant narrative reviews and major guidelines and systematic reviews have been produced within the last few years. It was agreed from the start that the literature searches carried out by these reviews

would be accepted as valid. Thus, for each PICO question, a search was carried out with a start date that was the same as the cut-off date for the search associated with the most recent systematic review for the PICO topic. This pragmatic selection approach, while being a compromise and open to criticism, made the task of searching the literature for such a large subject area possible within the available resources. For each section, the latest cut-off date for the relevant search is indicated.

Thus, for each PICO, a subsequent literature search was carried out (confined to Medline and Embase and to English language articles), which produced an initial list of abstracts (*see* Number of 'hits', Table 1). The abstracts were each assessed by two Panel members, who selected the studies relevant to the PICO question, and the full text for these was retrieved.

Table 1: Initial list of abstracts

Chapter	Latest 'cut-off' date for search	Number of 'hits'
Assessment and diagnosis	June 2010	1055
Conservative therapy	July 2010	1026
Drug therapy	February 2011	1162
Surgical therapy	May 2011	2191

Each PICO was then assigned to a Panel member, who read the paper and extracted the evidence for incorporation into standardised evidence tables, which are maintained online as an evidence resource for the Panel. This resource will continue to be available and will be continuously updated with each repeated review of the literature.

The existing evidence from previous systematic reviews and new evidence were then discussed, for each PICO in turn, at a Panel meeting before the Panel came to its conclusions. To help standardise the approach, modified process forms (data extraction and considered judgment) from the Scottish Intercollegiate Guidelines Network (SIGN) were used.

The quality of evidence for each PICO is commented on in the text, which then leads into the development of an evidence summary. This aims to synthesise the important clinical messages from the available literature and is presented as a series of 'evidence summaries', which follow the standard for levels of evidence used by the EAU (Table 2).

From the evidence summaries, the Panel then produced a series of action-based recommendations graded according to EAU standards (Table 3). These grades aim to make it clear what the clinician should or should not do in clinical practice, not merely to comment on what they might do.

The Panel has tried to avoid extensive narrative text. Instead, algorithms are presented for both initial and specialised management of men and women with non-neurogenic UI. Each decision node of these algorithms is clearly linked back to the relevant evidence and recommendations.

It must be emphasised that clinical guidelines present the best evidence available to the expert Panel at the time of writing. There remains a need for ongoing re-evaluation of the current guidelines by the Panel. However, following guidelines recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients; they aim to focus decisions. Clinical decisions must also take into account the patient's personal values, preferences and specific circumstances.

1.1.3 Level of evidence and grade of recommendation

References used in the text have been assessed according to their level of scientific evidence (Table 2), which is a modification of the system used by the Oxford Centre for Evidence Based Medicine (CEBM). A similar modification has been used for Guidelines recommendations. The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given. Diagnostic studies were assessed according to a similar modification of the CEBM evidence levels for diagnostic accuracy and prognosis.

Table 2: Level of evidence (LE)*

Type of evidence	LE
Evidence obtained from meta-analysis of randomised trials.	1a
Evidence obtained from at least one randomised trial.	1b
Evidence obtained from one well-designed controlled study without randomisation.	2a
Evidence obtained from at least one other type of well-designed quasi-experimental study.	2b
Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports.	3
Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities.	4

**Modified from Sackett et al. (5).*

It should be noted that when recommendations are graded, there is not an automatic relationship between the level of evidence and grade of recommendation. The availability of randomised controlled trials (RCTs) may not necessarily translate into a Grade A recommendation if there are methodological limitations or a disparity in published results.

Alternatively, an absence of high-level evidence does not necessarily preclude a Grade A recommendation; if there is overwhelming clinical experience and consensus to support a high level recommendation, this can be made. In addition, there may be exceptional situations in which corroborating studies cannot be performed, perhaps for ethical or other reasons. In this case, unequivocal recommendations are considered helpful for the reader. Whenever this occurs, it has been clearly indicated in the text with an asterisk, as 'upgraded based on Panel consensus'. The quality of the underlying scientific evidence is a very important factor, but it has to be balanced against benefits and burdens, values and preferences and economic cost when a grade is assigned (6-8).

The EAU Guidelines Office does not perform cost assessments nor can they address local/national preferences in a systematic fashion.

Table 3: Grade of recommendation (GR)*

Nature of recommendations	GR
Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial.	A
Based on well-conducted clinical studies, but without randomised clinical trials.	B
Made despite the absence of directly applicable clinical studies of good quality.	C

**Modified from Sackett et al. (5).*

1.2 Publication history

The complete update in 2009 was largely a synthesis of ICUD and NICE and so was the 2010 edition. In 2011 an addendum was added on the use of drugs, now incorporated in the full text under Chapter 4. This 2012 edition is also partly based on ICUD and NICE but new searches were conducted from June 2008 to present. An addendum to the guidelines is provided on mixed urinary incontinence (see Appendix).

1.4 Use in different healthcare settings and by healthcare professionals

The Guidelines have been written for urologists and for use in any healthcare setting in Europe. However, the Panel recognises that many different health professionals besides urologists use the Guidelines. The Panel also recognises that a patient's first point of contact may not always be a urologist, and that the healthcare professional delivering treatment, e.g. physiotherapy, may also not be a urologist. For this reason, some healthcare professionals may find that the Guidelines do not explain a particular topic in enough detail for their needs, e.g. delivery modalities for pelvic floor muscle training.

1.5 Terminology

Evidence summaries provide a succinct summary of what the currently available evidence tells us about an individual clinical question. They are presented according to the levels of evidence used by the EAU.

Recommendations have been deliberately written as 'action-based' sentences. The following words or phrases are used consistently throughout the Guidelines, as follows:

- **Consider** an action. This word is used when there is not enough evidence to say whether the action causes benefit or risk to the patient. However, in the opinion of the Panel, the action may be justified in some circumstances. Action is optional.
- **Offer** an action. This word is used when there is good evidence to suggest that the action is effective, or that, in the opinion of the Panel, it is the best action. Action is advisable.
- **Carry out (perform)** an action**. Do** something. This phrase is used when there is strong evidence that this is the only best action in a certain clinical situation. Action is mandatory.
- **Avoid** an action. This phrase is used when there is high-level evidence that the action is either ineffective or is harmful to the patient. Action is contraindicated.

2. ASSESSMENT AND DIAGNOSIS

2.1 History and physical examination

Taking a careful clinical history is fundamental to the clinical process. Despite the lack of formal evidence, there is universal agreement that taking a history should be the first step in the assessment of anyone with UI. The history should include details of the type, timing and severity of incontinence, associated voiding, and other urinary symptoms. The history should allow the UI to be categorised into stress, urgency or mixed. It should also identify patients who need rapid referral to a specialist. These include patients with associated pain, haematuria, a history of recurrent urinary tract infections (UTIs), pelvic surgery (particularly prostate surgery) or radiotherapy, constant leakage suggesting a fistula, voiding difficulty or suspected neurological disease. An obstetric and gynaecological history may help to understand the underlying cause and identify factors that may impact on treatment decisions. The patient should also be asked about comorbid conditions, as these may impact on symptoms of UI, or cause it, and details of current medications.

There is little evidence for the necessity to carry out a clinical examination. However, there is wide agreement that clinical examination is essential. In a patient with UI, this should include abdominal examination, to detect an enlarged bladder or other abdominal mass, and perineal and digital examination of the rectum

and/or vagina. Examining the perineum includes an assessment of oestrogen status in women and a careful assessment of any associated genitourinary prolapse. A cough test will often reveal stress incontinence, but only if the bladder contains urine during the examination. Pelvic floor contraction is assessed by means of digital vaginal examination. In men, it is essential to perform a digital examination of the rectum and prostatic assessment.

2.2 Patient questionnaires

Questionnaires may be symptom scores, symptom questionnaires, patient-reported outcome measures (PROMS) or health-related quality of life (HRQoL) measures. Questionnaires are widely used to record patients' symptoms, including their severity and impact on the patient, and have been used to monitor the symptom scores of individual patients or groups of patients over time, e.g. in the context of changes related to treatment. During the last 10 years, many questionnaires have been developed and studied, including ones specifically designed for lower urinary tract symptoms (LUTS), pelvic organ prolapse, faecal incontinence and both condition-specific quality of life (QoL) and generic QoL. The methodology for their development was reviewed in the 4th International Consultation on Incontinence (ICI) in 2008 (1).

*2.2.1 **Questions***

- In adults with UI, does assessment using either urinary symptom or QoL questionnaires improve the treatment outcome for UI?
- In adults with UI, does assessment of the patient perspective (concerns or expectations) improve patient outcomes, regarding either urinary symptoms or QoL, compared to no patient-reported assessment?

*2.2.2 **Evidence***

Although many studies have investigated the validity and reliability of questionnaires and PROMs, most have taken place in adults without UI. This greatly limits the extent to which results and conclusions from these studies can be applied in adults with UI.

Evidence summary	**LE**
There is no evidence that the use of either questionnaires or PROMs in the assessment of adults with UI has an influence on outcome.	4

*2.2.3 **Research priorities***

There is a lack of knowledge about whether using questionnaires to assess urinary symptoms or QoL helps to improve outcomes in adults with UI. Further research is needed to compare the use of questionnaires to assess urinary symptoms and/or QoL in addition to standard clinical assessment versus clinical measures alone. Patients should be closely involved in the design of such studies.

Incontinence. 4th International Consultation on Incontinence, Paris July 5-8, 2008. Plymouth: Health Publication Ltd, 2009. http://www.icud.info/incontinence.html

2.3 Voiding dairies

Measurement of the frequency and severity of LUTS is an important step in the evaluation and management of lower urinary tract dysfunction, including UI. Voiding diaries are a semi-objective method of quantifying symptoms, such as daytime and night-time frequency, urgency, urgency urinary incontinence (UUI) and stress urinary incontinence (SUI) episodes. They also quantify urodynamic variables, such as voided volume and 24-hour or nocturnal total urine volume. Voiding diaries are also known as micturition time charts, frequency/volume charts and bladder diaries.

Any discrepancy between diary recordings and the patient rating of symptoms, e.g. frequency or UI, can be useful in patient management. In addition, voided volume measurement can be used to support diagnoses, such as overactive bladder (OAB) or polyuria. Diaries can also be used to monitor treatment response and are widely used in clinical trials as a semi-objective measure of treatment outcome.

*2.3.1 **Questions***

- In adults with UI, what is the reliability, the diagnostic accuracy and predictive value of a voiding diary,

compared to patient history or symptom score?
- How does the accuracy of a computerised voiding diary compare to a paper diary?

2.3.2 ***Evidence***

Two recent articles have suggested a consensus has been reached in the terminology used in voiding diaries (1,2):

- Micturition time charts record only the times of micturitions for a minimum of 24 continuous hours.
- Frequency volume charts record voided volumes and times of micturitions for a minimum of 24 hours.
- Bladder diaries include information on incontinence episodes, pad usage, fluid intake, degree of urgency and degree of incontinence.

Several studies have compared patients' preference for, and the accuracy of, electronic and paper voiding diaries in voiding dysfunction (3-7). Several studies have compared shorter (3 or 5 days) and longer diary durations (7 days) (8-14). The choice of diary duration appears to be based upon the possible behavioural therapeutic effect of keeping a diary rather than on validity or reliability.

Two studies have investigated the reproducibility of voiding diaries in both men and women (8,9). Further studies investigated the variability of diary data within a 24-hour period (15) and compared voided volumes recorded in diaries with those recorded on uroflowmetry (16). Other studies have investigated the correlation between data obtained from voided diaries and standard symptom evaluation (17-20).

One study investigated the effect of diary duration on the observed outcome of treatment of LUTS (21). Another study found that keeping a voiding diary had a therapeutic benefit (22).

In conclusion, voiding diaries give reliable data on lower urinary tract function. There remains a lack of consensus about how long a diary should be kept and how well diary data correlate with some symptoms.

Evidence summary	**LE**
Voiding diaries of 3-7 days duration are a reliable tool for quantifying mean voided volume, daytime and night-time frequency.	2b
Voiding diaries are sensitive to change and are a reliable measure of outcome.	2b

Recommendations	**GR**
Voiding diaries should be used in urinary incontinence to evaluate co-existing storage and voiding dysfunction in clinical practice and in research.	A
A diary duration of between 3 and 7 days is recommended.	B

2.4 Urinalysis and urinary tract infection

Urinary incontinence is known to occur more commonly in women with UTIs and is also more likely in the first few days following an acute infection (1). In contrast with symptomatic UTI, asymptomatic bacteriuria appears to have little influence on UI. A study carried out in nursing home residents showed that the severity of UI was unchanged after eradication of bacteriuria (2).

Reagent strip ('dipstick') urinalysis may detect infection, proteinuria, haematuria and glycosuria:

- Nitrite and leucocyte esterase may indicate a UTI.
- Protein may indicate infection and/or renal disease.
- Blood may indicate malignancy (or infection).
- Glucose may indicate diabetes mellitus.

It is generally agreed that dipstick urinalysis provides sufficient screening information in both men and women with UI. Microscopy and other tests may be necessary to confirm any abnormalities identified on dipstick analysis. Urinalysis is usually carried out on a mid-stream urine specimen, but analysis of initial voided and terminal urine samples may be required for assessment of urethral and prostate infections.

*2.4.1 **Questions***

- In adults with UI, what is the diagnostic accuracy of urinalysis for UTIs?
- What is the benefit on UI of treating UTIs?

*2.4.2 **Evidence***

In both men and women with UI, diagnosis of a UTI by positive leucocytes or nitrites using urine culture as the reference standard had a low sensitivity and very high specificity (3,4). A negative urine dipstick test in patients with UI therefore excludes a UTI with a high degree of certainty.

There is a consensus that urinalysis should be a standard part of the basic evaluation of UI irrespective of gender, age or aetiology.

Evidence summary	**LE**
There is no evidence that a UTI causes UI.	4
There is no evidence that treating a UTI cures UI.	4
The presence of a symptomatic UTI worsens symptoms of UI.	3
Elderly nursing home patients with established UI do not benefit from treatment of asymptomatic bacteriuria.	2

Recommendations	**GR**
Do urinalysis as a part of the initial assessment of a patient with urinary incontinence.	A
In a patient with urinary incontinence, treat a symptomatic urinary tract infection appropriately *(see 'EAU Guidelines on Urological Infections' [5]).*	A
Do not treat asymptomatic bacteriuria in elderly patients to improve urinary incontinence.	B

2.5 Post-voiding residual volume

Post-voiding residual (PVR) volume (also known as residual urine, bladder residual) is the amount of urine that remains in the bladder after voiding. It indicates poor voiding efficiency, which may result from a number of contributing factors. It is important because it may worsen symptoms and, more rarely, may be associated with upper urinary tract dilatation and renal insufficiency. Both bladder outlet obstruction and detrusor underactivity contribute to the development of PVR.

Post-voiding residual can be measured by catheterisation or ultrasound (US). The prevalence of PVR is uncertain, partly because of the lack of a standard definition of an abnormal PVR volume.

*2.5.1 **Question***

In adults with UI, what are the diagnostic accuracy and predictive value of measurements of PVR?

*2.5.2 **Evidence***

Most studies investigating PVR have not included patients with UI. Although some studies have included women with UI and men and women with LUTS, they have also included children and adults with neurogenic UI. In general, the data on PVR can be applied with caution to adults with non-neurogenic UI. The results of studies investigating the best method of measuring PVR (1-6) have led to the consensus that US measurement of PVR is better than measurement using catheterisation.

Several studies have evaluated PVR in different subjects and patients cohorts (7-17). In peri- and post-menopausal women without significant LUTS or pelvic organ symptoms, 95% of women had a PVR < 100 mL (7). A comparison of women with and without LUTS suggested that symptomatic women had a higher incidence of elevated PVR (9). In women with UUI, a PVR > 100 mL was found in 10% of cases (8). Other research has found that a high PVR is associated with pelvic organ prolapse (> stage II), voiding symptoms and an absence of SUI (10,11,13,15). In women with SUI, the mean PVR was 38.5 mL measured by catheterisation and 62.8 mL measured by US, with 15.9% of women having a PVR > 100 mL (8). Overall, women with symptoms of lower urinary tract or pelvic floor dysfunction and pelvic organ prolapse have a higher risk of elevated PVR compared to asymptomatic subjects.

There is evidence to suggest that elevated PVR should be particularly looked for in patients with voiding symptoms (18-21). There is no evidence to define a threshold between normal and abnormal PVR values. Expert opinion has therefore been used to produce a definition of elevated PVR values (22-25).

There is a lack of evidence to support the routine measurement of PVR in patients with UI (26-30).

Evidence summary	**LE**
Ultrasonography provides an accurate estimate of post-voiding residual.	1b
Lower urinary tract dysfunction is associated with a higher risk of post-voiding residual compared to controls.	2
Elevated post-voiding residual is not a risk factor for poor outcome in the management of SUI.	2

Recommendations	**GR**
Post-voiding residual should be measured by ultrasound.	A
Measure post-voiding residual in patients with urinary incontinence who have voiding dysfunction.	B
Measure post-voiding residual when assessing patients with complicated urinary incontinence.	C
Post-voiding residual should be monitored in patients receiving treatments that may cause or worsen voiding dysfunction.	B

*2.5.3 **Research priority***

Further research is required to evaluate whether combining non-invasive tests provides greater diagnostic accuracy and prognostic value than tests viewed in isolation.

2.6 Urodynamics

In clinical practice, 'urodynamics' is generally used as a collective term for all tests of bladder and urethral function. These Guidelines will review both non-invasive estimation of urine flow, i.e. uroflowmetry, and invasive tests, including multichannel cystometry, ambulatory monitoring and videourodynamics, and different tests of urethral function, such as urethral pressure profilometry, Valsalva leak point pressure estimation, and retrograde urethral resistance measurement.

Multichannel cystometry, ambulatory monitoring and videourodynamics aim to observe the effects on intravesical and intra-abdominal pressures while reproducing a patient's symptoms. Bladder filling may be artificial or physiological and voiding is prompted. Any incontinence observed may be categorised as SUI, detrusor overactivity (DO) incontinence, a mixture of SUI/DO incontinence, or, rarely, urethral relaxation incontinence. A test may fail to reproduce a patient's symptoms because of poor diagnostic accuracy or because the symptoms are not directly attributable to a urodynamically measurable phenomenon. Despite these uncertainties, urodynamic testing is still used to establish an uncertain 'diagnosis', to direct decisions about treatment and to provide prognostic information.

*2.6.1 **Question***

In adults with UI, what is the diagnostic accuracy and predictive value of uroflowmetry, i.e. the measurement of maximum urinary flow rate (Q_{max}) and urodynamic testing?

2.6.2 ***Evidence***

2.6.2.1 Repeatability

Many studies have examined test-retest reliability for a range of urodynamic parameters, including eight studies on cystometry/pressure flow studies (1-8). No published studies on the reliability of ambulatory monitoring were found.

Various techniques are used to measure urethral profilometry. Individual techniques are generally reliable in terms of repeatability, but results may vary between different techniques, so that one type of test cannot be compared meaningfully to another (9-11).

The measurement of abdominal or Valsalva leak point pressures has not been standardised. It has not been possible to correlate consistently any method of measuring Valsalva leak point pressure with either UI severity or other measures of urethral function (12-17).

Studies of technical accuracy have included adults with LUTS, with or without UI. The studies used different equipment and lacked standardised techniques (18,19). As with all physiological investigation, results have shown a wide range of variability.

Inter-rater and intra-rater reliability of videourodynamics for the severity and type of SUI is good (20).

2.6.2.2 Diagnostic accuracy

The diagnostic accuracy of urodynamics cannot be measured against a 'gold standard' since all incontinence diagnoses are defined in urodynamic terms.

Detrusor overactivity may be found in asymptomatic patients, while normal cystometry is found in patients who are clearly symptomatic. There have been many studies of variable quality, investigating the relationship between UI symptoms and subsequent urodynamic findings. For their UK-based guidance, the National Institute for Health and Clinical Evidence (NICE) reviewed 11 studies (21), which investigated the relationship between clinical diagnosis and urodynamic findings and the diagnostic accuracy of urodynamic measurement, specifically in females. The Panel found no new evidence had been published since 2005 up until July 2011.

There is a consensus that urodynamic tests should aim to reproduce the patient's symptoms. If they do not, the findings are inevitably inconclusive. There is also a consensus that attention to technical and methodological detail during urodynamic testing may increase the accuracy of urodynamics in recording usual bladder behaviour.

In clinical practice, urodynamic testing (cystometry) may help to provide, or confirm, a diagnosis, predict treatment outcome, or facilitate discussion during a consultation.

2.6.2.3 Does urodynamics influence the outcome of conservative therapy?

A meta-analysis of 129 studies of diagnostic tests for incontinence, using economic modelling, concluded that urodynamics was not cost-effective in a primary care setting (22).

A few RCTs have investigated the ability of urodynamics to predict treatment decisions or treatment outcomes following conservative management. In 2009, a Cochrane review examined three small RCT studies, two of which were reported as abstracts (23,24). A further RCT, not included in the Cochrane review, also compared patients who underwent urodynamics with those who did not, though they did have urodynamics later in their care (25). Since then, another RCT addressing the same question has been published (26). Patients who underwent urodynamics were more likely to be treated by surgery or drugs or to have a change in their treatment (23). However, urodynamic tests made no difference to the outcomes of conservative treatment, including antimuscarinic therapy (27,28).

2.6.2.4 Does urodynamics influence the outcome of surgery for SUI?

There have been no RCTs specifically addressing this question, though trials are currently underway. Several case series have examined a possible relationship between individual urodynamic parameters and the subsequent success or failure of surgical treatment for SUI. Most were low-quality small studies. Post-hoc analysis of an RCT on surgery for SUI failed to confirm a predictive value for urodynamics, though the success rate for patients with urodynamic SUI exceeded that for women without urodynamic SUI (29).

Various studies have examined the relationship between measures of poor urethral function, i.e. low maximal

urethral closure pressure, low Valsalva leak point pressure, and subsequent failure of surgery. Some studies found a correlation between low urethral pressures and surgical failure, while other studies did not (30-33). A correlation, in itself, was not necessarily predictive.

2.6.2.5 Does urodynamics help to predict complications of surgery?
There have been no RCTs. A large number of case series, or post-hoc analyses of larger studies, have examined the relationship between urodynamic parameters and surgical outcome for SUI. A low Q_{max} or low pressure voiding has been inconsistently associated with post-operative voiding difficulty (34-40). However, the predictive value has rarely been calculated.

The presence of pre-operative DO has more consistently been associated with development of post-operative UUI. Post-hoc analysis of an RCT comparing the autologous fascial sling to Burch colposuspension showed inferior outcomes for women who suffered pre-operative urgency (41). However pre-operative urodynamics had failed to predict this outcome (29). Other case series, however, have shown a consistent association of poor outcomes with pre-operative DO, though the predictive value was not calculated (42,43).

2.6.2.6 Does urodynamics influence the outcome of surgery for DO?
No studies were found on the relationship between urodynamic testing and subsequent surgical outcome for DO. However, most studies reporting surgical outcomes for DO have included only patients with urodynamically proven DO or DO incontinence. Higher-pressure DO appears to be consistently associated with surgical failure and persistent or de-novo urgency. As with other suggested 'predictors', the predictive value has not often been formally calculated (30,44,45). Pre-operative urgency was resolved in some patients (46,47).

2.6.2.7 Does urodynamics influence the outcome of treatment for post-prostatectomy UI in men?
There are no RCTs examining the clinical usefulness of urodynamics in post-prostatectomy incontinence. However, many case series have demonstrated the ability of urodynamics to distinguish between different causes of UI (48-50). The ability of urodynamic testing to predict surgical outcome for post-prostatectomy incontinence is inconsistent (51,52).

Evidence summary	**LE**
Most urodynamic parameters show a high random immediate and short-term test-retest variability of up to 15% in the same subject.	2
Test-retest variability creates an overlap between 'normal' and 'abnormal' populations, which may make it more difficult to categorise urodynamic findings in a particular individua.l	2
Different techniques of measuring urethral function may perform reliably from one test to another, but do not reliably correlate to other tests and to the severity of UI.	3
The accuracy of ambulatory urodynamics remains uncertain.	4
There may be inconsistency between history and urodynamic results.	3
Preliminary urodynamics do not affect the outcome of conservative therapy for UI.	1a
There is limited evidence about whether preliminary urodynamic testing predicts surgical outcomes in adults with UI.	3
There is conflicting low-level evidence that tests suggesting poor urethral function predict surgery failure for SUI in women.	3
There is consistent low-level evidence that pre-operative DO predicts failure of mid-urethral sling surgery in women.	3
There is no evidence about whether preliminary urodynamics predicts outcomes of treatment for UI in men.	4

Recommendations	**GR**
Clinicians carrying out urodynamics in patients with urinary incontinence should: • Ensure that the test replicates patient's symptoms • Interpret results in context of the clinical problem • Check recordings for quality control • Remember there may be physiological variability within the same individual.	C

Advise patients that the results of urodynamics may be useful in discussing treatment options, although there is limited evidence that performing urodynamics will alter the outcome of treatment for urinary incontinence.	C
Do not routinely carry out urodynamics when offering conservative treatment for urinary incontinence.	B
Perform urodynamics if the findings may change the choice of surgical treatment.	C
Perform urodynamics prior to surgery for urinary incontinence if there are either symptoms of overactive bladder, a history of previous surgery or a suspicion of voiding difficulty.	C
Do not routinely carry out urethral pressure profilometry.	C

2.6.3 ***Research priority***

Future studies should address whether any urodynamic test influences the choice between treatments or prediction of the outcome of treatment.

2.7 Pad testing

A well-designed continence pad will contain any urine leaked within a period of time and this has therefore been used as a way of quantifying leakage. Although the International Continence Society has attempted to standardise pad testing, there remains variation in the duration of the test and the physical activity undertaken during the test.

2.7.1 ***Question***

In adults with UI, what are the reliability, the diagnostic accuracy and predictive value of pad testing?

2.7.2 ***Evidence***

The use of pad tests has been reviewed in the 4th International Consultation on Incontinence. Many studies have investigated the use of short-term and long-term pad tests to diagnose UI (1). Several other studies have investigated the correlation between pad test results and symptom scores for UI or LUTS (2-6). In addition, several studies have analysed the reproducibility of pad tests (6,7-11).

A few studies have tried to use pad testing to predict the outcome of treatment for UI with variable results (12,13). Currently, pad tests are mostly used as objective outcomes in clinical trials. However, pad tests may be helpful in daily clinical practice, and most guidelines already include the use of pad testing to evaluate treatment outcome (14,15). There is good evidence to show that repeat pad testing can detect change following treatment for UI (16-18).

Evidence summary	**LE**
A pad test can diagnose UI accurately, is reproducible and correlates with patients' symptoms.	1b
A pad test cannot differentiate between causes of UI.	4
An office-based pad test requires standardisation of bladder volume and a predefined set of exercises to improve diagnostic accuracy.	1b
A pad weight gain > 1 g in a 1-hour test can be used as a threshold to diagnose UI.	2b
Patient adherence to home pad testing protocols is poor.	1b
A weight gain > 1.3 g in a 24-hour home-based test can be used as a diagnostic threshold for UI.	1b
Home-based pad tests longer than 24 hours provide no additional benefit.	2b
Repeat pad tests can indicate treatment outcome.	1b

Recommendations	**GR**
Use a pad test when quantification of urinary incontinence is required.	C
Use repeat pad test if objective treatment outcome measure is required.	C

2.7.3 ***Research recommendation***

A systematic review of pad testing at home and in the office would clarify its role in routine care.

2.8 Imaging

Imaging improves our understanding of the anatomical and functional abnormalities that may cause UI. In clinical research, imaging is used to understand the relationship between conditions of the central nervous system (CNS) and of the lower urinary tract in causing UI, and to investigate the relationship between conditions of the lower urinary tract and treatment outcome.

Ultrasonography and magnetic resonance imaging (MRI) have replaced X-ray imaging as both procedures are safer than X-ray imaging and can provide both qualitative and quantitative data on the kidneys, bladder neck and pelvic floor.

Ultrasound is preferred to MRI because of its ability to produce three-dimensional and four-dimensional (dynamic) images at lower cost and wider availability. The current lack of knowledge about the pathophysiology of UI makes it difficult to carry out research in the imaging of UI. Studies on lower urinary tract imaging in patients with UI often include an evaluation of surgical outcomes, making design and conduct of these trials particularly challenging.

*2.8.1 **Questions***

- Can imaging aid selection of surgical procedure for SUI?
- How accurate is imaging in evaluating the outcome of UI surgery?

*2.8.2 **Evidence***

Several imaging studies have investigated the relationship between sphincter volume and function in women (1) and between sphincter volume and surgery outcome in men and women (2,3). Imaging of urethral anastomosis following radical prostatectomy has been used to investigate continence status (4). However, no imaging test has been shown to predict the outcome of treatment for UI.

Many studies have evaluated the imaging of bladder neck mobility by US and MRI, and concluded that UI cannot be identified by a particular pattern of urethrovesical movements (5). In addition, the generalised increase in urethral mobility after childbirth does not appear to be associated with de-novo SUI (6).

There is a general consensus that MRI provides good global pelvic floor assessment, including pelvic organ prolapse, defecatory function and integrity of the pelvic floor support structure (7). However, there is a large variation in MRI interpretation between institutions (8) and little evidence to support its clinical usefulness.

Studies have assessed the use of imaging to effect of mid-urethral sling insertion for SUI. One study suggested that mid-urethral sling placement decreased mobility of the mid-urethra, but not of the bladder neck (9). In addition, the position of mid-urethral slings with respect to the pubis has been associated with the cure of UI (10).

However, in conclusion, no studies were found which specifically addressed the PICO questions for this section. Lower urinary tract imaging does not appear to provide any clinical benefit in patients with UI (11). Despite this, however, some experts continue to recommend imaging (12-15).

Evidence summary	LE
Imaging can reliably measure bladder neck and urethral mobility, although there is no evidence of any clinical benefit in patients with UI.	2b
Imaging of the pelvic floor can identify levator ani detachment and hiatus, although there is little evidence of clinical benefit.	2b
Ultrasonography can image mid-urethral slings, although more research is needed into the relationship between sling position and surgical outcome.	2b

Recommendation	GR
Do not routinely carry out imaging of the upper or lower urinary tract as part of the assessment of uncomplicated SUI in women.	A

3. CONSERVATIVE TREATMENT

In clinical practice, it is a convention that non-surgical therapies are tried first because they usually carry the least risk of harm.

The Panel has grouped together simple clinical interventions, which are likely to be initiated by the healthcare professional at the first point of contact. These are followed by a series of treatments described as 'lifestyle interventions' because they are changes that a patient can make to improve symptoms. These are then followed by behavioural treatments, which require some form of training or instruction, and physical therapies, which require instruction and use some form of physical intervention. Drug treatment is described separately. The Panel recognises that in clinical practice a combination of these interventions may be recommended as a care package. Consequently, recommendations have been linked together in places where this reflects the way that care is often 'packaged'.

3.1 Simple clinical interventions

*3.1.1 **Underlying disease/cognitive impairment***

Urinary Incontinence, especially in the elderly, can be worsened or caused by underlying diseases, especially conditions that cause polyuria, nocturia, increased abdominal pressure or CNS disturbances. These conditions include:

- cardiac failure (1);
- chronic renal failure;
- diabetes (1,2);
- chronic obstructive pulmonary disease (3);
- neurological disorders;
- stroke;
- dementia;
- multiple sclerosis;
- general cognitive impairment;
- sleep disturbances e.g. sleep apnoea.

It is possible that correction of the underlying disease may reduce the severity of urinary symptoms. However, this is often difficult to assess as patients often suffer from more than one condition. In addition, interventions may be combined and individualised, making it impossible to decide which change in an underlying disease has affected a patient's UI.

3.1.1.1 Question

In adults with UI, does correcting an underlying disease or cognitive impairment improve UI or QoL compared to no correction of underlying disease?

3.1.1.2 Evidence

We found only one study that directly addressed the question. The study was a follow-up of an earlier RCT. The study found no correlation between earlier intensive treatment of type 1 diabetes mellitus and the prevalence of UI in later life versus conventional treatment (4). This was despite the known benefit of close control of blood glucose levels on other known consequences of type 1 diabetes mellitus, including renal and visual impairment. A higher prevalence of UI was associated with an increase in age and body mass index in this study.

Evidence summary	**LE**
Improved diabetic control neither resolves nor improves UI.	3

3.1.2 ***Adjustment of medication***

Although UI is listed as an adverse effect in many drug compendiums, e.g. *British National Formulary*, this is mainly due to uncontrolled individual patient reports and post-marketing surveillance. Few controlled studies have used the occurrence of UI as a primary outcome or were powered to assess the occurrence of statistically significant UI or worsening rates against placebo. It is therefore not possible in most cases to be sure that a drug causes incontinence.

In patients with existing UI, particularly the elderly, it may be difficult or impossible to distinguish between the effects on UI of medication, comorbidity, or ageing.

Although changing drug regimens for underlying disease may be considered a possible early intervention for UI, there is very little evidence of benefit (1). There is also a theoretical risk that stopping or altering medication may result in more harm than benefit.

3.1.2.1 Question

In adults with UI, does adjustment of medication improve UI or QoL compared to no change in treatment?

3.1.2.2 Evidence

A structured narrative review found there was only weak evidence for a causative effect for most medications associated with the adverse effect of new, or worsening, UI (2). A case-control study found that women with hypertension started on alpha-blockers were more likely to develop UI than untreated controls (3).

Several case series have suggested a link between drugs with a CNS site of action and UI (2). A secondary analysis of a large observational database of elderly Italians found a higher risk of UI among those taking benzodiazepines. In addition, a retrospective analysis of a large Dutch database of dispensed prescriptions found that patients started on a selective serotonin re-uptake inhibitor were more likely to require a subsequent prescription of antimuscarinic drugs or absorbent urinary pads, suggesting the development of UI (4). Limited evidence from case series and case-control studies suggests that diuretic therapy is not associated with a higher incidence or worsening of UI (2). It is possible that SUI may be worsened by the development of the chronic cough sometimes associated with ACE inhibitors prescribed for heart failure or hypertension.

Systemic oestrogen therapy for post-menopausal women was shown by a meta-analysis (5) to be associated with the development and worsening of UI. Systemic oestrogen, compared to placebo, worsened symptoms of UI, both in women who had undergone a hysterectomy, and in those who had not (5). In addition, data from a single large RCT (6) showed that previously continent women treated with systemic oestrogen were more likely to develop symptoms of UI compared to women given a placebo.

These more recent analyses have superseded conflicting results from earlier and smaller studies of the effect of oestrogen replacement therapy on UI. However, the number of women who gain relief from UI through stopping systemic oestrogen replacement is likely to be small, as there has been a decline in the use of oestrogen replacement therapy by post-menopausal women, due to concerns about developing cancer and the association of oestrogen replacement therapy with UI.

Evidence summary	LE
Alpha-blockers used to treat hypertension in women may cause or exacerbate UI, and stopping them may relieve UI.	3
Individuals taking drugs acting on the central nervous system may experience UI as a side effect.	3
Diuretics in elderly patients does not cause or worsen UI.	3
Systemic oestrogen replacement therapy in previously continent women approximately doubles the prevalence of UI at 12 months compared to placebo.	1b
Women with pre-existing UI, who use systemic oestrogen replacement therapy, are 30% more likely to experience worsening UI compared to placebo.	1a

Recommendations	GR
Take a drug history from all patients with urinary incontinence.	A
Inform women with urinary incontinence that begins or worsens after starting systemic oestrogen replacement therapy that it may cause urinary incontinence.	A
Review any new medication associated with the development or worsening of urinary incontinence.	C

*3.1.3 **Constipation***

Several studies have shown strong associations between constipation, UI and OAB. Constipation can be improved by behavioural and medical treatments.

3.1.3.1 Question

Does treatment for constipation therapy improve symptoms or QoL in patients with UI?

3.1.3.2 Evidence

One RCT found that a multimodal intervention in elderly patients, involving assisted toileting, fluid intake, etc., reduced the occurrence of UI and constipation, while behavioural therapy appeared to improve both constipation and UI (1). Another study found bowel function improved after successful treatment of voiding problems with sacral nerve stimulation (2). A different study recommended the simultaneous treatment of constipation and urinary disorders in children and adolescents with LUTS.

An observational study comparing women with UI and women with pelvic organ prolapse to controls found that a history of constipation was associated with both prolapse and UI (3). Two large cross-sectional population-based studies (4,5) and two longitudinal studies (6,7) showed constipation was a risk factor for LUTS.

In conclusion, constipation appears to be associated with LUTS. However, there is no evidence to show whether or not treating constipation improves LUTS, although both constipation and UI appear to be improved by certain behavioural interventions.

Evidence summary	LE
There is a consistent association between a history of constipation and the development of UI and pelvic organ prolapse.	3
There is no evidence that treatment of constipation improves UI.	4
Multimodal behavioural therapy improves both constipation and UI in the elderly.	1b
Simultaneous treatment of constipation and urinary incontinence in adolescents is beneficial.	3

Recommendation	GR
For adults with UI, treat co-existing constipation.	C

*3.1.4 **Containment***

Although initiation of assessment and treatment of UI should be the main priority for healthcare professionals, containment is of great practical importance to many patients with UI. Absorbent pads are predominantly used to absorb or collect leakage. However, if these are inadequate, an indwelling urethral or suprapubic catheter may then be used after taking into account the complications associated with catheter use, e.g. infection, bladder spasm, stone formation, etc.

3.1.4.1 Question

In adults with UI, does urinary containment improve patient outcomes, regarding either urinary symptoms or QoL, compared with no containment?

3.1.4.2 Evidence

There was a lack of consistency in the evidence reviewed. There have been two consensus statements in the 4th International Consultation on Incontinence (1) and one RCT comparing conservative treatment with urinary pads (2). There have been Cochrane reviews of devices (3) and pads (4), and three small trials of devices with differing outcomes (5-7). Few studies have been carried out in urinary catheterisation; these included an RCT comparing condom catheters with indwelling urinary catheters (8). A small open crossover RCT (11) evaluated different penile clamps and showed that none completely controlled urine leakage, but penile blood flow was reduced.

Evidence summary	LE
Pads are not effective as a treatment for UI.	1b
Different pads have different advantages and disadvantages.	1b
Intermittent catheterisation carries a lower risk of urinary tract infection and bacteriuria than indwelling catheterisation.	1b
Containment devices are better than no treatment.	4
There is not enough evidence to conclude which containment device is best.	4
Condom catheters are better than indwelling catheters if no residual urine is present.	1b
There is no evidence to compare mechanical devices with other forms of treatment.	4

Recommendations	GR
Offer pads when containment of urinary incontinence is needed.	B
Adapt the choice of pad to the type and severity of urinary incontinence and the patient's needs.	A
Offer catheterisation to manage urinary incontinence when no other treatments can be considered.	B
Offer condom catheters to men with urinary incontinence without significant residual urine.	A
Offer to teach intermittent catheterisation to manage UI associated with retention of urine.	A
Do not routinely offer intravaginal devices as treatment for incontinence.	B
Do not use penile clamps for control of UI in men.	A

3.2 Lifestyle interventions

Examples of lifestyle factors that may be associated with incontinence include obesity, smoking, level of physical activity and diet. It may therefore be possible to improve UI by beginning lifestyle interventions, such as weight loss, fluid restriction, reduction of caffeine or alcohol intake, limiting heavy activity and stopping smoking.

*3.2.1 **Caffeine reduction***

Many drinks contain caffeine, particularly tea, coffee and cola. The pharmacological actions of caffeine include CNS stimulation, diuresis and smooth muscle relaxation. Anecdotal evidence of urinary symptoms being aggravated by excessive caffeine intake has focussed attention on whether caffeine reduction may improve UI. However, a cross-sectional population survey found no statistical association between caffeine intake and UI (1). A lack of knowledge about the caffeine content of different drinks has made the role of caffeine reduction in alleviating UI more complex.

3.2.1.1 Question

In adults with UI, does caffeine reduction improve UI or QoL, compared to no caffeine reduction?

3.2.1.2 Evidence

Four studies were found on the effect of caffeine reduction on UI (2-5). They were of moderate quality and the results were inconsistent. The studies were mainly in women, so results can only be cautiously generalised to all adults. There were two RCTs investigating caffeine reduction (3,4). One RCT showed that reducing caffeine intake resulted in reduced urgency but not reduced UI (3). However, the study was not powered for UI and compared the interventions of bladder training (BT) and caffeine reduction against BT alone. Another RCT found that reducing caffeine had no benefit for UI (4). An uncontrolled study suggested that people with OAB and high caffeine intake were more likely to show DO on filling during conventional cystometry (2). A further interventional study in the elderly showed borderline significance for the benefit of reducing caffeine intake on UI (5).

Evidence summary	**LE**
Reduction of caffeine intake does not improve UI.	2
Reduction in caffeine intake may improve symptoms of urgency and frequency.	2

*3.2.2 **Physical exercise***

Regular physical activity may strengthen the pelvic floor musculature and possibly decrease the risk of developing UI, especially SUI. However, it is also possible that heavy physical exercise may aggravate UI.

3.2.2.1 Question

Does physical exercise cause, improve or exacerbate UI in adults?

3.2.2.2 Evidence

The association between exercise and UI is unclear. Four studies (1-4) in differing populations concluded that strenuous physical exercise increases the risk of SUI during periods of physical activity and there is consistent evidence that physically active females and elite athletes experience higher levels of SUI than control populations (5-10). On the other hand, the presence of UI may prevent women from taking exercise (11). There is no evidence that strenuous exercise predisposes athletes to the development of SUI later in life (12). Lower levels of UI have been observed in cohorts of women who undertake moderate exercise, but it remains unclear whether taking exercise can prevent development of UI (13,14).

Evidence summary	**LE**
Female athletes may experience UI during intense physical activity but not during common activities.	3
Strenuous physical activity does not predispose to UI for women later in life.	3
Although moderate exercise is associated with lower rates of UI in middle-aged or older women, there is no evidence that starting moderate exercise improves established UI in women.	2b

3.2.3 ***Fluid intake***

It is generally assumed that reduction in total volume of fluid intake may be beneficial for UI. Fluid restriction is a widely used, inexpensive and non-invasive intervention that is easily recommended. It is usually advised that fluid intake and output is monitored using a frequency volume chart. Daily urine output should not be less than 1500 mL and not more than 3000 mL. The restriction of fluid intake may have adverse effects, including a predisposition to UTI, dehydration, urinary tract stone formation and constipation. The cause of a high fluid intake should be investigated.

3.2.3.1 Question

In adults with UI, what is the effect of modifying fluid intake compared to not modifying fluid intake on symptoms and QoL?

3.2.3.2 Evidence

The few RCTs provide inconsistent evidence. In most studies, the instructions for fluid intake are individualised and it is difficult to assess participant adherence to protocol. All available studies are in women.

Two RCTs of limited quality due to high drop-out rates and small sample size (1,2) produced conflicting results regarding recommendations for fluid intake. One study found that increased fluid intake improved symptoms, while the other study, which was limited to patients with DO, found that decreased fluid intake improved QoL. A more recent RCT (3) showed that a reduction in fluid intake by 25% improved symptoms in patients with OAB but not incontinence. An observational study also addressed fluid intake as part of a behavioural regime (4).

Evidence summary	**LE**
There is conflicting evidence on whether fluid modification changes symptoms of urinary incontinence and quality of life.	2

3.2.4 ***Obesity and weight loss***

In most developed countries, nearly one-quarter to more than one-third of adult women are obese. Obesity and UI are serious health problems, adversely affecting QoL. Obesity has been identified as a risk factor for UI in many epidemiological studies (1,2). There is evidence that the prevalence of both UUI and SUI increases proportionately with rising body mass index. A significant proportion of patients who undergo surgery for incontinence are overweight or obese. In 2009, the 4th International Consultation on Incontinence recommended that the role of obesity in UI should be a research priority.

3.2.4.1 Question

In adults with UI, does weight loss lead to an improvement in symptoms of UI or QoL?

3.2.4.2 Evidence

All the available evidence relates to women. The prevalence of UI in overweight individuals is well established (1,2). Obesity appears to confer a four-fold increased risk of UI (3).

Two systematic reviews concluded that weight loss was beneficial in improving symptoms of UI (4,5). Four further RCTs reported a similar benefit beneficial effect on incontinence following surgical weight reduction

programmes (6-9). The largest study was in diabetic women, for whom weight loss was the main lifestyle intervention (9). There have been other cohort studies and case-control studies suggesting similar effects, including surgery for the morbidly obese (10-17). For example, in a longitudinal cohort study, a weight loss of 5-10% was associated with a significant reduction in pad test loss of urine (18).

Evidence summary	**LE**
Obesity is a risk factor for UI in women.	1b
Weight loss (> 5%) in obese women improves UI.	1b

*3.2.5 **Smoking***

The role of smoking and the importance of smoking cessation are discussed in the management of almost every disease. Smoking, especially if > 20 cigarettes per day, is considered to intensify UI.

3.2.5.1 Question

In adults with UI, does smoking cessation improve patient outcomes regarding either urinary symptoms or QoL versus continued smoking?

3.2.5.2 Evidence

Seven published articles were found, all in women, on whether smoking cessation improved patient outcome. There was no RCT, but several population studies were found, including a study including 83,500 people. The studies only provided a comparison of smoking rates between different populations and did not examine the role of smoking cessation.

Four of these studies, totalling more than 110,000 subjects, found an association between smoking and UI, for people smoking > 20 cigarettes per day (1-4). Both former and current cigarette smoking was positively associated with frequent and severe UI, with a stronger relationship in women who were current smokers (2). Other studies involving similar large populations have not shown an association. The effect of smoking cessation on UI was described as uncertain in the latest Cochrane review (5).

Evidence summary	**LE**
There is no consistent evidence that smokers are more likely to suffer from UI.	3
There is some evidence that smoking may be associated with more severe UI, but not mild UI.	3
There is no evidence that smoking cessation will improve the symptoms of UI.	4

Recommendations for lifestyle interventions	**GR**
Encourage obese women suffering from any urinary incontinence to lose weight (> 5%).	A
Advise adults with urinary incontinence that reducing caffeine intake may improve symptoms of urgency and frequency but not incontinence.	B
Patients with abnormally high or abnormally low fluid intake should be advised to modify their fluid intake appropriately.	C
Counsel female athletes experiencing urinary incontinence with intense physical activity that it will not predispose to urinary incontinence in later life.	C
Patients with urinary incontinence who smoke should be given smoking cessation advice in line with good medical practice although there is no definite effect on urinary incontinence.	A

3.3 Behavioural therapy/scheduled voiding

Scheduled voiding is a treatment programme designed to gradually increase a person's control over voiding function and urgency and to reduce episodes of incontinence. It is also known as bladder drill, bladder discipline, bladder re-education, or BT. The programme also aims to increase a person's self-confidence in bladder function, though this can take months to achieve and may not persist long term unless the programme is maintained.

Different strategies may be used since no single regimen has yet been proven ideal. As well as following a voiding pattern, the patient is instructed on bladder function and fluid intake, including caffeine restriction and bowel habits. Patients may be asked to void according to a fixed voiding schedule. Alternatively, patients may be encouraged to follow a schedule established by their own bladder diary/voiding chart (habit training). 'Timed voiding' is voiding initiated by the patient, while 'prompted voiding' is voiding initiated by the caregiver. Timed and habit voiding are recommended to patients who can void independently.

Bladder training can be offered to any patient with any form of UI, as a first-line therapy for at least a short period of time. The ideal form or intensity of a BT programme for UI is unclear. It is also unclear whether or not BT can prevent the development of UI.

*3.3.1 **Questions***

- Is BT better than no treatment for cure or improvement of UI?
- Is BT better than other conservative treatments for cure or improvement of UI?
- Is BT useful as an adjunct to other conservative treatments for UI?
- Are the benefits of BT durable in the longer term?
- Are there any patient groups for whom BT is more effective?

*3.3.2 **Evidence***

There have been four systematic reviews covering the effect of BT compared to standard care (1-4). Two key RCTs, which compared BT with no intervention, found that UI was improved, but not cured, by timed bladder voiding at intervals of between 2.5 and 4 hours (5,6). However, it is unclear whether these findings also applied to specific groups of individuals with UI. However, another two RCTs reported inconsistent findings regarding treatment adherence(7).

Bladder training has been compared with other treatments for UI in a number of other RCTs. BT alone is as effective in controlling UUI and nocturnal incontinence as oxybutynin, tolterodine and solifenacin (8-13).

Studies have shown that the addition of BT to antimuscarinic therapy gives either no (10,11) or minimal (12) added benefit in terms of improvement of UI compared with antimuscarinic treatment alone. BT combined with antimuscarinic therapy does provide a greater benefit in reducing urinary frequency and nocturia (10,14). BT does not improve an individual's capacity to discontinue drug therapy and maintain improvement of UUI (12). However, the addition of BT to antimuscarinic drugs may increase patient satisfaction with pharmacological treatment (15), including in patients previously dissatisfied with the antimuscarinic treatment (16).

Bladder training combined with pelvic floor muscle training (PFMT) is better than standard care for controlling UI in elderly women living in institutions (17). However, BT alone is inferior to a high-intensity programme of PFMT to improve SUI in elderly women (18). BT is better than intravaginal pessaries to control SUI, although the improvement may only be short term.

Whatever the method of training used, any benefit of BT on UI is likely to be of short duration unless the BT programme is practised repeatedly. No adverse events have been reported with BT.

Evidence summary	LE
There is limited evidence that supervised bladder training is better than no treatment in women with UUI and mixed urinary incontinence.	1b
The effectiveness of bladder training diminishes after the treatment has ceased.	2
There is inconsistent evidence to show whether bladder training is better than drug therapy.	2
The combination of bladder training with antimuscarinic drugs does not result in greater in improvement of UI but may have other benefits.	2
Bladder training is better than pessary alone.	1b
Timed voiding reduces leakage episodes in cognitively impaired men and women.	1b

For recommendations see page 46.

3.4 Physical therapies

*3.4.1 **Pelvic floor muscle training (PFMT)***

Pelvic floor muscle training is used to increase the strength and durability of contraction of the pelvic floor muscles. This increases urethral closure pressure and stabilises the urethra, preventing downward movement during moments of increased activity. Patients are sometimes taught to perform 'the knack' of contracting the pelvic floor at moments when predictable UI is likely to occur. Otherwise regular training aims to increase pelvic floor muscle strength. There is some evidence that increasing pelvic floor strength may help to inhibit bladder contraction in patients with an OAB.

Traditionally, following vaginal examination and pelvic floor assessment by a trained professional, patients are taught to contract their pelvic floor muscles, as hard as they can and for as long as they can, and to repeat these exercises a number of times every day. This training can be delivered in many ways, including women teaching themselves (e.g. using an information leaflet), group training in classes, or intensive one-to-one supervision from a highly trained physical therapist. PFMT may be used to prevent UI, e.g. in childbearing women before birth, in men about to undergo radical prostatectomy, or as part of a planned recovery programme after childbirth or surgery. Most often, PFMT is used to treat existing UI, and may be augmented with biofeedback, electrical stimulation or vaginal cones.

3.4.1.1 Methods used to augment PFMT

Biofeedback increases patient awareness of the pelvic floor muscles, using visual, tactile or auditory stimuli, e.g. vaginal manometry or electromyography, and is used to help teach patients to exercise their pelvic floor muscles more effectively. However, there is no guarantee that the signals recorded come from the pelvic floor and digital palpation or ultrasound may provide better reassurance of correct contraction. Biofeedback can be used at home or in an office setting.

In electrical stimulation, surface electrodes supply electrical current to stimulate the pelvic floor muscles via their nerve supply. Electrodes are available in several formats, including vaginal, anal, or skin. Electrical stimulation is often used to help patients recognise their pelvic floor muscles though there is no evidence supporting this concept. It is also used to exercise muscles in the hope of increasing pelvic floor strength. Electrical stimulation can also be used to inhibit overactive detrusor contractions.

Weighted vaginal cones are cone-shaped vaginal inserts of graduated weights. A woman learns first to insert the lightest cone and retain it using pelvic floor contraction. Gradually, she is able to hold increasingly heavy cones as her pelvic floor muscles become stronger.

3.4.1.2 Question

In adult men and women suffering from UI, does treatment with PFMT (given either alone or augmented with biofeedback, electrical stimulation or vaginal cones) improve or cure UI or improve QoL, compared to no treatment, sham treatment or other conservative treatments, e.g. bladder training, electrical stimulation or vaginal cones?

3.4.1.3 Evidence

Although there have been many randomised trials of PFMT, the trials vary widely in terms of quality, mode of delivery, intensity and duration of treatment, and the details of contractions and repetitions.

In a recent UK Health Technology Appraisal, the role of PFMT in the care of women with SUI was analysed in both direct comparisons and a mixed treatment comparison model, which compared different 'packages' of care (1). This extensive meta-analysis reviewed data from 37 interventions and 68 direct comparisons, while the mixed treatment comparisons examined combinations of 14 different types of intervention from 55 separate trials. The mixed treatment comparison used both indirect and direct comparisons and has probably provided more accurate estimates of effect. Where relevant, the Technology Appraisal has influenced the evidence and recommendations in these Guidelines.

3.4.1.4 Efficacy of PFMT in SUI, UUI and MUI in women

This question has been addressed by one Cochrane systematic review (2), which included six RCTs comparing PFMT to no treatment. Three RCTs evaluated PFMT for mixed urinary incontinence (MUI), while the other three RCTs compared a programme of treatment supervised by a professional versus either self-taught PFMT or unsupervised PFMT. There was inconsistency between studies because of poor reporting of technique and different outcome measures. Meta-analysis showed that PFMT achieved cure or improvement of incontinence more often compared to no treatment.

One recent RCT compared interpersonal support and digital vaginal palpation to PFMT and an instruction leaflet, finding superior efficacy for the former group (3). Another recent RCT found that PFMT delivered in a group setting can be as effective as individual treatment (4). Another RCT reported 15-year follow-up outcomes of an earlier RCT, showing that long-term adherence to treatment was poor. Half of patients had progressed to surgery, though the functional outcomes in those who had undergone surgery were less satisfactory than those who did not have surgery (5).

The 4th International Consultation on Incontinence 2009 (6) reviewed studies up to June 2008. This review included the following comparisons:

- vaginal cones: 8 RCTs
- different types of electrical stimulation: 8 RCTs
- BT: 3 RCTs
- different drugs: 4 RCTs
- surgery in which the operation was 'selected' by the surgeon (i.e. inconsistent): 1 RCT.

None of these RCTs were of good quality. In addition, inconsistent reporting of techniques and outcomes makes it difficult to compare studies.

The same review also included comparisons of PFMT with other therapies in women with SUI:

- PFMT versus PFTM + vaginal cones: 2 RCTs
- PFMT versus PFMT + electrical stimulation: 2 small RCTs
- PFMT versus PFMT + biofeedback: 9 RCTs of mixed quality, of which 5 RCTs were clinic-based and 4 RCTs used a home-based biofeedback device. Potential bias was caused by the inconsistent supervision of women between different treatment groups.

There has been one further RCT comparing PFMT + duloxetine versus duloxetine alone versus PFMT alone versus no treatment (6).

These studies, and two additional studies (8,9) were reviewed as part of the 2010 UK Health Technology Appraisal (1), which considered additional data as part of a mixed treatment comparison. The Appraisal resulted in a number of different findings from those based solely on direct comparisons. In conclusion, the Appraisal, using a revised methodology, supported the general principle that greater efficacy was achieved by adding together different types of treatment and increasing intensity.

3.4.1.5 Efficacy of PFMT in childbearing women

The Cochrane review in 2008 (10) reviewed sixteen RCTs in pregnant or post partum women which included PFMT in one arm of the trial. Five of these trials were in post partum women who had developed urinary incontinence. Eight trials reported mixed treatment and prevention groups. Treatment of UI with PFMT in the post partum period inreased the chances of continence at 12 months post partum.

3.4.1.6 Efficacy of PFMT in men with SUI following radical prostatectomy

There has been one systematic review of eleven RCTs. There have been three further RCTs of reasonable quality (11-13). These trials consistently demonstrated improved continence within the first few months after

radical prostatectomy (RP), but not thereafter, suggesting that PFMT speeds the recovery of UI. Two additional RCTs have shown that written instructions alone can achieve the same result (14,15).

3.4.1.7 Preventive value of PFMT in childbearing women and post-RP men

The Cochrane review by Hay Smith (10) reviews five RCTs in which PFMT was started in continent pregnant women. A number of other trials included both prevention and treatment groups in their comparisons. PFMT was found to reduce the risk of incontinence in late pregancny and up to 6 months post partum.

Ten RCTs of variable quality compared the preventative effect of PFMT prior to RP versus various different types of control treatments. These were generally small studies, which were difficult to compare with each other because of different times of delivery and different outcomes (16-24). However, one study was well designed and provided level 2 evidence confirming that pre-operative PFMT speeds recovery of continence post-operatively (25).

PFMT as monotherapy	**LE**
PFMT is better than no treatment for reducing incontinence episodes and improving quality of life in women with SUI, and MUI. There is no evidence that PFMT is better than no treatment in providing a cure.	1
Higher-intensity regimes, or the addition of biofeedback, confer greater benefit, but differences are not sustained long term.	1
A taught/supervised programme of PFMT is more effective than self-taught PFMT.	1
Group-based PFMT is as effective as treatment delivered individually.	1
Short-term benefits of intensive PFMT are not maintained at 15 years' follow-up.	2
PFMT compared with other conservative treatments	**LE**
PFMT results in better reduction in leakage episodes than training using vaginal cones, but no difference in self-reported cure or improvement.	1
PFMT results in fewer incontinence episodes than electrical stimulation.	1
PFMT does not result in measurable improvement in quality of life.	2
PFMT is better than bladder training for improvement of leakage and quality of life, in women with SUI.	2
There is no consistent difference between PFMT and bladder training for women with UUI or MUI.	2
PFMT is as effective as duloxetine in women with SUI and has fewer side effects.	2
PFMT is better tolerated than oxybutynin for UUI.	2
PFMT is better than alpha-blockers for women with SUI.	2
PFMT for UI in childbearing women	**LE**
PFMT commencing in early pregnancy reduces the risk of incontinence in late pregnancy, and up to 6 months post partum.	1
PFMT commencing in the early post partum period improves UI in women for up to 12 months.	1
PFMT for post-prostatectomy incontinence	**LE**
Men undergoing some form of PFMT, before or after radical prostatectomy achieve continence more quickly than non-treated men.	2
There is conflicting evidence on whether the addition of electrical stimulation or biofeedback or supervised training increases the effectiveness of PFMT alone.	2
There is no evidence that pre-operative PFMT prevents UI following radical prostatectomy. As with post-operative PFMT, it appears to lead to earlier recovery of continence.	2
What remains unproven about PFMT	**LE**
There is a lack of evidence about what is the most effective regimen for PFMT.	4
The long-term durability of PFMT, augmented or not by other therapies, remains uncertain in all clinical situations.	4
There is insufficient evidence that adding electrical stimulation or vaginal cones to PFMT alters the efficacy of PFMT alone.	2

3.4.2 ***Electrical stimulation (surface electrodes)***

Electrical stimulation with surface electrodes can be delivered vaginally, anally or with skin electrodes on the perineum or suprapubic region. Stimulation parameters vary considerably from one study to another. Generally, low-intensity levels are used in home-based, self-administered therapy and high-intensity levels in clinic-based settings. Maximal stimulation under general anaesthesia has been described. The treatment regimes (number and frequency of sessions) vary considerably.

Electrical stimulation can also be combined with other forms of conservative therapy, e.g. PFMT and biofeedback. Electrical stimulation is often used to assist women who cannot initiate contractions to identify their pelvic floor muscles.

3.4.2.1 Question

In adults with UI, does treatment with electrical stimulation improve or cure symptoms of UI or QoL compared to no treatment or sham treatment?

3.4.2.2 Evidence

Most evidence on electrical stimulation refers to women. Five recent systematic reviews of electrical stimulation were found (1-5), although there was no specific Cochrane review. The five reviews included analysis of 15 RCTs, of which eight were comparisons to no treatment or sham treatment - seven studies were comparisons to other physical or behavioural therapies - and a further eight studies were comparisons of electrical stimulation combined with other therapies, usually PFMT.

The studies were considered to be of generally low quality, with small sample size and a variety of stimulation parameters, treatment regimes and outcome parameters. In addition, most of the studies lacked detail of the statistical methods used, e.g. power calculation. Due to the lack of consistency in the parameters used for electrical stimulation and in the outcome measures, it has not been possible to compare or pool data from most of these studies.

The role of electrical stimulation is complicated by a lack of knowledge of how it might work in UI.

Physiotherapists have used electrical stimulation to help women identify and contract pelvic floor muscles during PFMT. It has been suggested that electrical stimulation probably targets the pelvic floor directly in SUI, and the detrusor muscle or pelvic floor muscle or afferent innervation in UUI.

Evidence summary	LE
The evidence is inconsistent for whether electrical stimulation alone can improve UI.	2

*3.4.3 **Magnetic stimulation***

(Extracorporeal) magnetic stimulation stimulates the pelvic floor musculature and/or the sacral roots in a non-invasive way. The patient is seated over a magnetic field generator. This produces a steep gradient magnetic field, which may stimulate the pelvic floor muscles and sphincters. Magnetic stimulation can also be given via a portable electromagnetic device. Magnetic stimulation may be effective in SUI and UUI. The mechanism of action is not understood.

3.4.3.1 Question

In adults with SUI or UUI or MUI, what is the clinical effectiveness of magnetic stimulation versus sham treatment?

3.4.3.2 Evidence

Eight RCTs and two cohort studies have investigated the question of whether magnetic stimulation is effective in UI. The RCTs were mostly of poor quality. The technique of electromagnetic stimulation was poorly standardised and involved different devices, mode of delivery, and stimulation parameters. Blinding was difficult to achieve and this resulted in a high risk of bias in some trials.

Three RCTs induced magnetic stimulation in women with UI, using a coil placed over the sacral foramina. Two were poor-quality RCTs, with a short follow-up and an inconclusive effect in SUI and UUI or OAB (1,2). The third better-quality RCT observed no improvement in UUI or OAB after a longer 12-week follow-up and did not recommend treatment with magnetic stimulation (3).

A portable device (Pulsegen) was compared in two RCTs to sham treatment in women with UI. Inconclusive effects were obtained. Both trials were poor quality with a short follow-up (4,5).

In adult women with SUI, an RCT using the NeoControl chair found no improvement (6). A cohort study for 6 weeks, but with a follow-up of 2 years, showed a moderate improvement in incontinence measured by pad test (7), while another cohort study found no improvement (8). A further poor-quality RCT using the NeoControl chair also found no benefit in women with UUI or OAB (9). No clinical benefits were reported when magnetic stimulation using the NeoControl chair was also compared to functional electrical stimulation with surface electrodes (10).

The negative or inconclusive effects obtained from the reviewed literature were considered to be consistent

and generally applicable to adult women with SUI or UUI. There was a lack of evidence in men with UI.

Evidence summary	LE
There is no consistent evidence of efficacy of magnetic stimulation for the cure or improvement of UI.	2a
There are no reports of adverse events for magnetic stimulation.	1b

*3.4.4 **Posterior (percutaneous) tibial nerve stimulation***

Electrical stimulation of the posterior tibial nerve (PTNS) delivers electrical stimuli to the sacral micturition centre via the S2-S4 sacral nerve plexus. The PTNS is stimulated with a fine, 34-G, needle, which is inserted just above the medial aspect of the ankle (equivalent to the SP6 acupuncture point). Treatment cycles typically consist of 12-weekly treatments of 30 minutes. PTNS may be effective in patients with UUI.

3.4.4.1 Question

In adults suffering from UUI, what is the clinical effectiveness of PTNS compared to sham treatment or antimuscarinic drug treatment?

3.4.4.2 Evidence

Seven studies were reviewed, including two RCTs of PTNS against sham treatment (1,2) and one comparing PTNS to tolterodine in patients with UUI (3). Four relevant case series were also included because they were either extension studies of an RCT population (5-7) or provided data on a large sample. Other studies of PTNS in UUI were excluded because of an inadequate study design (small case series, case series with no follow-up)

or a lack of relevance (series with combination treatment, reviews or studies from which specific results in UUI patients could not be extracted).

The results of studies of PTNS in women with refractory UUI are consistent. Considered together, these results allow the conclusion that that PTNS has a benefit in women with UUI not able to tolerate antimuscarinic therapy. However, there is no evidence of benefit for women who do not respond to antimuscarinic therapy. In men there is insufficient data to make a conclusion about efficacy.

Evidence summary	**LE**
There are not enough data to make a conclusion about the effectiveness of PTNS in men.	4
PTNS is effective in women with UUI, who cannot tolerate anticholinergic medication.	2a
PTNS does not give benefit for women with UUI who have not responded to anticholinergic medication.	1b
No serious adverse events have been reported for PTNS in UUI.	2a

Recommendations for behavioural and physical therapies	**GR**
Offer supervised PFMT, lasting at least 3 months, as a first-line therapy to women with stress or mixed urinary incontinence.	A
PFMT programmes should be as intensive as possible.	A
Consider using biofeedback as an adjunct in women with stress urinary incontinence.	A
Offer supervised PFMT to continent women in their first pregnancy to help prevent incontinence in the postnatal period.	A
Offer instruction on pelvic floor exercises to men undergoing radical prostatectomy to speed recovery of urinary incontinence.	B
Offer bladder training as a first-line therapy to adults with urgency urinary incontinence or mixed urinary incontinence.	A
Offer timed voiding to adults with urinary incontinence, who are cognitively impaired.	A
Do not offer electrical stimulation with surface electrodes (skin, vaginal, anal) alone for the treatment of urinary incontinence.	A
Do not offer magnetic stimulation for the treatment of urinary incontinence or overactive bladder in adult women.	B
Offer PTNS to women with urgency urinary incontinence who cannot tolerate anticholinergic medication.	A

PFMT = pelvic floor muscle training; PTNS = posterior tibial nerve stimulation.

3.4.4.3 Research priorities

There is a need for well-designed studies of both electrical stimulation and magnetic stimulation in adults with UI.

4. DRUG TREATMENT

4.1 Antimuscarinic drugs

Antimuscarinic drugs are currently the mainstay of treatment for UUI. They act by blocking muscarinic receptors in the bladder wall. This reduces detrusor contractility and also alters sensation. Antimuscarinic agents differ in their pharmacological profiles, e.g. muscarinic receptor affinity and other modes of action, in their pharmacokinetic properties, e.g. lipid solubility and half-life, and in their formulation, e.g. immediate release (IR) or extended release (ER) and transdermal.

The evaluation of cure/improvement of UI using oxybutynin and tolterodine IR formulations is made harder by the lack of a standard definition of improvement. Outcome measures vary and are not standardised, and never use 'cure' as a primary outcome. Meta-analysis of the published evidence is therefore not always possible.

There have been many publications of variable quality about the pharmacological treatment of the overactive bladder (OAB), including several systematic reviews and meta-analyses. The systematic reviews, published in 2009 (1), on behalf of the US Agency for Healthcare Research and Quality (AHRQ) and the Oregon Health and Science University (2), have collated together much of the relevant evidence. As well as the studies included in these reviews, the Panel have examined studies published since these reviews up until July 2010.

Dry mouth is the commonest side effect though others include constipation, blurred vision, fatigue and congnitive dysfuction. When people have a dry mouth they may be inclined to drink more but it is not clear whether this adversely influences the effect of the drug.

*4.1.1 **Immediate-release antimuscarinic agents***

The IR formulation of oxybutynin is the prototype drug in the treatment of UUI. Oxybutynin IR provides maximum dosage flexibility, including an off-label 'on-demand' use. Immediate-release drugs have been the only available formulation for many years. They have a greater risk of side effects than ER formulations because of their higher plasma peak levels. A transdermal delivery system (TDS) and gel developed for oxybutynin has improved its safety profile while maintaining efficacy.

4.1.1.1 Question

In adults with UI, are IR formulations of antimuscarinic drugs, and TDS application of oxybutynin, more effective than placebo in reducing UI episodes and achieving continence?

4.1.1.2 Evidence

Four systematic reviews of individual antimuscarinic drugs versus placebo were included by the Panel for this section (1-4).

A systematic review and meta-analysis by Chapple et al. in 2008 (2), which updated previous reviews, showed that oxybutynin IR versus placebo was better for improvement and cure of UUI. In patients receiving oxybutynin IR, 15 mg daily, there were statistically significant improvements compared to placebo. However, the absolute changes in incontinence episodes were small. Treated patients were 3.53 times more likely to achieve complete continence than controls (7-11). Similar changes have been reported for tolterodine IR, 4 mg daily, versus placebo (12-20), although the changes reported for tolterodine IR, 2 mg daily, were smaller

than for the higher dose (15-19). With propiverine IR, a cure of incontinence was 1.8 times more likely than with placebo (21-23). For trospium IR, no cure rates were available (24).

Randomised controlled trials of oxybutynin TDS versus placebo and other oral formulations have shown a significant improvement in the number of incontinence episodes and micturitions per day.

In Staskin et al. oxybutynin topical gel was superior to placebo for improvement of UUI with a higher proportion of participants being cured (25).

Evidence summary	**LE**
Oxybutynin IR and transdermal, tolterodine IR, and propiverine IR provide a significantly better rate of cure/improvement compared to placebo.	1a
Trospium IR provides significantly better reduction in incontinence episodes than placebo.	1a

*4.1.2 **Extended-release and longer-acting antimuscarinic agents***

4.1.2.1 Question

In men and women with UUI, do oral extended-release and longer-acting antimuscarinic drugs cure or improve the symptoms of UUI compared with no treatment?

4.1.2.2 Evidence

Most studies included patients with OAB, with a mean age of 55-60 years. Because most patients were women, the results can be generalised to women, but not to men. The reported rates for improvement or cure of UUI were only short term (up to 12 weeks). The evidence reviewed was consistent, indicating that ER formulations of antimuscarinics offer clinically significant short-term cure rates and improvement rates for UUI.

A comprehensive review of antimuscarinic therapy by the AHRQ was published in 2009. The references to individual RCTs included in this review have not been listed separately for this section (1).

Darifenacin
Two RCTs compared darifenacin to placebo, involving 838 patients (681 women). One study included only patients older than 65 years. The second study by Hill et al. found that darifenacin was superior to placebo for cure of UUI. No new data comparing darifenacin with placebo have been published since the AHRQ and Oregon Health and Science University systematic reviews, published in 2009 (1,2).

Fesoterodine
Two randomised trials have been reported since the AHRQ review (4,5). Both trials compared fesoterodine, 8 mg/day, versus tolterodine ER, 4 mg/day, versus placebo. The first study reported higher cure rates with fesoterodine than with placebo, but also higher rates of dry mouth. In the second study, the cure rates were also higher than with placebo, but again with higher rates of dry mouth. These trials are consistent with previous reports showing the effectiveness of fesoterodine compared to no treatment (placebo) described in the AHRQ and Oregon systematic reviews (1-3).

Oxybutynin
None of the identified studies that compared oxybutynin ER with placebo included incontinence as a measured outcome. One study reported that oxybutynin ER produced less cognitive disturbance than placebo (6).

Tolterodine
A study of mostly women (n = 361) compared tolterodine ER, transcutaneous oxybutynin, and placebo (7). Tolterodine ER resulted in a significantly higher chance of cure than placebo. Another study (8) in 337 incontinent men and women calculated the daytime incontinence outcomes in a secondary analysis of data from a previous study of tolterodine ER in OAB with nocturia. The analysis found higher cure rates of UUI using tolterodine ER. These data are consistent with the studies summarised in the AHRQ and Oregon systematic reviews (1,2) showing that tolterodine was effective for improvement of UUI compared to placebo.

Propiverine
We found three RCTs comparing propiverine ER with placebo, all with improvement of UUI as an outcome (9-11). All trials showed propiverine ER had a significant benefit over placebo in terms of improvement (11) and cure (9,10). Adverse effects reported included dry mouth and a prolonged QTc interval (9,10).

Solifenacin
Karram et al. reported a study in 707 patients comparing solifenacin and placebo, although their primary outcome measure was urgency rather than incontinence (12). Cure rates for urgency were 58% for solifenacin and 42% for placebo. Concerning an improvement in UUI, there have been no high-quality studies published since the AHRQ and Oregon systematic reviews (1,2), which already contained useful data on improvement in UI with solifenacin.

Trospium
Several authors (13-15) have done a secondary analysis of two previously published studies of trospium ER versus placebo (16,17). Cure rates for UUI were reported as 21% with trospium ER and 11% with placebo (14).

Evidence summary	**LE**
ER formulations of antimuscarinic agents are effective for improvement and cure of UUI.	1b
ER formulations of antimuscarinic agents result in higher rates of dry mouth compared to placebo.	1b
The clinical significance of prolonged QT for propiverine is uncertain.	3

4.2 Comparison of antimuscarinic agents

Head-to-head comparison trials of the efficacy and side effects of different antimuscarinic agents can help clinicians and patients to decide on the best initial agent to use, and the most appropriate second-line agent to try if the initial agent provides little benefit or has troublesome side effects.

4.2.1 ***Question***

In adults with UUI, does one type of antimuscarinic drug result in a greater likelihood of cure or improvement in UUI, and/or a greater improvement in QoL, and/or a lesser likelihood of adverse effects compared to an alternative antimuscarinic drug?

4.2.2 ***Evidence***

There is a considerable body of evidence covering this question, comprising over 40 RCTs and five systematic reviews. Nearly all the primary studies have been funded and sponsored by the manufacturer of the newer drug under evaluation, which forms the experimental arm of the RCT. It was noted that upward dose titration is often included in the protocol for the experimental arm, but not for the comparator arm (Table 4).

Table 4: Description of trials comparing antimuscarinic agents

Comparison of agents	No. of trials
Experimental IR agent vs. standard IR drug	11
Experimental ER agents vs. standard IR drug	19
Experimental ER agents vs. standard ER drug	12
Transcutaneous oxybutynin vs. standard IR oral drug	1
Transcutaneous oxybutynin vs. standard oral ER drug	1

In general, these studies have been designed for regulatory approval. They have a short treatment duration of typically 12 weeks and a primary outcome of a change in OAB symptoms rather than a cure of, or an improvement in, UUI, which were generally analysed as secondary outcomes. It is therefore difficult to use the results from these trials in daily clinical practice to select the best first-line drug or second-line alternative following the failure of initial treatment. A quality assessment carried out as part of the most recent systematic review (1) found that all the trials were of low or moderate quality.

Two, recent, high-quality systematic reviews from the USA included RCTs published up to the end of October 2008 (1,2). One review specifically addressed evidence of the comparative efficacy of antimuscarinic drugs (2). A European review included drugs not available in the USA and included literature published up to the end of August 2008 (3). Both reviews broadly agreed with two earlier reviews (4,5). Between December 2008 and July 2010 (the literature search cut-off date for the present review), two further relevant trials were published (6,9).

For cure of UI, there was weak evidence that oxybutynin ER was more effective than tolterodine ER (1,7). Three recent studies found some evidence that fesoterodine, 8 mg daily, was better than tolterodine ER, 4 mg daily, for cure of UI (6,8,9).

For improvement in UI, there was weak evidence that both oxybutynin ER and tolterodine ER were superior to tolterodine IR (2,3), and that oxybutynin ER was superior to tolterodine ER (3,7). The meta-analysis by Chapple et al. (4), which concluded that solifenacin was better than tolterodine IR for improving UI, has been challenged by more recent systematic reviews, which have concluded that there is no difference (1,2). Evidence from two trials where improvement in UI was the primary outcome suggests greater benefit is obtained with fesoterodine, 8 mg daily, compared with tolterodine ER, 4 mg daily (6,10). All other comparisons showed no difference in efficacy for improvement of UI.

There was no evidence that any one antimuscarinic agent improved QoL more than another agent (1).

Dry mouth is the most prevalent and most studied adverse effect of antimuscarinic agents. Good evidence indicates that, in general, ER formulations of both short-acting drugs and longer-acting drugs are associated with lower rates of dry mouth than IR preparations (1,3). Oxybutynin IR showed higher rates of dry mouth than tolterodine IR and trospium IR, but lower rates of dry mouth than darifenacin, 15 mg daily (1,3). Overall, oxybutynin ER had higher rates of dry mouth than tolterodine ER, but generally oxybutynin did not have higher rates for moderate or severe dry mouth. Transdermal oxybutynin was associated with a lower rate of dry mouth

than oxybutynin IR and tolterodine ER, but had an overall higher rate of withdrawal due to an adverse skin reaction (1). Solifenacin, 10 mg daily, had higher rates of dry mouth than tolterodine ER (1). Fesoterodine, 8 mg daily, had a higher rate of dry mouth than tolterodine, 4 mg daily (6,10). In general, discontinuation rates were similar for each treatment arm in comparative RCTs, irrespective of differences in the occurrence of dry mouth.

In conclusion, there is no consistent evidence for the superiority of one antimuscarinic agent over another for the cure or improvement of UI. Recent trials with incontinence as the primary outcome suggest that fesoterodine, 8 mg daily, is superior to tolterodine ER, 4 mg daily, but meta-analysis is required to determine the size of effect. There is good evidence that ER, once-daily, and transdermal preparations, are associated with lower rates of dry mouth than ER preparations, although discontinuation rates are similar.

Evidence summary	**LE**
There is no consistent evidence that one antimuscarinic drug is superior to an alternative antimuscarinic drug for cure or improvement of UUI.	1a
The ER formulation of oxybutynin is superior to the ER and IR formulations of tolterodine for improvement of UUI.	1b
Fesoterodine, 8 mg daily, is more effective than tolterodine ER, 4 mg daily, for cure and improvement of UUI.	1b
ER and once-daily formulations of antimuscarinic drugs are generally associated with lower rates of dry mouth than IR preparations, although discontinuation rates are similar.	1b
A transdermal oxybutynin (patch) is associated with lower rates of dry mouth than oral antimuscarinic drugs, but has a high rate of withdrawal due to skin reaction.	1b
Oxybutynin IR or ER shows higher rates of dry mouth than the equivalent formulation of tolterodine.	1a
There is no evidence that any particular antimuscarinic agent is superior to another for improvement in QoL.	1a

4.3 Antimuscarinic drugs versus non-drug treatment

The choice of drug versus non-drug treatment of UUI is an important question for many clinicians. Especially in less economically developed countries, conservative treatment remains a cheap, effective alternative treatment to drug therapy, with a low risk of side effects.

4.3.1 ***Question***

In adults with UUI, does one type of antimuscarinic drug result in a greater likelihood of cure or improvement in UUI and/or greater improvement in QoL, and/or lesser likelihood of adverse effects compared to an alternative non-drug treatment?

4.3.2 ***Evidence***

There is a large body of evidence comparing non-drug and drug treatment, including more than 100 RCTs and four, recently published, high-quality reviews (1-4). Most of these studies were not funded by the pharmaceutical industry, whose main focus is on drug treatment rather than on conservative treatment.

The US Health Technology Appraisal found that trials were of low- or moderate-quality with none categorised as high quality. The main focus of the review was to compare the different drugs used to treat UUI. Non-drug treatments were mentioned only in the evidence tables for the treatment of UUI. This review included studies comparing behavioural and pharmacological treatments. Nine studies, including one prospective cohort study and eight RCTs, provided direct comparisons between behavioural and pharmacological treatment arms. The behavioural approaches included bladder training, multicomponent behavioural approaches and electrical stimulation. Only one of these studies showed superiority for behavioural therapy. In one study, multicomponent behavioural modification produced significantly greater reductions in incontinence episodes compared to oxybutynin, and higher patient satisfaction for behavioural versus drug treatment.

The Health Technology Appraisal included a comparison between procedural and pharmaceutical treatments, including one RCT that showed a substantial benefit for sacral neuromodulation compared with medical therapy (5).

The most recently published systematic review in 2010 (3) found that medication was less effective than behavioural therapy in a comparative effectiveness trial (81% vs. 69% reduction in UI episodes). In addition, the use of antimuscarinic agents had side effects.

Two older RCTs (6,7), in only small patient groups, reported a similar improvement in subjective parameters with either transcutaneous electrical nerve stimulation or Stoller afferent nerve stimulation. However, only oxybutynin-treated patients showed significant improvements in objective urodynamic parameters (capacity). The oxybutynin-treated group had more side effects.

An important question addressed by multiple studies is how well the combination of antimuscarinic drugs and behavioural therapy compare to either treatment alone. This has been previously discussed in Section 3.3 Behavioural therapy/scheduled voiding. In summary, although medication may enhance the effect of behavioural therapy, there is no evidence that behavioural therapy enhances the effect of drugs.

In conclusion, there is no consistent evidence for the superiority of antimuscarinic drugs over non-drug treatments, especially behavioural treatment. More side effects have been reported for drug therapy compared to non-drug treatment. Electrical stimulation appears to be inferior to other treatment alternatives. Several trials have suggested that a combination of drug and behavioural therapy produce the best results, including in long-term follow-up.

Evidence summary	**LE**
There is no consistent evidence to show superiority of drug therapy or behavioural therapy.	1b
Behavioural treatment results in increased patient satisfaction versus drug treatment alone.	1b

4.4 Antimuscarinic agents: adherence and persistence

Most studies on antimuscarinic medication provide information only about short-term outcomes (12 weeks), with a smaller number of trials providing longer-term follow-up data. However, it is recognised that in clinical practice many patients stop taking their medication rather more readily than tends to occur in RCTs, where the methodology tends to enhance adherence to allocated medication.

4.4.1 ***Question***

Do patients with UUI adhere to antimuscarinic drug treatment and persist with prescribed treatment everyday clinical practice?

4.4.2 ***Evidence***

Twelve papers have been published on adherence/persistence to antimuscarinic medication in everyday clinical practice (1-12). Ten papers used established pharmaco-epidemiological parameters (1-7,9-11), including:

- Persistence. This is calculated from the index date until the patient discontinues treatment or is lost to follow-up, or the maximum follow-up period has ended, whichever occurs first.
- Medication possession rate (MPR). This is the total days of medication dispensed, except for the last refill, divided by the number of days between the first date on which medication was dispensed and the last refill date.
- Adherence ratio (MPR $\geq$ 0.8). This is the percentage of patients with MPR $\geq$ 0.8.

One study was in an open-label extension population (8). One study used only self-reports of patients and did not follow patients from the start of treatment (12). Most of the data was not derived from RCTs, but from pharmacy refill records. Pharmacy records are likely to overestimate adherence and persistence, because it is often not clear whether patients have been monitored from the start of treatment or whether monitoring (for the purpose of the study) was started in patients already taking the drug for some time and therefore defined as persistent users.

The main drugs studied in adherence/persistence trials were oxybutynin IR and ER and tolterodine IR and ER. These reviews demonstrated high non-persistence rates for tolterodine at 12 months, and particularly high rates (68-95%) for oxybutynin (1-3,5,6).

Five articles reported 'median days to discontinuation' as between < 30 days and 50 days (2,3,5,6,10), with one study reporting 273 days in a military health system (which provides patients with free medication) (6).

Only one RCT (8) included solifenacin, darifenacin and trospium. The only open-label extension study included

in the review also studied solifenacin, darifenacin and trospium. However, determining adherence/persistence in an open-label extension population is not the preferred methodology, as these patients will not have been monitored from the start of treatment and are therefore self-selected as persistent patients.

Several of the RCT trials tried to identify the factors associated with a lower, or low, adherence or persistence of antimuscarinic agents (2,6,7,9). These were identified in order of importance as:

- low level of efficacy (41.3%);
- adverse events (22.4%);
- cost (18.7%), as most adherence measures were higher in populations, which did not pay for medication, e.g. patients with health insurance (6).

Other reasons for poor adherence included:

- IR versus ER formulations;
- age, with persistence lower among younger adults;
- unrealistic expectations of treatment;
- gender distribution, because adherence/persistence was better in studies that include relatively more female patients;
- ethnic group because African-Americans and other minorities were more likely to discontinue or switch treatment;
- effectiveness of treatment because in Campbell et al. only 52% were somewhat satisfied to very satisfied with treatment.

In addition, the source of data influenced the adherence figures.

Evidence summary	**LE**
More than half of patients will stop antimuscarinic agents within the first 3 months because of ineffectiveness, adverse events and cost.	2

4.5 Antimuscarinic agents, the elderly and cognition

Although the prevalence of UI increases with age, this is not reflected by research targeted to elderly people with UI. Drug trials usually exclude patients with several comorbidities and those taking multiple medications. However, the mechanisms underlying UI in the elderly are more likely to be multifactorial than in younger patients. The elderly are also likely to be taking medications that may affect the efficacy or adverse effects of a new drug.

Muscarinic receptors exist throughout the body and are involved in many physiological processes. Most anticholinergics used to treat OAB are directed against the M2 and M3 receptors. The M1 receptor is involved in memory processes. The specificity of a drug for one or another receptor and the degree of penetration into the CNS through the blood-brain barrier may impact on cognitive function. In recent years, the effects of antimuscarinic agents on cognition have been studied in more detail.

4.5.1 ***Question***

What is the comparative efficacy, and risk of adverse effects, particularly the cognitive impact, of treatment with antimuscarinic medication in elderly men and women with UUI compared to younger patients?

4.5.2 ***Evidence***

There have been two systematic reviews of antimuscarinic agents in elderly patients (1,2). One review was confined to evidence on nursing home residents with UUI (2). A community-based cohort study on the burden of antimuscarinic drugs in an elderly population (n = 372) found a high incidence of cognitive dysfunction (3). The Oregon systematic review of treatments for OAB reported specifically on outcomes in elderly patients (4).

There have been very few trials specifically investigating the cognitive changes that might occur with the use of antimuscarinic agents. Most trials have been done in healthy volunteers of different age groups and only for a short period (varying from a single dose to 12 weeks). Other publications describe post-hoc analyses of other trials or reviewed only a number of selected publications. In general, these trials have measured CNS side effects in a non-specific way that does not allow the impact on cognition to be considered in a particular patient population (5,6). Meta-analyses have been limited by study heterogeneity, dosing inconsistency and reporting bias. There is a need for more detailed, standardised measurement of age-stratified CNS outcomes in clinical trials to provide better information to patients and clinicians about the CNS risks associated with antimuscarinic agents.

Studies on antimuscarinic effects have been done in elderly persons (7), and in people with dementia with UUI (8). There have been no specific studies in vulnerable patient populations, who are likely to have cognitive dysfunction and might suffer deterioration of their cognitive function due to using antimuscarinic medication.

Although there have been no RCTs specifically designed to examine the impact of antimuscarinic medication on elderly patients compared with younger patients, it is possible to extract relevant evidence from several RCTs, which have provided outcomes for specific age groups, and other studies of the risks/benefits of antimuscarinic agents in an elderly population. There are many case studies that report adverse effects of antimuscarinic agents in elderly patients, particularly those with serious cognitive dysfunction. There are also a number of studies that address the cardiovascular risk, which is mainly associated with antimuscarinic agents, in this age group. It should be noted that the definition of an elderly patient and the exclusion criteria vary from study to study.

Oxybutynin

There is substantial evidence that oxybutynin may cause or worsen cognitive dysfunction in adults (5,7,9).

A crossover RCT in elderly volunteers given oxybutynin IR reported increased cognitive dysfunction with oxybutynin, while a short-term RCT of oxybutynin ER in elderly women with cognitive dysfunction observed no increase in delirium (10).Two studies in the elderly demonstrated additional benefit from oxybutynin IR combined with scheduled voiding versus scheduled voiding alone. Another study found no differences between oxybutynin ER and IR in elderly patients, although the study did not reach its recruitment target (11).

A large observational study (n = 3536) suggested that more rapid functional deterioration might result from the combined use of cholinesterase inhibitors with antimuscarinic agents in elderly patients with cognitive dysfunction (12). However, the nature of the interaction with cholinesterase inhibitors is unclear. No general conclusions can be made, but caution is advised in prescribing these combinations.

Solifenacin
One pooled analysis from several RCTs (13) has shown that solifenacin has good efficacy and does not increase cognitive impairment in the elderly. Another RCT found no age-related differences in the pharmacokinetics of solifenacin between elderly, middle-aged or younger patients. One post-marketing surveillance study reported more frequent adverse events in subjects over 80 years old. Another study on healthy elderly volunteers showed no cognitive effect (9).

Tolterodine
Pooled data from RCTs showed no change in efficacy or side effects related to age, but reported a higher discontinuation rate for both tolterodine and placebo in elderly patients (5). Two RCTs of tolterodine specifically designed in the elderly found that tolterodine showed a similar efficacy and side effect profile, as in younger patients. Post-hoc analysis from other RCTs has shown little effect on cognition.

Darifenacin
Two RCTs carried out specifically in the elderly population (one RCT in patients with UUI and the other RCT in volunteers) concluded that darifenacin was effective and had no cognitive side effects (16,17). Another comparison between darifenacin and oxybutynin ER in elderly subjects concluded that the two agents had a similar efficacy, but that cognitive function was more often affected in patients receiving oxybutynin ER (7).

Trospium chloride and fesoterodine
No published evidence was found regarding the comparative efficacy and side effect profiles of trospium or fesoterodine in the elderly compared with younger patients. However, there is good evidence that trospium does not impair cognitive function.

Applicability of evidence to general elderly population
It is not clear how much the data from pooled analyses and subgroup analyses from large RCTs can be extrapolated to a general ageing population. The community-based studies of the prevalence of antimuscarinic side effects in this age group may be the most helpful (3).

When starting anticholinergic medication in patients at risk of worsening cognitive function, it has been suggested that mental function is assessed objectively and monitored to detect any significant changes during treatment (18).

Evidence summary	**LE**
Oxybutynin IR may worsen cognitive function.	1b
Trospium chloride has not been reported to affect cognitive function.	1b
Solifenacin, tolterodine and darifenacin have not been shown to impair cognitive function in healthy volunteers.	3
Oxybutynin ER, 5 mg/day, does not cause delirium in the short term in cognitively impaired elderly women.	1b
Oxybutynin IR is less effective in people with impaired orientation, cerebral cortical underperfusion and reduced bladder sensation.	2
The effectiveness and risk of adverse events of solifenacin, tolterodine and darifenacin do not differ with patient age.	3
There is conflicting evidence about whether the efficacy of antimuscarinic drugs is different in elderly people compared to younger populations.	3

Recommendations for antimuscarinic drugs	GR
Offer IR or ER formulations of antimuscarinic drugs as initial drug therapy for adults with urgency urinary incontinence.	A
If IR formulations of antimuscarinic drugs are unsuccessful for adults with urgency urinary incontinence, offer ER formulations or longer-acting antimuscarinic agents.	A
Consider using transdermal oxybutynin if oral antimuscarinic agents cannot be tolerated due to dry mouth.	B
Offer and encourage early review (of efficacy and side effects) of patients on antimuscarinic medication for urgency urinary incontinence (< 30 days).	A
When prescribing antimuscarinic drugs to elderly patients, be aware of the risk of cognitive side effects, especially in those receiving cholinesterase inhibitors.	C
Avoid using oxybutynin IR in patients who are at risk of cognitive dysfunction.	A
Consider use of trospium chloride in patients known to have cognitive dysfunction.	B
Use solifenacin, tolterodine and darifenacin with caution in patients with cognitive dysfunction.	B
Do an objective assessment of mental function before treating patients whose cognitive function may be at risk.	C
Check mental function in patients on antimuscarinic medication if they are at risk of cognitive dysfunction.	C

IR = Immediate release; ER = extended release.

4.5.3 ***Research priority***

As it is difficult to predict the longer-term benefit from the effect seen in short-term trials, it is recommended that cure of UUI should be a primary outcome measure in future research.

4.6 Duloxetine

Duloxetine inhibits the presynaptic re-uptake of the neurotransmitters, serotonin (5-HT) and norepinephrine (NE) leading to an increase in levels of these neurotransmitters in the synaptic cleft. In the sacral spinal cord, an increased concentration of 5-HT and NE in the synaptic cleft increases stimulation of 5-HT and NE receptors on the pudendal motor neurones, which in turn increases the resting tone and contraction strength of the urethral striated sphincter.

4.6.1 ***Questions***

- In adults with SUI, does duloxetine cure or reduce UI and/or improve QoL compared to no treatment?
- In adults with SUI, does duloxetine result in a greater cure or improvement of incontinence, or a greater improvement in QoL or a lesser likelihood of adverse effects, compared to any other intervention?

4.6.2 ***Evidence***

Duloxetine was evaluated as a treatment for female SUI or MUI in two systematic reviews (1,2) including 10 RCTs (3-12). The typical dose of duloxetine was 80 mg daily, with dose escalation up to 120 mg daily allowed in one study (4), over a period of 8-12 weeks. One RCT extended the observation period up to 36 weeks and used the Incontinence Quality of Life (I-QoL) score as a primary outcome (6).

The studies provided reasonably consistent results demonstrating improvement in UI compared to placebo. There were no clear differences between SUI and MUI. One study reported cure for UI in about 10% of patients (3). An improvement in I-QoL was not found in the study using I-QoL as a primary endpoint (6). A further study compared duloxetine, 80 mg daily, with PFMT alone, PFMT + duloxetine, and placebo (13). Duloxetine reduced leakage compared to PFMT or no treatment. Global improvement and QoL were better for combined therapy than no treatment. There was no significant difference between PFMT and no treatment.

The long-term effect of duloxetine in controlling SUI was evaluated by two open-label studies with a follow-up of 1 year or more (14,15). However, the studies had high rates of discontinuation.

Duloxetine, 80 mg daily, which could be increased up to 120 mg daily, was investigated in a 12-week study in patients, who had OAB but not SUI (16). Episodes of UUI were also significantly reduced by duloxetine.

One study (17) compared PFMT + duloxetine versus PFMT + placebo, for 16 weeks, followed by 8 weeks of PFMT alone in males with post-prostatectomy incontinence. Duloxetine + PFMT significantly improved UI, but the effect did not last to the end of the study, indicating that duloxetine only accelerates cure and does not increase the percentage of patients cured.

In general, all studies had a high patient withdrawal rate of about 20-40% of patients in short-term studies and up to 90% in long-term studies. The high withdrawal rate was caused by a combination of a lack of efficacy and a high incidence of adverse events, including nausea and vomiting (40% or more of patients), dry mouth, constipation, dizziness, insomnia, somnolence and fatigue.

Evidence summary	**LE**
Duloxetine does not cure incontinence.	1b
Duloxetine, 80 mg daily, can modestly improve episodes of SUI and UUI in women and men.	1b
Duloxetine causes significant gastrointestinal and CNS side effects leading to a high rate of treatment discontinuation.	1b

Recommendations	**GR**
Duloxetine should not be offered to women or men who are seeking a cure for their incontinence.	A
Duloxetine can be offered to women or men who are seeking temporary improvement in incontinence symptoms.	A
Duloxetine should be initiated using dose titration because of high adverse effect rates.	A

4.7 Intravaginal oestrogen

Oestrogen treatment for UI can be given orally, vaginally or even intravesically. Oral oestrogen has been shown to worsen UI. Topical oestrogen treatment has less systemic effect and is not associated with an increased risk for cancer or thromboembolism. Topical treatment is used to treat urogenital disorders in post-menopausal women.

*4.7.1 **Question***

In women with UI, does intravaginal oestrogen cure or improve UI compared to no treatment?

*4.7.2 **Evidence***

A recent Cochrane systematic review looked at the use of oestrogen therapy in post-menopausal women (1). The review identified 33 trials, with a total of 19,313 incontinent women, including 1,262 women who were given local oestrogen therapy. There is also a more recent narrative review of oestrogen therapy in urogenital diseases (2). However, since the Cochrane review, no new RCTs have been published up to July 2010. Evidence from a large RCT showed that systemic oestrogen therapy leads to an increased incidence of UI in post-menopausal women, including both SUI and UUI (3).

Local oestrogen therapy can be given as conjugated equine, oestriol or oestradiol in vaginal pessaries, vaginal rings or creams. Besides improving vaginal atrophy (4), local oestrogen therapy reduces incontinence and frequency and urgency in OAB. Local oestrogens were more effective than placebo at improving or curing UI, and reducing frequency (1). The current data do not allow differentiation among the various types of oestrogens or delivery methods. Moreover, the ideal duration of this type of therapy and the long-term effects have been poorly studied.

In conclusion, the evidence for the use of oestrogens in UI is consistent, but is only available in post-menopausal women. This means that any conclusions can only be applied to post-menopausal women with UI. Thus, post-menopausal women taking oral oestrogens should be advised that they have an increased risk for developing or worsening UI. Local oestrogens can be used to reduce incontinence, urgency and frequency in post-menopausal women.

Evidence summary	LE
Systemic oestrogen therapy can worsen existing UI and carries an increased risk of UI developing in post-menopausal women.	1a
Local oestrogen therapy in post-menopausal women can at least temporarily improve or cure UI.	1a
There is no evidence available on the neoadjuvant or adjuvant use of local oestrogens at the time of surgery for UI.	1a

Recommendations	GR
Women using systemic oestrogen should be counselled that they have an increased risk for developing urinary incontinence or worsening of their existing incontinence.	A
Offer post-menopausal women with urinary incontinence local oestrogen therapy, although the ideal duration of therapy and best delivery method are unknown.	A
Advise post-menopausal women who are taking oral oestrogens that they have an increased risk for developing urinary incontinence or worsening of their existing urinary incontinence.	A

4.8 Desmopressin

Desmopressin is a synthetic analogue of vasopressin (also known as antidiuretic hormone), which increases water re-absorbtion in the renal collecting ducts without increasing blood pressure. It can be taken orally, nasally or by injection. Desmopressin is most commonly used to treat diabetes insipidus and, when used at night, to treat nocturnal enuresis.

*4.8.1 **Questions***

- In adults with nocturnal UI, does desmopressin cure or reduce nocturnal UI and/or improve QoL compared to no treatment?
- In adults with nocturnal UI, does desmopressin result in a greater cure or improvement in nocturnal UI, or a greater improvement in QoL or a lesser likelihood of adverse effects, compared to any other intervention?

*4.8.2 **Evidence***

4.8.2.1 Improvement of incontinence

Most studies of desmopressin in UI have been designed to investigate its effect on nocturia. Few studies have examined the use of desmopressin exclusively for the treatment of UI. Only two RCTS have compared desmopressin to placebo with UI as an outcome measure. A pilot RCT study (n = 128) in women demonstrated improved incontinence during the first 4 hours after taking desmopressin (1). An RCT in 176 men and women with OAB concluded that continuous use of desmopressin improved frequency and urgency, but did not improve UI (2). There is no published evidence reporting desmopressin cure rates for UI and no evidence that compares desmopressin with other non-drug treatments for UI.

4.8.2.2 Monitoring for hyponatraemia

Importantly, the use of desmopressin carries a risk of developing hyponatraemia (12%) (3). Elderly patients started on this drug should have their serum sodium checked regularly, beginning in the first few days after starting treatment.

Evidence summary	LE
The risk of UI is reduced within 4 hours of taking oral desmopressin, but not after 4 hours.	1b
Continuous use of desmopressin does not improve or cure UI.	1b
Regular use of desmopressin may lead to hyponatraemia.	3

Recommendations	GR
Offer desmopressin to patients requiring occasional short-term relief from urinary incontinence, inform them that this drug is not licensed for this indication.	B
Do not use desmopressin for long-term control of urinary incontinence.	A

*4.8.3 **References***

5. SURGICAL TREATMENT

Surgery for the treatment of UI is usually considered as an option in pathways of care only after the failure of conservative therapy or drug treatment, although the emergence of minimally invasive procedures with low rates of adverse effects may modify this principle in the future. The aim of all operations for incontinence is to make patients continent, usually by allowing them to store urine normally. However, the mechanisms for achieving this vary widely.

Some generic principles apply to good surgical practice. Any operation for UI should be preceded by a discussion with the patient and/or carers, about the purpose of the operation, the likely benefits and possible risks. It is also important to explain when there are alternative approaches, even if these procedures are not available locally. Surgeons performing operations for UI should be properly trained and perform an adequate number of procedures to maintain expertise. Most importantly, they should be able to demonstrate their competence by being aware of the outcomes of individual operations in their own hands, and should share this information with their patients.

Some newer surgical interventions can be very costly. The Panel is well aware that the availability of devices varies from one healthcare system to another. We have tried to recognise this in the recommendations by suggesting that procedures should be offered ‘when available’.

The section considers surgical options for the following situations:

- Women with uncomplicated SUI. This means no history of previous surgery, no neurological LUTD, no bothersome genitourinary prolapse, and not considering further pregnancy.
- Women with complicated SUI. Neurogenic LUTD is reviewed in the EAU Guidelines on Neurogenic Lower Urinary Tract Dysfunction (1).
- Associated genitourinary prolapse has not been included in these Guidelines, but will be reviewed for 2013.
- Men with SUI. This applies mainly to post-prostatectomy incontinence in men without neurological disease affecting the lower urinary tract.
- Patients with refractory DO incontinence.

5.1 Women with uncomplicated SUI

*5.1.1 **Open and laparoscopic surgery for SUI***

The open ‘Burch’ colposuspension aims to approximate the lateral tissues of the vaginal vault to the pectineal

ligament by means of insertion of several, interrupted, non-absorbable sutures. The operation has been much modified over the years, most notably as the vagino-obturator shelf procedure. This has provided less elevation of the vaginal wall by inserting suspensory sutures into the obturator fascia instead of the pectineal ligament.

Autologous fascial slings have been used for many years to provide support or elevation to the mid- or proximal urethra. Again, there have been many different descriptions of this technique.

For decades, open colposuspension has been considered the gold standard surgical intervention for SUI, and has often been used as the comparator in RCTs of new, less invasive, surgical techniques. These include laparoscopic techniques, which have enabled colposuspension to be performed with a minimally invasive approach.

Although the outcome of open and laparoscopic procedures should be considered in absolute terms, it is also important to consider any associated complications, adverse events and costs. The outcome parameters used to evaluate surgery for SUI have included:

- continence rate and number of incontinence episodes;
- general and procedure-specific complications;
- generic, specific (UI) and correlated (sexual and bowel) QoL.

The large number of RCTs available for standard review and meta-analysis suggest that the evidence can be generalised to all women with SUI. There is also a good degree of consistency between the different RCTs.

5.1.1.1 Question

In women with SUI, what is effectiveness of open and laparoscopic surgery, compared to no treatment or compared to other surgical procedures, measured in terms of cure or improvement of incontinence or QoL, or the risk of adverse events?

5.1.1.2 Evidence

Four systematic reviews were found, which covered the subject of open surgery for SUI, including 46 RCTs (1-4), but no RCTs comparing any operation to a sham procedure.

Open colposuspension

The Cochrane review (6) included 46 trials (4738 women) having open colposuspension. In most of these trials, open colposuspension was used as the comparator to an experimental procedure. Consequently, for this review we have only considered the absolute effect of colposuspension but have not reviewed all of these comparisons. No additional trials have been reported since this review.

Within the first year, complete continence rates of approximately 85-90% were achieved for open colposuspension, while failure rates for incontinence were 17% up to 5 years and 21% over 5 years. The re-operation rate for incontinence was 2%, but there was a higher rate of development of genitourinary prolapse than for other open operations.

Seven trials, covered by the review, compared open colposuspension to needle suspension. These trials found similar levels of effectiveness at 85-90% and lower rates of failure at 5 years for the Marshall Marchetti Krantz procedure.

Open colposuspension was compared with conservative treatment in one small study (7). One trial compared open colposuspension with antimuscarinic treatment, while another compared it with periurethral injection of bulking agents. Colposuspension resulted in superior outcomes, but had significantly higher rates of adverse events.

Four trials compared Burch colposuspension to the Marshall Marchetti Krantz procedure and one trial evaluated Burch colposuspension with paravaginal repair in both cases showing fewer surgical failures up to 5 years but otherwise similar outcomes.

Anterior colporrhaphy

Anterior colporrhaphy is now mainly considered to be an obsolete operation for UI. In a Cochrane review (3), 10 trials compared anterior colporrhaphy (385 women) with colposuspension (627 women). The failure rate for incontinence at follow-up of up to 5 years was worse for anterior colporrhaphy with a higher requirement for re-operation for incontinence.

Autologous fascial sling
The Cochrane review (5) described 26 RCTs, including 2284 women undergoing autologous sling procedure in comparison to other operations. The trials did not identify those women undergoing repeat surgery for recurrent UI. No further studies have been reported.

There were seven trials of autologous fascial sling versus colposuspension. Except for one very high-quality study (8), most of the studies were of variable quality, with a few very small studies, and a short follow-up. The meta-analysis showed that fascial sling and colposuspension had a similar efficacy at 1 year. Colposuspension had a lower risk of voiding difficulty and UTIs, but a higher risk of bladder perforation.

In 12 trials of autologous fascial sling versus mid-urethral synthetic slings, the procedures showed similar efficacy. However, use of the synthetic sling resulted in shorter operating times and lower rates of complications, including voiding difficulty. Six trials compared autologous fascial slings with other materials of different origins, with results favouring traditional autologous fascial slings. There were no trials compared traditional suburethral slings with anterior colporrhaphy, laparoscopic retropubic colposuspension or the artificial urinary sphincter device.

Laparoscopic colposuspension
The Cochrane review (2) identified 22 RCTs, of which 10 trials compared laparoscopic colposuspension to open colposuspension. No other trials have been identified. Although these procedures had a similar subjective cure rate, there was limited evidence suggesting the objective outcomes were less good for laparoscopic colposuspension. However, laparoscopic colposuspension had a lower risk of complications and shorter duration of hospital stay.

In eight RCTs comparing laparoscopic colposuspension to self-fixing slings, the subjective cure rates were similar, while the objective cure rate favoured the mid-urethral sling at 18 months. Complication rates were similar for the two procedures and operating times were shorter for the mid-urethal sling.

Evidence summary	**LE**
Anterior colporrhaphy has lower rates of cure for UI especially in the longer term.	1a
Open colposuspension and autologous fascial sling are similarly effective for cure of SUI in women.	1b
Laparoscopic colposuspension has similar efficacy to open colposuspension for cure of SUI and a similar risk of voiding difficulty or de-novo urgency.	1a
Laparoscopic colposuspension has a lower risk of other complications and shorter hospital stay than open colposuspension.	1a
Autologous fascial sling has a higher risk of operative complications than open colposuspension, particularly voiding dysfunction and post-operative UTI.	1b

*5.1.2 **Mid-urethral slings***

The description of tension-free support for mid-urethra using a synthetic sling was an important new concept in the treatment of women with urodynamic SUI, which led to the development of synthetic mesh materials and devices to allow minimally invasive insertion (1). Early clinical studies identified that slings should be made from monofilament, non-absorbable material, typically polypropylene, and constructed as a 1-2 cm wide mesh with a relatively large pore size (macroporous). Mid-urethral slings are now the most frequently used surgical intervention in Europe for women with SUI.

*5.1.2.1 **Questions***

In women with SUI, what is the effectiveness in curing SUI and adverse effects at 1 year of:

- mid-urethral synthetic sling insertion compared to Burch colposuspension?
- one method of insertion of a mid-urethral synthetic sling compared to another method?
- one direction of insertion of a mid-urethral synthetic sling compared to another direction of insertion?

5.1.2.2 Evidence

For the purposes of this guideline, a new meta-analysis was performed.

Mid-urethral sling insertion compared to colposuspension

Thirteen RCTs (n = 1037) compared mid-urethral sling (retropubic) and colposuspension (open and laparoscopic). The meta-analysis found no difference in patient-reported cure rates at 12 months (2-15). The overall patient-reported cure rate was 75%. There was weak evidence of higher clinician-reported cure rates at 12 months after mid-urethral sling (83%) compared to colposuspension (78%) (7-15). However, longer-term follow-up for up to 5 years reported no difference in effectiveness, though the numbers of participants lost to follow-up was high (5,12,13). Voiding dysfunction was more likely for colposuspension (relative risk 0.34; 95%CI 0.16-0.7) whilst bladder perforation was higher for the mid-urethral sling (15% vs. 9%, and 7% vs. 2%, respectively) (3,4,14,16,17).

A single randomised trial, comparing the mid-urethral sling (transobturator) with open colposuspension, reporting similar rates of patient-reported and clinician-reported cure and no evidence of differential harms (18). In all the trials, operative time and duration of hospital stay was shorter for women randomised to insertion of the mid-urethral synthetic sling.

Transobturator route versus retropubic route

Thirty-four RCTs (5786 women) compared insertion of the mid-urethral sling by the retropubic and transobturator routes. There was no difference in cure rates at 12 months in either patient-reported or clinically reported cure rates (77% and 85%, respectively) (20-49). Voiding dysfunction was less common (4%) following transobturator insertion compared to retropubic insertion (7%), as was the risk of bladder perforation (0.3%) or urethral perforation (5%). Similarly, the risks of de-novo urgency and vaginal perforation were 6% and 1.7%, respectively. Chronic perineal pain at 12 months after surgery was reported by 21 trials and meta-analysis of these data showed strong evidence of a higher rate in women undergoing transobturator insertion (7%) compared to retropubic insertion (3%).

Insertion using a skin-to-vagina direction versus a vagina-to-skin direction

A Cochrane systematic review and meta-analysis found that the skin-to-vagina direction (outside in) for retropubic insertion of mid-urethral slings was less effective than the vagina-to-skin (inside out) direction and was associated with higher rates of voiding dysfunction, bladder perforation, and vaginal erosion (50). A further systematic review and meta-analysis found that the skin-to-vagina (outside in) direction of transobturator insertion of mid-urethral slings was equally effective compared to the vagina-to-skin route (inside out) using direct comparison. However, indirect comparative analysis gave weak evidence for a higher rate of voiding dysfunction and bladder injury (51). These differences in adverse effects were not found in the Cochrane review, which only used the limited amount of direct head-to-head comparative data and found no differences in effectiveness or adverse effects (50).

Generalisability of evidence to adult women with SUI

Analysis of the heterogeneity of trials in this meta-analysis suggests that the evidence is generalisable to women, who have predominantly SUI, and no other clinically severe lower genitourinary tract dysfunction. The evidence is not adequate to guide choice of surgical treatment for those women with MUI, severe pelvic organ prolapse, or a history of previous surgery for SUI.

The results of the EAU Panel meta-analysis were consistent with those of the Cochrane systematic review (52), except that in our meta-analysis the objective cure rates appeared slightly higher for retropubic (88%) compared to transobturator insertion (84%). The Panel finding is consistent with an additional systematic review and meta-analysis (53), and the difference may result from the Panel's decision to only consider trial data with at least 12 months of follow-up. The cure rates at 12 months in our meta-analysis for mid-urethral sling were similar to those calculated in the meta-analysis for the American Urological Association guidelines (54). In addition, our results and recommendations are consistent with those of the Society of Obstetricians and Gynaecologists of Canada (55) and those of the UK National Institute for Health and Clinical Excellence (66).

Evidence summary	**LE**
Compared to colposuspension, the retropubic insertion of a mid-urethral synthetic sling gives equivalent patient-reported cure of SUI and superior clinician-reported cure of SUI at 12 months.	1a
Compared to colposuspension, the transobturator insertion of a mid-urethral synthetic sling gives equivalent patient-reported and clinician-reported cure of SUI at 12 months.	2
Insertion of a mid-urethral synthetic sling by the transobturator route gives equivalent patient-reported and clinician-reported cure rates at 12 months compared to retropubic insertion.	1a
The skin-to-vagina direction of retropubic insertion of mid-urethral sling is less effective than a vagina-to-skin direction.	1a
Mid-urethral sling insertion is associated with a lower rate of a new symptom of urgency, and voiding dysfunction, compared to colposuspension.	1a
The retropubic route of insertion is associated with a higher intra-operative risk of bladder perforation and a higher rate of voiding dysfunction than the transobturator route.	1a
The transobturator route of insertion is associated with a higher risk of chronic perineal pain at 12 months than the retropubic route.	1a
The skin-to-vagina direction of both retropubic and transobturator insertion is associated with a higher risk of post-operative voiding dysfunction.	1b

5.1.3 ***Single-incision slings***

There is continued innovation to reduce the invasiveness of procedures for SUI. Single-incision mid-urethral slings have been introduced on the basis of providing mid-urethral support, using a variety of modifications to a short macroporous polypropylene tape. These modifications allow the tape to be fixed to the retropubic tissues, endopelvic fascia or obturator fascia, while avoiding the troublesome complications of obturator nerve injury or passage through the gracilis muscle or skin of the inner thigh, or through the retropubic space. These procedures are usually performed as day cases under local anaesthesia.

5.1.3.1 Questions

- In women with SUI, do 'single-incision' slings cure UI or improve QoL, or cause adverse outcomes?
- How does a 'single-incision' sling compare to other surgical treatments for SUI?

5.1.3.2 Evidence

Although there have been many studies published on single-incision devices, it should be noted that there are significant differences in design between devices and it may be misleading to make general statements about them as a class of operations.

One systematic review has been published (1), which included RCTs and quasi-RCTs, comparing single-incision slings to either retropubic or transobturator mid-urethral slings. The literature search included non-English trials and unpublished studies. A further systematic review is currently being undertaken by the Cochrane centre (2).

The nine RCTs in the current Cochrane review included 758 participants, who were followed up for a mean of 9.5 months. There was poor reporting of allocation concealment, as well as poorly reported randomisation, resulting in a high risk of bias. One centre provided several of the studies. Seven studies included only patients with tension-free vaginal tape secure (TVTS). The remaining two studies include only patients with a Miniarc® device.

Meta-analysis showed that the outcome of single-incision sling insertion was consistently worse compared with mid-urethral slings in terms of patient-reported cure of UI. Single-incision techniques had a shorter operating time, lower blood loss and and lower pain levels compared to a standard mid-urethral sling. One RCT found no difference in effectiveness between two different methods of insertion of the TVTS® device with 12 months' follow-up (3). One RCT designed to compare the TVTS device to a standard retropubic mid-urethral sling in 280 women found a significantly lower objective cure at 2 months for TVTS and a higher complication rate and was terminated early (4). Another RCT (5) compared the TVTS device to a standard transobturator mid-urethal sling but was underpowered to show a statistical difference between the techniques. A small, three-treatment arm, phase II RCT compared standard transobturator mid-urethral sling to TVTS and Miniarc® devices [6]. The results suggested that cure rates were lower for TVT but no statistical analysis was presented.

A more recent RCT comparing the TVTS device to standard transobturator mid-urethral sling, not included in the Cochrane review, demonstrated a lower objective cure rate and lower pain levels for the TVTS device [7].

Another recent non-randomised study compared the TVTS to the Curemesh® device showed no difference in outcomes at a minimum of 15.5 months (8). Similarly, a quasi-RCT comparing a standard transobturator mid-urethral sling to a Contasure® device found no difference in cure of UI or adverse events (9).

There are a number of case series with a minimum of 12 months' follow-up, including five series using the Miniarc device (10-15), two series using the TVTS device (11,16) and one series using the Minitape® device (17). The 12-month outcomes range from 52% objective cure to 92% subjective cure. Results from one study reporting outcome at 2 years found that only 10% of included participants remained cured (17). One study reported a 24% rate of de-novo urgency but generally there were few reported adverse effects (11).

There are no RCTs relating to the Solyx® device. There is one retrospective review of 63 women with short-term follow-up (18), and one report of 12 months' follow-up of the Ophira® device 176 women (19). These studies did not report outcomes of interest for these Guidelines.

Evidence summary	LE
Single-incision mid-urethral slings are effective in curing SUI in women in the short term.	1b
Operation times for insertion of single-incision mid-urethral slings are shorter than for standard retropubic slings.	1b
Blood loss and immediate post-operative pain are lower for insertion of single-incision slings compared with standard mid-urethral slings.	1b
Single-incisions slings are less effective than other mid-urethral slings at medium-term follow-up*.	1b
There is no evidence that other adverse outcomes from surgery are more or less likely with single-incision slings than with standard mid-urethral slings.	1b

**NB: Most evidence on single-incision slings comes from studies using the tension-free vaginal tape secure (TVTS) device.*

5.1.4 ***Adjustable sling***

Voiding dysfunction is an adverse effect of anti-incontinence procedures and may require further intervention such as clean intermittent self-catheterisation. One possible cause is overcorrection of the anatomical deformity by the sling. Adjustable slings seek to overcome this problem because they enable the tension of the newly implanted sling to be increased or decreased, either during or shortly after the operation. An adjustable sling aims to optimise the balance between correcting the SUI, while allowing normal voiding to continue. However, this concept has not been adequately tested. There is still no evidence to show that being able to adjust the tension of a sling has a beneficial effect on outcome.

5.1.4.1 Questions

- In women with SUI, does an adjustable sling cure SUI and improve QoL or does it cause adverse outcome(s)?
- How does an adjustable sling compare to other surgical treatments for SUI?

5.1.4.2 Evidence

There are no RCTs investigating outcome of adjustable sling insertion for women with SUI. There is limited data from cohort studies on adjustable tension slings with variable selection criteria and outcome definition. Few studies include sufficient numbers of patients or have a long enough follow-up to provide useful evidence. The available devices have differing designs, making it difficult to use existing data to make general conclusions about adjustable slings as a class of procedure. Three adjustable sling devices were reviewed: Remeex®, Safyre®, Ajust®. The latter is an adjustable single-incision sling.

Remeex®

Two cohort studies included a total of 155 patients and had more than 22 months' follow-up (1,2). The results showed that at least 86% of women had objective cure of SUI, with re-adjustment of the device required in up to 16% of women.

Saffyre®

Two cohort studies included a total of 208 patients with a minimum of 12 months follow-up (3,4). The reported cure rate was up to 92% with adverse effects of late vaginal erosion in 8% and dyspareunia in 11% (3).

Ajust®
A single cohort study reported an 80% success rate (patient's global impression of improvement) in 90 women after 12 months of follow-up.

Evidence summary	LE
Adjustable mid-urethral synthetic sling devices may be effective for cure or improvement of SUI in women.	3
There is no evidence that adjustable slings are superior to standard mid-urethral slings.	4

*5.1.5 **Bulking agents***

Injection of a bulking agent into the submucosal tissues of the urethra is thought to increase the coaptation of the urethral walls, in turn leading to increased urethral resistance and improved continence. Whether this is achieved through causing obstruction or improving the mucosa-to-mucosa sealing is unknown. The recommended site of injection varies with the bulking agent, and numerous materials have been developed for this use over 20 years (see below). They are injected transurethrally or paraurethrally under urethroscopic control, or alternatively using a purpose-made device (implacer), which reliably positions the needle-tip under local anaesthetic at the required position in the urethral wall.

5.1.5.1 Question

In women with SUI, does injection of a urethral bulking agent cure SUI or improve QoL, or cause adverse outcomes?

5.1.5.2 Evidence

There is one Cochrane systematic review (1), which reported on 12 RCTs or quasi-RCTs of injectable agents. In general, the trials were only of moderate quality and small, and many of them had been reported in abstract form. Wide confidence intervals meant a meta-analysis was not possible. Since the Cochrane review, two further RCTs have been reported (2,3).

Each injectable product has been the subject of many case series. Short-term efficacy in reducing the symptoms of SUI has been demonstrated for all materials used. In 2006, NICE published an extensive review of these case series (4). These case series have added very little to the evidence provided by RCTs. There has been only one placebo-controlled RCT, in which an autologous fat injection was compared with the placebo of a saline injection.

Polytetrafluoroethylene (Polytef)

There are no RCTs available. NICE 2006 (4) did not recommend this treatment because of the high incidence of adverse events.

Glutaraldehyde cross-linked bovine collagen (Contigen)

Most evidence from RCTs of the efficacy of collagen comes from six trials, in which collagen has been used as a comparator to an experimental synthetic product (see below). This implies that collagen has been regarded as the 'gold standard' bulking agent. In one RCT, collagen was compared to open surgery (5).

Autologous fat
One study found no difference in efficacy between autologous fat and saline injection (22% vs. 20% improvement at 3 months, respectively) (6). Due to a fatality from fat embolism, NICE 2006 (4) and the Cochrane Review (1) made a strong recommendation that this treatment should not be used.

Silicon particles (Macroplastique™)
Silicon particles have been compared to collagen in two RCTs, only one of which has been published as a full article (7). No significant difference in efficacy was found.

Carbon beads (Durasphere™)
Carbon beads have been compared to collagen in two RCTs (3,8). Although one study lacked appropriate statistical power, the other was a good-quality study (n = 235), with 12 months' follow-up, that showed no difference in efficacy.

Calcium hydroxylapatite (CaHA) (Coaptite™)
A study with small sample size comparing collagen to hydroxylapatite found the failure rate was significantly higher at 6 months for collagen (6/18 vs. 3/22, respectively) (9).

Ethylene vinyl alcohol copolymer (EVOH) (Uryx™)
There is one RCT (n = 210), comparing ethylene copolymer to collagen, which demonstrated similar efficacy at 6 months' follow-up (10).

Porcine dermal implant (Permacol™)
There is one very small RCT comparing porcine dermis to silicon particles. There was no significant difference in failure rates between the two procedures at 6 months' follow-up (11).

Hydrogel cross-linked with polyacrilamide (BulkamidTM)
No RCT data are available. There is a single multicentre case series of 135 women, which reported 66% success rate with 35% participants requiring re-injection (12).

Non-animal stabilised hyaluronic acid/dextranomer (NASHA/Dx) (Zuidex™)
There is one RCT, comparing dextranomer (placed in mid-urethra) to collagen injection (at the bladder neck). At 12 months, results were inferior in women given dextranomer (13).

Stem cells
Early reports of dose-ranging studies (14) suggest that stem cell injection is a safe procedure in the short term. However, its efficacy (compared to its bulking effect) has yet to be established.

Comparison with open surgery
Two RCTs studies compared collagen injection to conventional surgery for SUI (autologous sling vs. silicon particles and collagen vs. assorted procedures). The studies reported greater efficacy but higher complication rates for open surgery. In comparison, collagen injections showed inferior efficacy but equivalent levels of satisfaction and fewer serious complications (5,15).

Another trial found that a periurethral route of injection can carry a higher risk of urinary retention compared to a transurethral injection (16). A recent small RCT found no difference in efficacy between a mid-urethral and bladder neck injection of collagen (2).

Evidence summary	**LE**
Periurethral injection of bulking agent may provide short-term improvement in symptoms (3 months), but not cure, in women with SUI.	2a
Repeat injections to achieve therapeutic effect are very common.	2a
Bulking agents are less effective than colposuspension or autologous sling for cure of SUI.	2a
Adverse effect rates are lower compared to open surgery.	2a
There is no evidence that one type of bulking agent is better than another type.	1b
Periurethral route of injection may be associated with a higher risk of urinary retention compared to transurethral route.	2 b

Recommendations for surgery for uncomplicated stress urinary incontinence in women	GR
Offer the mid-urethral sling to women with uncomplicated stress urinary incontinence as the preferred surgical intervention whenever available.	A
Offer colposuspension (open or laparoscopic) or autologous fascial sling to women with stress urinary incontinence if mid-urethral sling cannot be considered.	A
Warn women who are being offered a retropubic insertion synthetic sling about the relatively higher risk of peri-operative complications compared to transobturator insertion.	A
Warn women who are being offered transobturator insertion of mid-urethral sling about the higher risk of pain and dyspareunia in the longer term.	A
Warn women undergoing autologous fascial sling that there is a high risk of voiding difficulty and the need to perform clean intermittent self-catheterisation; ensure they are willing and able to do so.	A
Do a cystoscopy as part of retropubic insertion of a mid-urethral sling, or if difficulty is encountered during transobturator sling insertion, or if there is a significant cystocoele.	C
Women being offered a single-incision sling device for which an evidence base exists, should be warned that short-term efficacy is inferior to standard mid-urethral slings and that long-term efficacy remains uncertain.	C
Only offer single-incision sling devices, for which there is no level 1 evidence base, as part of a structured research programme.	A
Only offer adjustable mid-urethral sling as a primary surgical treatment for stress urinary incontinence as part of a structured research programme.	C
Do not offer bulking agents to women who are seeking a permanent cure for stress urinary incontinence.	A

5.2 Complicated SUI in women

This section will address surgical treatment for women who have had previous surgery for SUI, which has failed, or those women who have undergone previous radiotherapy affecting the vaginal or urethral tissues. Neurological lower urinary tract dysfunction is not considered because it is reviewed by the EAU Guidelines on Neurogenic Lower Urinary Tract Dysfunction (1). Women with associated genitourinary prolapse will be included in the next edition of these Guidelines in 2013.

*5.2.1 **Failed surgery***

The reported failure rates from any operation for SUI vary widely from 5-80%, depending on how failure was defined. Even using a very strict definition, this means that at least hundreds of the many thousands of women undergoing primary surgery for SUI will require further surgery for recurrent symptoms. A primary operation may fail from the start or may occur some years after the original procedure. There may be persistent or recurrent SUI, or the development of de-novo UUI or voiding difficulty. Expert opinion therefore considers careful urodynamic evaluation to be an essential part of the work-up of these patients.

However, the underlying reasons for failure are poorly understood. Consequently, which operation to offer women with failed previous surgery for UI is usually driven by individual clinician opinion about the mechanisms of failure, familiarity with certain procedures, and experience in personal series. Most surgeons believe the results of any operation will be inferior to the same operation used as a primary procedure and will warn their patients of this.

The Panel have limited their literature search to the surgical management of recurrent SUI. It is presumed that the management of de-novo UUI will follow the pathway recommended for the management of primary UUI and DO, starting with conservative management. The Panel has not addressed the management of voiding difficulty because this does not require further treatment for incontinence.

5.2.1.1 Question

In women who have recurrent SUI following previous corrective surgery, what is the best surgical treatment?

5.2.1.2 Evidence

Most data on surgery for SUI are for primary surgery. When secondary procedures are included, it is unusual

for the outcomes to be separately reported. Even if they are, the numbers of patients are usually too small to allow meaningful comparisons.

The 4th International Consultation on Incontinence included a review of this topic up until 2008, and the subject has also been reviewed by Ashok and Wang (1). Cochrane reviews of individual operative techniques have not included a separate evaluation of outcomes in women undergoing second-line surgery. However, there is a current protocol advising on this issue (2). A further literature review up until October 2011 has been carried out since that time by the EAU Panel with the following findings.

Three RCTs were found. Two of the trials compared Burch colposuspension to a biological sling in recurrent SUI (3,4). There was no difference in efficacy between the procedures, but the complication rates were higher for slings. Another small RCT (abstract only) compared retropubic mid-urethral sling to laparoscopic colposuspension in women with recurrent SUI and reported similar short-term cure rates and adverse events (5).

Post-hoc analysis of high-quality RCTs comparing one surgical procedure to another reported higher failure rates for SUI and higher rates for adverse effects in women who had had previous surgery for SUI. There was no difference in these rates between the compared procedures (4,6-8). A history of prior surgery for UI was not an independent predictor of failure at 2 years in women undergoing open colposuspension or autologous fascial sling (4).

One large non-randomised cohort study suggested that cure rates after more than two previous operations were 0% for open colposuspension and 38% for autologous sling (9).

Several cohort studies have reported outcomes for retropubic mid-urethral synthetic sling specifically for primary and secondary cases. There is conflicting evidence on the effectiveness of second-line retropubic sling insertion, with some series showing equivalent outcomes for primary and secondary cases (10-12) and other series showing inferior outcomes for secondary surgery (13,14). Other confounding variables make meaningful conclusions difficult. There appears to be no evidence supporting the concept that the original mid-urethral sling should be removed.

Many small case series report satisfactory outcomes for repeat procedures of many types, but this evidence is not suitable to generate guidance.

A systematic review of older trials of open surgery for SUI suggests that the longer-term outcomes of repeat open colposuspension may be worse than those seen with autologous fascial slings (15). Successful results have been reported from mid-urethral slings after various types of primary surgery, while good outcomes are reported for both repeat retropubic mid-urethral sling and for 'tightening' of existing mid-urethral slings, but data were limited to small case series only.

Finally, clinical guidelines have been developed by the Society of Obstetricians and Gynaecologists of Canada, based on a literature review and expert opinion. Unfortunately, the methodology and the rationale for grading decisions were not clear (16).

Evidence summary	**LE**
The risk of treatment failure from surgery for SUI is higher in women who have had prior surgery for incontinence or prolapse.	1b
Open colposuspension and autologous fascial sling appear to be as effective for first-time repeat surgery as for primary surgery.	1b
The mid-urethral sling is less effective as a second-line procedure than for primary surgery.	2

5.2.1.3 Research priority on failed SUI surgery

There is a need for well-structured research trials to compare surgical procedures in women who have had previous failed surgery for SUI.

*5.2.2 **External compression devices***

Some of the earliest techniques for treating SUI simply applied intra-corporeal compression external to the urethra. External compression devices are still widely used in the treatment of recurrent SUI after the failure of

previous surgery. They are also commonly used in women with neurological LUTD, in whom there is thought to be profound intrinsic failure of the sphincter mechanism, characterised by very low leak point pressures or low urethral closure pressures.

There are two intracorporeal external urethral compression devices available. They are the adjustable compression therapy (ACT) device and the artificial urinary sphincter (AUS). Using ultrasound or fluoroscopic guidance, the ACT device is inserted by placement of two inflatable spherical balloons on either side of the bladder neck. Each volume of each balloon can be adjusted through a subcutaneous port placed within the labia majora. More recently, an adjustable artificial urinary sphincter (Flowsecure) has been introduced. It has the added benefit of 'conditional occlusion', enabling it to respond to rapid changes in intra-abdominal pressure.

5.2.2.1 Question

- In women with SUI, does insertion of an external compressive device cure SUI, improve QoL or cause adverse outcomes?
- How do external compression devices compare to other surgical treatments for SUI?

5.2.2.2 Evidence

The major advantage of artificial sphincters over other anti-incontinence procedures is the perceived ability of women to be able to void normally. However, voiding dysfunction is a known side effect, with a lack of data making it difficult to assess its importance. Because of significant differences in design between devices and in selection criteria between case series, results obtained with specific devices cannot be extrapolated generally to the use of adjustable devices. A recent consensus report has standardised the terminology used for reporting complications arising from implantation of materials into the pelvic floor region (1).

Artificial urinary sphincter

The 2011 Cochrane review on AUS (2) applies only to men with post-prostatectomy incontinence. A previous review of mechanical devices concluded that there was insufficient evidence to support the use of artificial sphincters in women (3).

There are no RCTs regarding the AUS in women. There are a few case series in women, including four series (n = 611), with study populations ranging from 45 to 215 patients and follow-up ranging from 1 month to 25 years (4-7). Case series have been confounded by varying selection criteria, especially the proportion of women who have neurological dysfunction or who have had previous surgery. Most patients achieved an improvement in SUI, with reported subjective cures in 59-88% of patients. However, common side effects included mechanical failure requiring revision (up to 42% at 10 years) and explantation (5.9-15%). In a retrospective series of 215 women followed up for a mean of 6 years, the risk factors for failure were older age, previous Burch colposuspension and pelvic radiotherapy (6). Peri-operative injury to the urethra, bladder or rectum was also a high-risk factor for explantation (4).

Early reports of laparoscopically implanted AUS do not have sufficient patient populations and/or sufficient follow-up to be able to draw any conclusions (8,9).

Adjustable compression device

There are no RCTs on use of the ACT device. There are four case series (n = 349), with follow-up ranging from 5 to 84 months (11-14). An improvement in UI outcomes was reported, ranging from 47% objective cure to 100% subjective improvement. However, most patients required adjustment to achieve continence and 21% required explantation.

Evidence summary	**LE**
Implantation of an artificial sphincter may achieve continence in women with complicated SUI.	3
Implantation of the ACT device may improve complicated UI.	3
Failure and device explantation are common adverse effects of both the artificial sphincter and the adjustable compression device.	3
Explantation is more frequent in older women and among those who have had previous Burch colposuspension or pelvic radiotherapy.	3

Recommendations for surgery for complicated stress urinary incontinence in women	GR
The choice of surgery for recurrent stress urinary incontinence should be based on careful evaluation of the individual patient.	C
Women should be warned that the outcome of second-line surgical procedures is likely to be inferior to first-line treatment, both in terms of reduced benefit and increased risk of harm.	C
Offer implantation of AUS or ACT as an option for women with complicated stress urinary incontinence if they are available and appropriate monitoring of outcome is in place.	C
Warn women receiving AUS or ACT that there is a high risk of mechanical failure or a need for explantation.	C

AUS = Artificial Urinary Sphincter; ACT = Adjustable Compression Therapy.

5.3 Men with SUI

*5.3.1 **Bulking agents in men***

Injection of bulking agents has been used to try and improve the coaptation of a damaged sphincter zone. More recently, more modern compounds have been used to treat female and male SUI, e.g. bovine collagen (Contigen™), cross-linked polyacrylamide hydrogel (Bulkamid™) and dextranomer/hyaluronic acid copolymer (Deflux™), pyrolytic carbon particles (Durasphere™) and polymethylsyloxane (Macroplastique™). Initial reports showed limited efficacy in treating incontinence following radical prostatectomy incontinence (1,2).

5.3.1.1 Question

In men with post-prostatectomy incontinence or SUI, does injection of a urethral bulking agent cure SUI, improve QoL, or cause adverse outcomes?

5.3.1.2 Evidence

Most studies are case series with small sample sizes. Small cohort studies showed a lack of benefit using a number of different materials (3,4) However, polyacrylamide hydrogel resulted in limited improvement in QoL without curing the UI (4). A Cochrane review on the surgical treatment of post-prostatectomy incontinence found only one study that fulfilled the inclusion criteria (5). A prospective, randomised study compared the AUS to silicon particles (Macroplastique™) in 45 patients (1). Eighty-two per cent of patients receiving an AUS were continent compared to 46% of patients receiving silicone particles. In patients with severe incontinence, this difference was significant, but in patients with moderate and mild incontinence, the difference was less.

Evidence summary	**LE**
There is no evidence that bulking agents cure post-prostatectomy incontinence.	2a
There is weak evidence that bulking agents can offer temporary improvement in QoL in men with post-prostatectomy incontinence.	3
There is no evidence that one bulking agent is superior to another.	3

http://www.ncbi.nlm.nih.gov/pubmed/21491408

5.3.2 ***Fixed male sling***

As well as external compression devices and bulking agents, slings have been introduced to treat post-prostatectomy incontinence. Fixed slings are positioned under the urethra and fixed by a retropubic or transobturator approach. The tension is adjusted during the surgery and cannot be re-adjusted post-operatively.

For the restoration of continence by these male slings, two concepts are now being proposed:

- continence restoration by urethral compression (InVance®, TOMS , Argus®)
- continence restoration by repositioning the bulb of urethra (AdVance) (1).

In principle, the AUS can be used for all degrees of post-prostatectomy incontinence, while male slings are advocated for mild-to-moderate incontinence. However, the definitions of mild and moderate incontinence are not clear. The definition of cure, used in most studies, was no pad use or one security pad per 24 hours. Some authors used a stricter criterion of less than 2 g urine loss in a 24-hour pad test (2).

5.3.2.1 Question

In men with post-prostatectomy SUI, does insertion of a fixed suburethral sling cure SUI, improve QoL, or cause adverse outcomes?

5.3.2.2 Evidence

Concerning the surgical treatment of post-prostatectomy incontinence, three recent literature reviews are available (3-5). There are a large number of uncontrolled case series concerning men implanted with several types of slings (6-14).

For the repositioning sling (AdVance), the benefit after a mean follow-up of 3 years has been published on 136 patients (15). Data were available on at least 614 patients with a mean follow-up of between 3 months and 3 years (2,12,15-21). Subjective cure rates for the device vary between 8.6% and 73.7%, with a mean of 49.5%. Radiotherapy was a negative prognostic factor (13,21). Post-operative voiding dysfunction occurred in 5.7-1.3%, while erosions and chronic pain were uncommon (0-0.4%). The overall failure rate was about 20%.

For the compression sling (InVance), 5-year data were available on 27 patients, 3-year data were available on 45 patients, and 1-year data were available on an additional 177 patients (22,23-27) The cure rate for this device varied between 36% and 62.7%, with a mean of 51.8% (22,23,25,26). Radiotherapy was a negative prognostic factor. Infection occurred in 3.2-15%, while de-novo urgency was reported in 2.3-11.9% of patients. The overall failure rate was about 20%.

Evidence summary	**LE**
There is limited short-term evidence that fixed male slings cure post-prostatectomy incontinence in patients with mild-to-moderate incontinence.	3
Men with severe incontinence, previous radiotherapy or urethral stricture surgery have poor outcomes from fixed male slings.	3
There is no evidence that one type of male sling is better than another.	3

*5.3.3 **Adjustable slings in males***

Adjustability in male sling surgery attempts to adjust the tension of the sling post-operatively. Two main systems are used in men:

- The Remeex® system consists of tension wires, which are adjusted using a type of screwdriver that temporarily comes out of the suprapubic wound. Once the ideal tension is achieved, it is easy to dislodge the screwdriver and close the wound. It is possible to repeat the procedure later during secondary surgery.
- The Argus® system consists of a silicone cushion, which is placed under the urethra and tensioned by two silicone arms, positioned either retropubically or in a transobturator fashion. Re-adjustment is usually carried out several months after the initial implant, by tightening or loosening the tensioning arms during a second surgical intervention.

5.3.3.1 Question

In men with post-prostatectomy incontinence or SUI, does insertion of an adjustable suburethral sling cure SUI, improve QoL, or cause adverse outcomes?

5.3.3.2 Evidence

There are no prospective RCTs comparing adjustable male slings to any other procedure. Most studies consist of prospective or retrospective case series, with variable follow-up and different definitions of success. Some have been published only as conference abstracts.

Remeex® system

For the Remeex® system, only two abstracts, with conflicting findings, have been published. One study followed 19 patients for nearly 7 years and reported 70% success (1), with no explants, infections or erosions. The second study followed 14 patients for 25 months. Only 36% of patients were satisfied and multiple re-adjustments were needed. Mechanical failure was reported in 21% (2).

Argus® system

Data on the Argus® system have been reported for 404 men, but only four series have reported on more than 50 patients (3-6), with the longest follow-up being 2.4 years. Success rates varied between 17% and 91.6%, with a mean of 57.6% predominantly reporting a subjective cure. The number of implants requiring re-adjustment was reported as between 22.9% and 41.5% (5,7,8). Infection of the device occurred in 5.4-8% (3,6,9). Erosions were reported in 5-10% (9,10). Urethral perforations occurred in 2.7-16% (3,4,6). Pain at the implant site was usually only temporary, but chronic pain has been reported (4,8,10,11). These complications resulted in explantation rates of 10-15% (5,8).

Evidence summary	LE
There is limited evidence that adjustable male slings are effective at curing SUI in men.	3
There is limited evidence that early explantation rates are high.	3
There is no evidence that adjustability of the male sling offers additional benefit over other types of sling.	3

*5.3.4 **Compressive devices in males***

External compression devices can be divided into two types: circumferential and non-circumferential compression of the urethral lumen (1). The artificial urinary sphincter (AUS) has been used for more than 30 years and is the standard treatment for moderate-to-severe male SUI. Most data available on the efficacy and adverse effects of AUS implantation is from older retrospective cohort studies with RCTs not performed due to the lack of a comparator. Several modifications of the standard single-cuff transperineal technique have been described, including transcorporeal implantation, double-cuff implants and trans-scrotal approaches (2). Men considering insertion of an AUS should understand that they must be able to operate a scrotal pump, requiring adequate dexterity and cognitive function. If the ability of an individual to operate the pump is uncertain, it may not be appropriate to implant an AUS. There are several recognised complications of AUS implantation, e.g. mechanical dysfunction, urethral constriction by fibrous tissue, erosion and infection.

The non-circumferential compression devices consist of two balloons placed close to the anastomotic urethra. The balloons can be filled and their volume can be adjusted post-operatively through an intrascrotal port.

5.3.4.1 Question

In men with post-prostatectomy SUI, does insertion of an external compression device cure SUI, improve QoL, or cause adverse outcomes?

5.3.4.2 Evidence

Artificial urinary sphincter

Although the AUS is considered to be the standard treatment for men with SUI, the quantity and level of evidence is low. There are no well-designed prospective RCTs with most information gained from older case series (2). More recent case series confirm the previous data (3,5). A continence rate of about 80% can be expected, while this may be lower in men who have undergone pelvic radiotherapy (3).

Trigo Rocha et al. published a prospective cohort study on 40 patients with a mean follow-up of 53 months (6). Pad use was reduced significantly and continence was achieved in 90%, with a significant improvement in QoL. The revision rate was 20%. From all urodynamic parameters, only low bladder compliance had a negative impact on the outcome, although another retrospective study showed that no urodynamic factors adversely altered the outcome of AUS implantation (7).

The penoscrotal approach was introduced to limit the number of incisions and to allow simultaneous implantation of penile and sphincter prostheses. It is uncertain whether this approach alters the outcome (8-10). The transcorporeal technique of placement can be used for repeat surgery but evidence of effectiveness is lacking (11,12).

The dual-cuff placement was introduced to treat patients who remained incontinent with a single 4-cm cuff in place. However, it has not improved control of continence, while the availability of a 3.5-cm cuff may have eliminated the need for a dual cuff (13-15). Patients who experienced complete continence after AUS implantation had a higher erosion risk (16).

Non-circumferential compression device (ProAct®)

There have been trials to treat post-prostatectomy SUI by insertion of a device consisting of balloons with adjustable volume external to the proximal bulbar urethra. A prospective cohort study (n = 128) described the functional outcome as 'good' in 68%, while 18% of the devices had to be explanted (17). A subgroup of radiotherapy patients only had 46% success and a higher percentage of urethral erosions.

A quasi-randomised trial comparing a non-circumferential compression device (ProAct®) with bone-anchored male slings found both types of device resulted in similar improvement of SUI (68% vs. 65%, respectively) (18). Other prospective series have shown similar continence outcomes, but several re-adjustments of the balloon volume were required to achieve cure. Adverse events were frequent, leading to an explantation rate of 11-58% (3,19-23). Although most studies have shown a positive impact on QoL, a questionnaire study showed that 50% of patients were still bothered significantly by persistent incontinence (24).

Evidence summary	**LE**
There is limited evidence that primary AUS implantation is effective for cure of SUI in men.	2b
Long-term failure rate for AUS is high although device replacement can be performed.	3
Previous pelvic radiotherapy does not appear to affect the outcome of AUS implantation.	3
Men who develop cognitive impairment or lose manual dexterity are likely to have difficulty operating an AUS.	3
Tandem-cuff placement is not superior to single-cuff placement.	3
The penoscrotal approach and perineal approach appear to give equivalent outcomes.	3
Very limited short-term evidence suggests that the non-circumferential compression device (ProACT®) is effective for treatment of post-prostatectomy SUI.	3
The non-circumferential compression device (ProACT®) is associated with a high failure and complication rate leading to frequent explantation.	3

Recommendations for surgery in men with stress urinary incontinence	GR
Only offer bulking agents to men with mild post-prostatectomy incontinence who desire temporary relief of UI symptoms.	C
Do not offer bulking agents to men with severe post-prostatectomy incontinence.	C
Offer fixed slings to men with mild-to-moderate post-prostatectomy incontinence.	B
Warn men that severe incontinence, prior pelvic radiotherapy or urethral stricture surgery, may worsen the outcome of fixed male sling surgery.	C
Offer AUS to men with persistent (more than 6 months) moderate-to-severe post-prostatectomy incontinence that has not responded to conservative management.	B
Warn about the long-term risk of failure and need for revision when counselling men for insertion of AUS.	C
Only offer the non-circumferential compression device (ProACT®) if arrangements for men with post-prostatectomy incontinence if arrangements for monitoring of outcome are in place.	C
Warn men considering a non-circumferential compression device (ProACT®) that there is a high risk of failure and subsequent explantation.	C
Do not offer non-circumferential compression device (ProACT®) to men who have had pelvic radiotherapy.	C

AUS = Artifical urinary sphincter.

5.4 Surgical interventions for refractory DO

*5.4.1 **Intravesical injection of botulinum toxin A***

Botulinum toxin (BTX) A injections into the bladder wall are being increasingly used to treat persistent or refractory UUI in adult women, as well as in men despite the lack of high-quality data on BTX in males. Almost all reported studies have used BTX A (1,2). Injection techniques have not been standardised and the various studies differ with reference to the number of injections, the sites of injection and the injection volumes (1,2). Surgeons must realise that there are different products of Botulinum Toxin, onabotulinumtoxina (Botox in Europe) and abobotulinumtoxina (Dysport in Europe) and that the doses are not interchangeable. The effects

of repeat injection have not been well studied in patients with UUI. The most important adverse event is an increase in PVR that may require clean intermittent catheterisation (CIC). CIC in turn is associated with an increased risk of UTIs (1,2).

5.4.1.1 Question

In adults with refractory UUI, does botulinum toxin injection in the bladder wall lead to a reduction in the number of incontinence episodes and/or to a higher percentage of continent patients compared to placebo?

5.4.1.2 Evidence

Two systematic reviews on the use of BTX have recently been published (1,2). The Cochrane analysis (1), which included patients with neurogenic or idiopathic DO, reported on RCTs comparing BTX with placebo. (It was not possible to draw conclusions about non-neurogenic incontinence from this review.) Reduction of incontinence episodes favoured BTX over placebo at both 4-6 weeks and 12 weeks. The mean difference in the reduction of incontinence episodes per day was -2.74 (95% CI: -4.47 to -1.01; p = 0.002). The rise in PVR favoured the placebo group, with a mean increase in PVR of 70.2 mL with the BTX. The question of the best injection technique remained largely unanswered. Studies were uniformly small with a maximum of 77 patients in any one study. Up to 66% of patients achieved complete continence, with an effect lasting between 3 and 12 months. The need for CIC was related to how aggressively patients are investigated for PVR. There was some evidence that lower doses produced fewer adverse events in terms of increased PVR and necessity for CIC. The UTI rates are consistently comparable to rates with cystoscopy alone but increase when CIC is required.

The systematic review by Mangera et al. (2) analysed the effect of BTX in adults with idiopathic DO in four RCTs (3-6). These studies (all using Onabotulinum toxin a) all demonstrated significant improvements in adults with idiopathic DO, at doses of 200 U in Brubaker et al. (4), 200/300 U in Flynn et al. (5) and 200 U in Sahai et al. (6). Dmochowski et al. compared a range of doses of BTX (3). These authors reported a change in incontinence episodes per day from baseline, but did not show the original baseline values, so that their results could not be included in the Mangera analysis. Additionally, an abstract from Tincello et al. (7) has recently reported results from the largest RCT of BTX to date. The study of 200 U Botox in 227 patients reported significant improvements in symptoms and QoL parameters versus placebo (7). The analysis of the efficacy data produced similar results to the Cochrane review.

The Cochrane and Mangera et al. reviews (1,2) also showed that the number of injection sites varied from 3 to 40, with 20 being most common, and the injection volume ranged between 3 and 30 mL, with 20 mL being the most common. The choice of injection site did not seem to impact on efficacy or adverse events. A range of 27-43% of patients had a PVR > 200 mL, while 13-44% suffered from UTI (1,2).

The Cochrane and Mangera et al. reviews accounted for all the major RCTs in BTX (1,2). However, cure-dry rates were not used as an outcome measure, and a separate meta-analysis using the original data (3,5-7) and data from a recent paper (8) was performed. Although the Dmochowski study (3) was not included in the analysis for the Mangera review, the EAU Panel have now obtained supplementary data from the authors, including dry rates at 6 and 12 weeks.

The meta-analysis (3,5-8) yielded the following results: the odds ratio (95% CI) of becoming dry with BTX versus placebo are 2.28 (0.95-5.49; p = 0.07) for 50 U, 4.39 (1.91-10.12; p = 0.0005) for 100 U, 4.96 (2.14-11.53; p = 0.0002) for 150 U, 4.34 (2.49-7.59, p < 0.00001) for 200 U and 7.05 (2.68-18.51, p < 0.0001) for 300 U. These results showed that 50 U had inferior efficacy to higher dosages. Although 300 U was the most efficacious dose, it is not a recommended dose because of the high rates of PVR necessitating CIC. A dose of 100-200 U seems to have comparable efficacy in the meta-analysis.

In the Dmochowski study, the cure-dry rate at 12 weeks was 37.0% and 50.9% for 100 U and 200U, respectively. Higher rates of PVR requiring CIC were found with higher doses showing a clear dose-response relationship (3).

Evidence summary	LE
A single treatment session of intravesical Onabotulinum toxin A (100-300 U) is more effective than placebo at curing and improving UUI for up to 12 months.	1a
There is no evidence that repeated injections of botulinum toxin A have reduced efficacy.	3
There is a high risk of increased PVR, which is dose dependent and may require intermittent self-catheterisation.	1b
There is a high risk of UTI in those who require intermittent self-catheterisation.	1b
There is no evidence that one technique of injecting botulinum toxin A is more efficacious than another.	1b

Recommendations	GR
Offer botulinum toxin A intravesical injections to patients with urgency urinary incontinence refractory to antimuscarinic therapy.	A
Warn patients of the possible need to self-catheterise and the associated risk of urinary tract infection; ensure that they are willing and able to do so.	A
Patients should also be warned of the licensing status of botulinum toxin A, and that the long-term effects remain unknown.	A

5.4.1.4. Research priorities

More research is needed to investigate the optimum injection technique and regimen, as well as the long-term effects of intravesical injection of botulinum toxin.

5.4.2 ***Sacral nerve stimulation (neuromodulation)***

Under fluoroscopic control, an electrode is placed percutaneously in the sacral foramen alongside a sacral nerve, usually S3, in the first stage of a two-stage implantation (FS2S). Once it has been shown that the patient can respond, the patient proceeds to the second stage of implantation, in which the electrode is connected

by cables under the skin to an implanted, programmable, pulse generator. The generator provides stimulation within established stimulation parameters. In earlier techniques for stimulating the sacral nerve, a temporary test (wire) electrode was placed near the nerve, and then percutaneous nerve evaluation (PNE) and test stimulation, provided by an external pulse generator, was performed. Generally, the PNE lasted for 5-7 days.

More recently, the permanent electrode has been used for a longer test phase, as part of a two-stage procedure. Once the PNE or FS2S has been shown to be successful, the patient proceeds to full implantation with the pulse generator. Patients, in whom selected symptoms of UUI are reduced by more than 50% during the test phase, are candidates for the permanent implant. Schmidt et al. first described the technique of PNE of the S3 sacral nerve (1). The two-stage implant was introduced by Janknegt et al. (2). Spinelli et al. introduced the minimally invasive percutaneous implantation of a tined lead (3).

5.4.2.1 Question

In adults suffering from refractory UUI, what is the clinical effectiveness of sacral nerve neuromodulation compared to alternative treatments?

5.4.2.2 Evidence

A Cochrane review of the literature until March 2008 (4) identified three RCTs that investigated sacral nerve stimulation in patients with refractory UUI. One of these RCTs was only published as an abstract and is not considered here (5,6). The quality of the other two RCTs was poor. No details of method of randomisation or concealment of randomisation were given. Assessors were not blind to the treatment allocation; it was impossible to blind the patients since all had to respond to a PNE before randomisation. In addition, the numbers randomised did not match the numbers in the results in these two studies.

One multicentre RCT involved implantation of half of the participants (5), while the remaining patients formed the control group (delayed implantation) staying on medical treatment for 6 months. The control group was subsequently offered implantation. Fifty percent of the immediately implanted group had > 90% improvement in UUI at 6 months compared to 1.6% of the control group (5). The other RCT (6) achieved similar results, although these patients had already been included in the first report (5). However, Weil et al. (6) showed that the effect on generic QoL measured by the SF-36, was unclear as it differed between the groups in only one of the eight dimensions.

The results of 17 case series of patients with UUI, who were treated early in the experience with sacral nerve stimulation were reviewed (7). After a follow-up duration of between 1 and 3 years, approximately 50% of patients with UUI, demonstrated > 90% reduction in incontinence, 25% demonstrated 50-90% improvement, and another 25% demonstrated < 50% improvement. Adverse events occurred in 50% of implanted cases, with surgical revision necessary in 33% (7).

In a subanalysis of the RCT, the outcome of UUI patients, with or without pre-implant DO were compared. Similar success rates were found in patients with and without urodynamic DO (8).

There are two case series describing the longer-term outcome of sacral nerve neuromodulation, with a mean or median follow-up of at least 5 years, in patients with refractory UUI (9,10). These studies have reported continued success (> 50% improvement on original symptoms) experienced by 50-63% in those patients available for follow-up. Only one study reported cure rates averaging 15% (10).

Technical modifications have been made, including a change in the anatomical site of the pulse generator, introduction of the tined lead and different test-phase protocols prior to definitive implantation. The lead may also be implanted using a minimally invasive percutaneous procedure (3). The effect of these changes on the outcome of implantation is uncertain.

Evidence summary	**LE**
Sacral nerve neuromodulation is more effective than continuation of failed conservative treatment for cure of UUI, but no sham controls have been used.	1b
In those patients who have been implanted, more than 50% improvement is maintained in at least 50% of patients at 5 years' follow up, and 15% remain cured.	3
One-stage implantation results in more patients receiving the final implant than occurs with prior temporary test stimulation.	4

Recommendations	GR
If available, offer patients with urgency urinary incontinence that is refractory to conservative therapy, the opportunity to be treated by sacral nerve neuromodulation before bladder augmentation or urinary diversion is considered.	A

5.4.2.3 Research priority

A RCT comparing a strategy of botulinum toxin injection, repeated as required, against a strategy of test and permanent sacral nerve neuromodulation with an accompanying health economic analysis is required.

5.4.3 ***Cystoplasty/urinary diversion***

5.4.3.1 Augmentation cystoplasty

In augmentation cystoplasty (also known as clam cystoplasty), a detubularised segment of bowel is inserted into the bivalved bladder wall. The aim is to disrupt involuntary detrusor contraction, increase compliance and increase bladder capacity. The segment of bowel most often used is distal ileum, but any bowel segment can be used if it has the appropriate mesenteric length to reach the pelvic cavity without tension. One study did not find any difference between bivalving the bladder in the sagittal plane and bivalving it in the coronal plane (1).

There are no RCTs comparing bladder augmentation to other treatments for patients with UUI. Most often, bladder augmentation is used to correct neurogenic DO or small-capacity, low-compliant, bladders caused by fibrosis, tuberculosis, radiation or chronic infection.

A number of case series have been reported (1-8), but none within the last 10 years. All these series included a large proportion of patients with neurological bladder dysfunction. The largest case series of bladder augmentation in UUI included 51 women with UUI (2). At an average follow-up of 74.5 months, only 53% were continent and satisfied with the surgery, whereas 25% had occasional leaks and 18% continued to have

disabling UUI. It is difficult to extract data on non-neurogenic patients from these case series, but in general the results for patients with idiopathic DO (58%) seemed to be less satisfactory than for patients with neurogenic overactivity (90%).

Adverse effects were common and have been summarised in a review over 5-17 years of more than 267 cases, 61 of whom had non-neurogenic UUI (9). In addition, many patients may require self CIC to obtain adequate bladder emptying.

.

Table 6: Complications of bladder augmentation

Short-term complications	**Affected patients (%)**
Bowel obstruction	2
Infection	1.5
Thromboembolism	1
Bleeding	0.75
Fistula	0.4
Long-term complications	
Clean intermittent self-catheterisation	38
Urinary tract infection	70% asymptomatic; 20% symptomatic
Urinary tract stones	13
Metabolic disturbance	16
Deterioration in renal function	2
Bladder perforation	0.75

5.4.3.2 Detrusor myectomy (bladder auto-augmentation)

Detrusor myectomy aims to increase bladder capacity and reduce storage pressures by incising or excising a portion of the detrusor muscle, to create a bladder mucosal 'bulge' or pseudodiverticulum. It was initially described as an alternative to bladder augmentation in children (10). An additional, non-randomised study (11), which compared bladder augmentation with detrusor myectomy in adult patients with neurogenic and non-neurogenic bladder dysfunction, demonstrated a much lower incidence of short-term complications. However, the poor long-term results caused by fibrosis of the pseudodiverticulum led to the abandonment of this technique in patients with neurogenic dysfunction. A small study of five patients with UUI (12) showed good outcome in all patients at the initial post-operative visit, but clinical and urodynamic failure in four of the five patients at 3 months.

5.4.3.3 Urinary diversion

Urinary diversion remains a reconstructive option for patients, who decline repeated surgery for UI. It is rarely needed in the treatment of non-neurogenic UUI. There are no studies that have specifically examined this technique in the treatment of non-neurogenic UI, although the subject has been reviewed by the Cochrane group (13).

Evidence summary	**LE**
There is limited evidence on the effectiveness of augmentation cystoplasty and urinary diversion in treatment of idiopathic DO.	3
Augmentation cystoplasty and urinary diversion are associated with high risks of short-term and long-term severe complications.	3
The need to perform clean intermittent self-catheterisation following augmentation cystoplasty is very common.	3
There is no evidence comparing the efficacy or adverse effects of augmentation cystoplasty with urinary diversion.	3
There is no evidence on the long-term effectiveness of detrusor myectomy in adults with idiopathic DO.	3

Recommendations	GR
Only offer augmentation cystoplasty to patients with detrusor overactivity incontinence who have failed conservative therapy, in whom the possibility of botulinum toxin and sacral nerve stimulation has been discussed.	C
Warn patients undergoing augmentation cystoplasty of the high risk of having to perform clean intermittent self-catheterisation; ensure they are willing and able to do so.	C
Do not offer detrusor myectomy as a treatment for urinary incontinence.	C
Only offer urinary diversion to patients who have failed less invasive therapies for the treatment of urinary incontinence and who will accept a stoma.	C
Warn patients undergoing augmentation cystoplasty or urinary diversion of the high risk of short-term and long-term complications, and the possible small risk of malignancy.	C
Life-long follow-up is recommended for patients who have undergone augmentation cystoplasty or urinary diversion.	C

APPENDIX A: MIXED URINARY INCONTINENCE

About one-third of women with UI have mixed incontinence (MUI), rather than pure stress UI (SUI) or urge UI (UUI). In addition, a mixed combination of symptoms becomes more common with increasing age. However, although many studies include patients with MUI, it is rare for these studies to provide a separate analysis of MUI. It is therefore difficult to find evidence specifically related to MUI.

This issue has been addressed by the Panel after the initial work on the preceding chapters had been completed. It was realised that a crucial part of developing the clinical algorithms was to provide advice on how to mange this large group of patients. A decision was therefore made to include a rapid review of this topic, but the iterative process underpinning the Panel's advice on this issue was necessarily shorter and less robust that for the preceding sections, and will be addressed more systematically for future editions.

A limited literature search was carried out from June 2008 for the terms, 'mixed incontinence' and 'mixed urinary incontinence' in PubMed. A separate search was also done for these terms within all known systematic reviews published since 2008 that had already been used for the rest of the guideline.

A.2 Question

In adults with MUI, is the outcome of a certain treatment different to that obtained with the same treatment in patients with either pure SUI or pure UUI?

A.3 Evidence

No specific systematic reviews were found that addressed the above question. Systematic reviews on conservative therapies, drug therapy and surgery were also reviewed for any analyses of specific incontinence categories, but none were found.

However, a Cochrane report on pelvic floor muscle training (1) concluded that training was less likely to result in a cure in patients with MUI than in patients with pure SUI, though it is not clear from the report how this conclusion was reached.

A.3.1 ***RCTs in MUI population, which compare one treatment to another***

An RCT in MUI patients compared intravaginal electrical stimulation to pelvic floor muscle training. No difference was seen in outcome, but this was a small underpowered study (2).

A.3.1.1 Duloxetine

In one RCT, involving 588 women, subjects were stratified into either stress-predominant, urge-predominant or balanced MUI groups and randomised to receive duloxetine or placebo. Duloxetine was effective in reducing episodes of incontinence and improving QoL compared to placebo in all subgroups (3).

A.3.1.2 Transvaginal obturator tape

In an RCT including 96 women with MUI, objective improvement was better for patients treated with transvaginal obturator tape + the Ingelman Sundberg operation versus patients treated with obturator tape alone (4).

A.3.1.3 Tolterodine

In an RCT of 854 women with MUI, tolterodine ER was effective compared to placebo in reducing frequency, urgency and UUI, but not SUI. These results show that the effect of tolterodine was not altered by the presence of SUI (5).

A.3.2 ***RCTs, including a subanalysis of MUI patients within treatment arms and allowing comparison to patients with pure SUI or pure UUI***

Many RCTs include both patients with pure UI (stress or urge) and patients with MUI, in which pure UI predominates. However, very few RCTs report separate outcomes for MUI and pure UI groups.

A small and underpowered RCT (n = 71) compared delivery of pelvic floor muscle training, with or without an instructive audiotape. It showed equal efficacy for different types of UI (6).

An RCT in 121 women with stress, urgency or mixed UI compared transvaginal electrical stimulation with sham stimulation and was found to be equally effective in urgency UI as in mixed UI (7).

A.3.2.1 Drugs

Duloxetine was found to have equal efficacy for Stress UI and Mixed UI in an RCT (n = 553) following

secondary analysis of subpopulations (8). In another study, secondary analysis showed that tolterodine compared to placebo (n = 1380) was equally effective in reducing urgency and urgency UI symptoms, regardless of whether there was associated stress incontinence (9). Similar findings apply to solifenacin (10,11).

A.3.2.2 Surgery

Post-hoc analysis of the SISTER trial showed that in women undergoing either autologous fascial sling or Burch colposuspension, the outcomes were poorer for women with a concomitant complaint of pre-operative urgency. This applied to both stress-specific and non-stress incontinence outcomes(12).

A similar post-hoc review of an RCT comparing transobturator and retropubic midurethral slings showed that the greater the severity of pre-operative urgency the more likely that treatment would fail, as assessed objectively, even if surgery had been similar (13).

However, an earlier study had found that surgery provided similar outcomes, whether or not urgency was present prior to surgery (14). (This study included only a few patients with urodynamic detrusor overactivity.)

A.3.3 ***Large cohort studies, including a separate analysis of patients with MUI***

Following a RCT of pelvic floor muscle training, a review of 88 women available for follow-up at 5 years found that outcomes were less satisfactory in women with MUI than in women with pure SUI (15).

A.3.3.1 Surgery for SUI

Some authors have reported the disappearance of urgency in up to 40% of women after successful SUI surgery for MUI, suggesting that urgency is an accompanying feature of SUI (14,16-18).

In a case series of 192 women undergoing midurethral sling insertion, overall satisfaction rates were lower for women with mixed symptoms and overactive detrusor function according to pre-operative urodynamics compared to those with pure SUI and normal urodynamics (75% vs 98%, respectively) (19). One study compared two parallel cohorts of patients undergoing surgery for SUI, with and without detrusor overactivity, and found inferior outcomes in women with MUI (20).

However, in a study of the bulking agent, Bulkamid, similar outcomes were reported in women with pure SUI and MUI (21).

One cohort of 450 women, undergoing midurethral sling surgery, had significantly worse outcomes for increased amounts of urgency. In urgency-predominant MUI, the success rate fell to 52% compared to 80% in stress-predominant MUI (22). In a second study in 1,113 women treated with transvaginal obturator tape, Stress UI was cured equally in stress-predominant MUI or urgency-predominant MUI. However, women with stress-predominant MUI were found to have significantly better overall outcomes than women with urgency-predominant MUI (23).

A.4 Evidence statements

Evidence summary	**LE**
Pelvic floor muscle training is less effective for mixed UI than for SUI alone.	2
Electrical stimulation is equally effective for mixed UI and SUI.	1b
Antimuscarinic drugs are equally effective in improving symptoms of urgency and urgency UI, in patients with mixed UI as in patients with urgency UI alone.	1a
Duloxetine is equally effective in improving SUI in patients with MUI as in patients with SUI alone.	1a
Women with mixed UI are less likely to be cured of their incontinence, by SUI surgery, than women with SUI alone.	1c
The response of pre-existing urgency symptoms to SUI surgery is unpredictable, and symptoms may improve or worsen.	3

A.5 Recommendations

Recommendations	GR
Treat the most bothersome symptom first in patients with mixed urinary incontinence.	C
Warn patients with mixed urinary incontinence that the chance of success of pelvic floor muscle training is less satisfactory than for stress urinary incontinence alone.	B
Offer antimuscarinic drugs to patients with urge-predominant mixed urinary incontinence.	A
Warn patients with mixed urinary incontinence that surgery is less likely to be successful than surgery in patients with stress urinary incontinence alone.	A

A.6 Research priority

There is a need for well-designed trials comparing treatments in populations with MUI, and in which the type of MUI has been accurately defined.

Researchers should be more precise about the definitions of MUI, when evaluating the effects of treatment in this group.

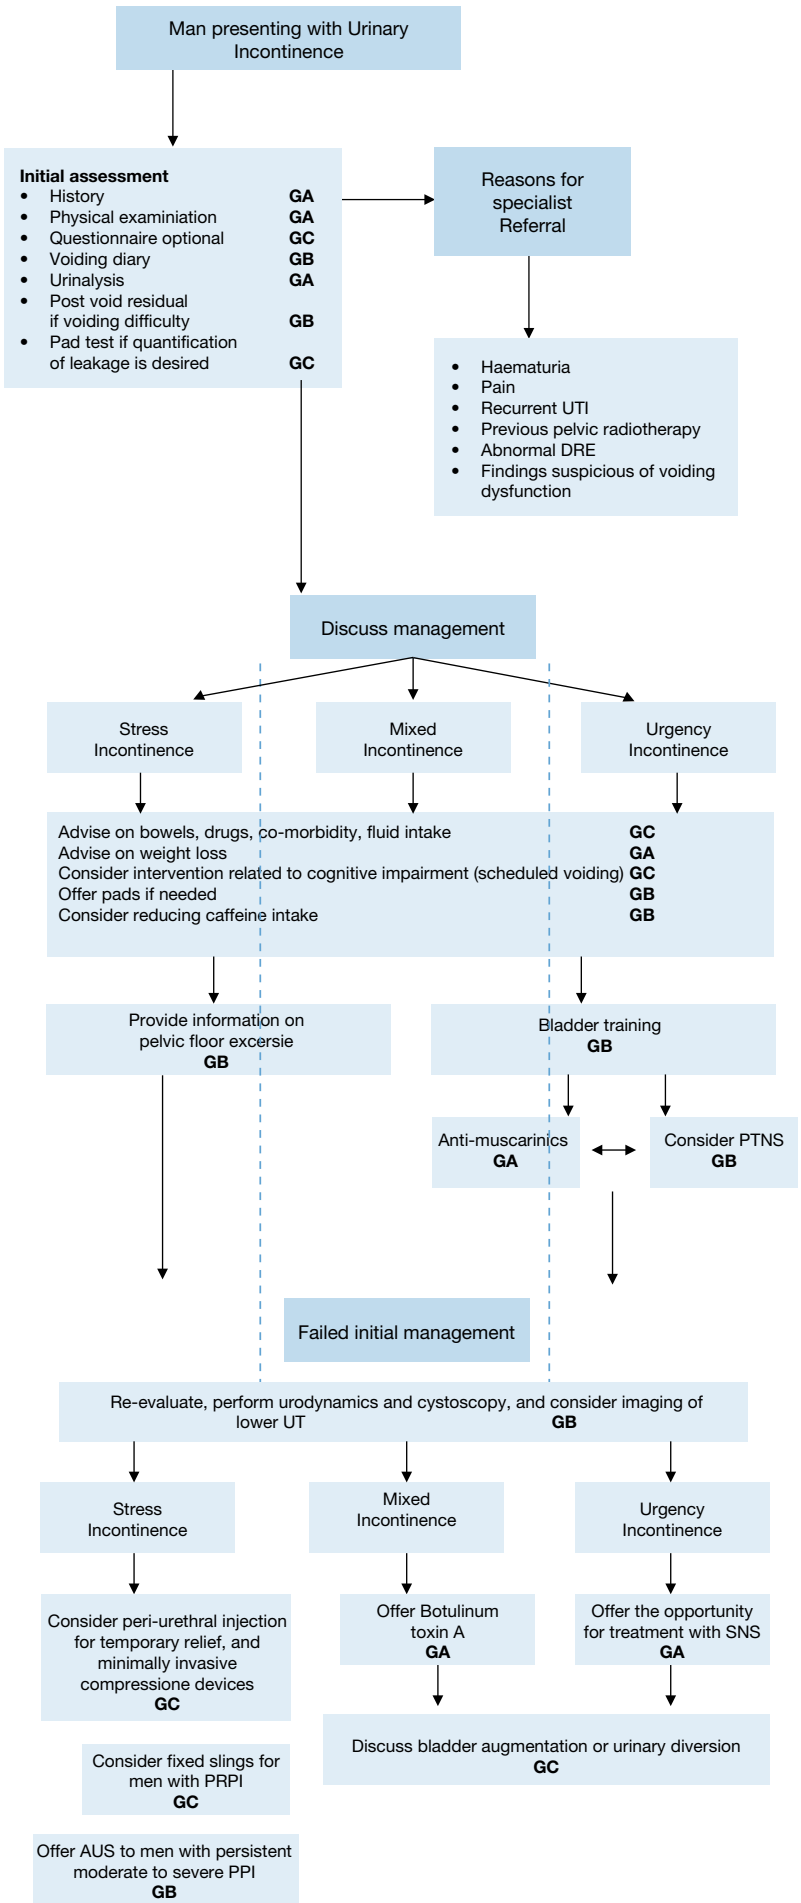
Woman presenting with Urinary Incontinence
Initial assessment
History GA
Physical examiniation GA
Questionnaire optional GC
Voiding diary GB
Urinalysis GA
Post void residual if voiding difficulty GB
Pad test if quantification of leakage is desired GC
Reasons for specialist Referral
Haematuria
Pain
Recurrent UTI
Grade 3 or symptomatic prolapse
Previous pelvic radiotherapy
Previous surgery for UI (go to bottom of pathway)
Pelvic mass
Suspicion of fistula
Discuss management
Stress Incontinence
Mixed Incontinence
Urgency Incontinence
Advise on bowels, drugs, co-morbidity, fluid intake GC
Advise on weight loss GA
Consider intervention related to cognitive impairment (scheduled voiding) GC
Offer pads if needed GB
Consider reducing caffeine intake GB
Consider topical oestrogen for post-menopausal women GA
Supervised, intensive PFMT +/- Biofeedback GA +/- Bladder training GB
Bladder training GB
Anti-muscarinics GA
Consider PTNS GB
Failed initial management
Consider urodynamics GA
Stress Incontinence
Mixed Incontinence
Urgency Incontinence
Stress predominant
Urgency predominant
Offer MUS GA Consider peri-urethral injections for temporary
Offer fascial sling or colposuspension if MUS unavailable GA
Failure
Re-evaluate patient and consider second-line surgery GC
Re-evaluate and re-enter algorithm at appropriate stage
Offer Botulinum toxin A or the opportunity for SNS GA
Offer the opportunity for SNS GA
Discuss bladder augmentation on urinary diversion GA



Man presenting with Urinary Incontinence
Initial assessment
History GA
Physical examiniation GA
Questionnaire optional GC
Voiding diary GB
Urinalysis GA
Post void residual if voiding difficulty GB
Pad test if quantification of leakage is desired GC
Reasons for specialist Referral
Haematuria
Pain
Recurrent UTI
Previous pelvic radiotherapy
Abnormal DRE
Findings suspicious of voiding dysfunction
Discuss management
Stress Incontinence
Mixed Incontinence
Urgency Incontinence
Advise on bowels, drugs, co-morbidity, fluid intake GC
Advise on weight loss GA
Consider intervention related to cognitive impairment (scheduled voiding) GC
Offer pads if needed GB
Consider reducing caffeine intake GB
Provide information on pelvic floor excersie GB
Bladder training GB
Anti-muscarinics GA
Consider PTNS GB
Failed initial management
Re-evaluate, perform urodynamics and cystoscopy, and consider imaging of lower UT GB
Stress Incontinence
Mixed Incontinence
Urgency Incontinence
Consider peri-urethral injection for temporary relief, and minimally invasive compressione devices GC
Offer Botulinum toxin A GA
Offer the opportunity for treatment with SNS GA
Consider fixed slings for men with PRPI GC
Discuss bladder augmentation or urinary diversion GC
Offer AUS to men with persistent moderate to severe PPI GB

6. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations.

ACT	adjustable compression therapy (device)
AHRQ	Agency for Healthcare Research and Quality
AUS	artificial urinary sphincter
BT	bladder training
BTX	botulinum toxin
CIC	clean intermittent catheterisation
CNS	central nervous system
DO	detrusor overactivity
EAU	European Association of Urology
ER	extended release
FS2S	first stage of two-stage [implantation of sacral neuromodulator]
GR	grade of recommendation
HRQoL	health-related quality of life
ICI	International Consultation on Incontinence
I-QoL	Incontinence Quality of Life
IR	immediate release
LE	level of evidence
LUTS	lower urinary tract symptoms
MPR	medication possession rate [drug adherence]
MRI	magnetic resonance imaging
MUI	mixed urinary incontinence
NICE	National Institute for Health and Clinical Excellence (UK)
OAB	overactive bladder
PFMT	pelvic floor muscle training
PICO	Population, Intervention, Comparison, Outcome
PNE	percutaneous nerve evaluation
PROMS	patient-reported outcome measures
PTNS	posterior tibial nerve stimulation
PVR	post-voiding residual volume
Q_{max}	maximum urinary flow rate
QoL	quality of life
RCT	randomised controlled trial
RP	radical prostatectomy
SIGN	Scottish Intercollegiate Guideline Network
SUI	stress urinary incontinence
TDS	transdermal delivery system
TVTS	tension-free vaginal tape secure
UI	urinary incontinence
US	ultrasound
UTI	urinary tract infection
UUI	urgency urinary incontinence

Conflict of interest

All members of the Urinary Incontinence Guidelines panel have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on

Neurogenic Lower Urinary Tract Dysfunction

TABLE OF CONTENTS PAGE

1. BACKGROUND

1.1 Aims and objectives

The purpose of these clinical guidelines is to provide useful information for clinical practitioners on the incidence, definitions, diagnosis, therapy, and follow-up observation of the condition of neurogenic lower urinary tract dysfunction (NLUTD). These guidelines reflect the current opinion of the experts in this specific pathology and thus represent a state-of-the-art reference for all clinicians, as of the date of its presentation to the European Association of Urology (EAU).

The EAU Guidelines panel consists of an international multidisciplinary group of experts, including urologists specialised in the care of spinal cord injured (SCI) patients, as well as a specialist in the field of urodynamic technologies.

The terminology used and the diagnostic procedures advised throughout these guidelines follow the recommendations for investigations on the lower urinary tract (LUT) as published by the International Continence Society (ICS) (1-3).

1.2 Methodology

*1.2.1 **Data identification***

Literature searches were carried out for all sections of the Neurogenic Lower Urinary Tract Dysfunction guidelines. Focus of all searches was identification of all level 1 scientific papers (systematic reviews and meta-analyses of randomised controlled trials) in accordance with EAU methodology. In case sufficient data was identified to answer the clinical question, the search was not expanded to include lower level literature. The search was limited to English language publications, animal studies were excluded. Additionally, the guidelines panel have included scientific material from foreign language publications and textbooks.

*1.2.2 **Evidence sources***

Searches were carried out in Medline and Embase on the Dialog-Datastar platform. The searches used the controlled terminology of the respective databases. Both MesH and EMTREE were analysed for relevant terms. In many cases the use of free text ensured the sensitivity of the searches.

Randomised controlled trial (RCT) strategies used were based on Scottish Intercollegiate Guidelines Network (SIGN) and Modified McMaster/Health Information Research Unit (HIRU) filters for RCTs, systematic reviews and practice guidelines on the OVID platform and then translated into Datastar syntax.

*1.2.3 **Level of evidence and grade of recommendation***

References used in the text have been assessed according to their level of scientific evidence (Table 1), and guideline recommendations have been graded (Table 2) according to the Oxford Centre for Evidence-based Medicine Levels of Evidence (4). The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence (LE)*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

** Modified from Sackett, et al. (4).*

It should be noted that when recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of RCTs may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Alternatively, absence of high level evidence does not necessarily preclude a grade A recommendation, if there

is overwhelming clinical experience and consensus. In addition, there may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful for the reader. The quality of the underlying scientific evidence – although a very important factor – has to be balanced against benefits and burdens, values and preferences and costs when a grade is assigned (5-7).

The EAU Guidelines Office, do not perform cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever this data is available, the expert panels will include the information.

Table 2: Grade of recommendation (GR)*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett, et al. (4).*

*1.2.4 **Publication history***

The current guidelines present a limited update of the 2008 publication. The EAU published the first guidelines on Neurogenic LUTS 2003 with an update in 2008. A review paper was published in the scientific journal of the association in 2009 (8).

A quick reference document presenting the main findings of the Neurogenic LUTS guidelines is available. All texts can be viewed and downloaded for personal use at the EAU website: http://www.uroweb.org/guidelines/online-guidelines/.

There is a need for ongoing re-evaluation of the information presented in the current guidelines by an expert panel. It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions – also taking personal values and preferences/individual circumstances of patients into account.

Summary of updated information

An updated literature search was done covering the chapters on Epidemiology, Diagnosis and assessment, Medical Treatment, Sexuality/Fertility and Quality of life. New additions are the Introduction in this chapter 1, Bladder rehabilitation and the chapters on Infections, Sexual Dysfunction and Fertility. Chapter 2 “Epidemiology” has been updated and chapter 3 “Diagnosis” completely renewed.

Readers are adviced to consult the other EAU guidelines which may address different aspects of the topics discussed in this document.

1.3 Introduction

The function of the lower urinary tract (LUT) is mainly storage and voiding of urine, which is regulated by a neural control system in the brain and spinal cord that coordinates the activity of the urinary bladder and bladder outlet. Therefore, any disturbance of the nervous systems that control the LUT, including the peripheral nerves in the pelvis, can result in neurogenic lower urinary tract dysfunction (NLUTD). Depending on the extent and location of the disturbance, a variety of different NLUTDs might occur, which can be symptomatic or asymptomatic. Moreover, NLUTD can cause a variety of long-term complications; the most dangerous being damage of renal function. As symptoms and long-term complications do not correlate (9), it is important to identify patients with NLUTD, and establish if they have a low or high risk of subsequent complications.

According to current knowledge, elevated storage pressure in the bladder, either alone or combined with vesicoureteric reflux, is the most important risk factor for renal damage (10). Sustained elevated storage pressure in the bladder is mainly due to a combination of increased detrusor activity during the storage phase (detrusor overactivity (DO) or low compliance), combined with detrusor-sphincter-dyssynergia (DSD). The combination of these two findings is mainly caused by suprasacral infrapontine spinal lesions. Furthermore, elevated detrusor leak point pressure has been demonstrated to be a risk factor for renal deterioration in patients with meningomyelocele (11). Therefore, renal failure has been the leading cause of death in patients with spinal cord injury for a long time (12). Even today, 26% of patients with meningomyelocele who do not

undergo urological treatment develop renal damage. Detrusor leak point pressure ≥ 40 cm H_2O and low bladder compliance are the main risk factors for renal damage (13).

In recent years, adequate diagnosis and treatment of NLUTD in patients with spinal cord lesions have improved the situation of these patients. Nowadays, respiratory diseases are the most frequent (21%) cause of death in patients with SCI (14).

In all other patients with NLUTD, the risk of renal damage is significantly lower. However, in Multiple Sclerosis (MS), urodynamics and clinical symptoms do not correlate, which means that asymptomatic patients can present with abnormal urodynamic findings (15). LUT symptoms do not always lead to urological evaluation in patients with MS, even if the symptoms are troublesome (16). Therefore, urological assessment is important in MS patients (17), although respiratory diseases are currently the leading cause of death for patients with MS, as well those with SCI (18).

In Parkinson disease (PD), NLUTD has not been mentioned as a significant cause of death. Moreover, patients with PD commonly suffer from overactive bladder without DSD (19), which does not seem to be as threatening to the upper urinary tract as DO with DSD. In patients with PD, urodynamic diagnosis of DO correlates well with diagnosis made by questionnaires (20). For these reasons, regular urodynamic follow-up might be less important in PD patients compared with patients suffering from MS or SCI. The same is true for type 2 diabetes, which frequently leads to NLUTD (21), but cardiovascular diseases are the main cause of death in these patients (22).

In summary, treatment and intensity of follow-up examinations are based on the type of NLUTD and the underlying cause.

2. RISK FACTORS AND EPIDEMIOLOGY

2.1 Introduction

Neurogenic lower urinary tract dysfunction may be caused by various diseases and events affecting the nervous systems controlling the LUT.
The resulting LUTD depends grossly on the location and the extent of the neurological lesion (see also Section 2.3).

There are no figures on the overall prevalence of NLUTD in the general population, but data are available on the prevalence of the underlying conditions and the relative risk of those for the development of NLUTD. It is important to realise that most of these data show a very wide range of prevalence figures because of the low level of evidence in most published data and smaller sample sizes.

*2.1.1 **Brain tumours***

Brain tumours can cause LUTD in 24% of patients (1). More recently, mostly case reports to small series have been published (2-3). In a series of patients with brain tumours, voiding difficulty was reported in 46/152 (30%) of patients with tumours in the posterior fossa, while urinary incontinence occurred in only three (1.9%) patients (4). Urinary retention was found in 12/17 (71%) children with pontine glioma (5).

*2.1.2 **Dementia***

It is not easy to distinguish dementia-associated LUTD from LUTD caused by age-related changes of the bladder and other concomitant diseases. Therefore, the true incidence of incontinence caused by dementia

is unknown. However, it has been shown that incontinence is much more frequent in geriatric patients with dementia than in patients without dementia (6,7).

Alzheimer, Lewy body dementia, Binswanger, Nasu-Hakola and Pick diseases frequently cause NLUTD (8-13). The occurrence of incontinence is reported to be between 23% and 48% (14,15) in patients with Alzheimer's disease. In Lewy body dementia, 92% of NLUTD is attributed to DO and 53% to incontinence (16). The onset of incontinence usually correlates with disease progression (17). A male-to-female ratio of dementia-related incontinence was found to be 1:15.

*2.1.3 **Mental retardation***

In mental retardation, depending on the grade of the disorder, 12-65% of LUTD was described (18,19).

*2.1.4 **Cerebral palsy***

Lower urinary tract dysfunction has been described in about 30-40% (20,21).

*2.1.5 **Normal pressure hydrocephalus***

There have only been case reports of LUTD (22-24).

*2.1.6 **Basal ganglia pathology (Parkinson disease, Huntington's disease, Shy-Drager syndrome, etc.)***

Parkinson disease is accompanied by NLUTD in 37.9-70% (25-27).

In the rare Shy-Drager syndrome, almost all patients have NLUTD (27), with incontinence found in 73% (28).

Hattori, et al. (29) reported that 60% of Parkinson patients had urinary symptoms. However, Gray et al. (30) reported that functional disturbances of the LUT in PD were not disease-specific and were correlated only with age. Recent, control-based studies have given the prevalence of LUT symptoms as 27-63.9% using validated questionnaires (31-33), or 53% in men and 63.9% in women using a validated questionnaire, which included a urinary incontinence category (33), with all these values being significantly higher than in healthy controls. Ransmayr reported a prevalence of urge episodes and urge incontinence in 53% Lewy body patients, whereas this was observed in 27% of the PD study population, of which 46% were also diagnosised with DO (34).

In most patients, the onset of the bladder dysfunction occurred after the motor disorder had appeared.

*2.1.7 **Cerebrovascular pathology***

Cerebrovascular (CVA) pathology causes hemiplegia with remnant incontinence NLUTD in 20-50% of patients (35,36), with decreasing prevalence in the post-insult period (37). In 1996, 53% of patients with CVA pathology had significant urinary complaints at 3 months (38). Without proper treatment, at 6 months after the CVA, 20-30% of patients still suffered from urinary incontinence (39). The commonest cystometric finding was DO (40-45).

In 39 patients who had brainstem strokes, urinary symptoms were present in almost 50%, nocturia and voiding difficulty in 28%, urinary retention in 21%, and urinary incontinence in 8%. Several case histories have been published presenting difficulties with micturition in the presence of various brainstem pathologies (46-48).

*2.1.8 **Demyelinisation***

Multiple sclerosis causes NLUTD in 50-90% of the patients (49-51).

The reported incidence of voiding dysfunction in multiple sclerosis is 33-52% in patients sampled consecutively, regardless of urinary symptoms. This incidence is related to the disability status of the patient (52). There is almost a 100% chance of having LUTD once these patients experience difficulties with walking. NLUTD is the presenting symptom in 2-12% of patients, with this finding being as high as 34% in some studies (53). LUTD appears mostly during the 10 years following the diagnosis (54).

*2.1.9 **Spinal cord lesions***

Spinal cord lesions can be traumatic, vascular, medical or congenital. An incidence of 30-40 new cases per million population is the accepted average for the USA. Most of these patients will develop NLUTD (55). The prevalence of spina bifida and other congenital nerve tube defects in the UK is 8-9 per 10,000 aged 10-69 years, with the greatest prevalence in the age group 25-29 years (56), and in the USA 1 per 1,000 births (57). The incidence of urethrovesical dysfunction in myelomeningocele is not completely known, but most studies suggest it is very high at 90-97% (58). About 50% of these children will have DSD (59,60).

In a large review specific data have been given for intradural metastasis from renal carcinoma with 22% of patients presenting with NLUTD (61).

Central cord syndrome is an incomplete SCI. A case series (n = 50) presented NLUTD in 42% of patients at admission, 12 % had residual disturbance during follow up, but most of the 12% related to patients > 70 years old (60% of that age bracket) (62).

In a hereditary spastic paraplegia series, 38 (77.6%) out of 49 patients presented with NLUTD (63).

Caudal Regression Syndrome (CRS): In a case series 61% of patients diagnosed with CRS presented with NLUTD (n = 69). 20% of these CRS patients presented with one kidney (64).
Special attention is to be paid to the combination of traumatic SCI and brain injuries: the incidence of tramatic SCI with clinical concomitant brain injury has increased over the passed 50 years. These finding have consequences for the diagnosis and treatment of NLUTD (65).
In 25% of children with high anorecta malformationi, innate NLUTD is present (66).

2.1.10 ***Disc disease***

This is reported to cause NLUTD in 28-87% of the patients (< 20%) (67,68). The incidence of cauda equine syndrome due to central lumbar disc prolapse is relatively rare and is about 1-5% of all prolapsed lumbar discs (68-75). There have been case reports of NLUTD without cauda equine syndrome (76) and small series with 90% cure of incontinence (77).

2.1.11 ***Spinal stenosis and spine surgery***

About 50% of patients seeking help for intractable leg pain due to spinal stenosis report symptoms of LUTD, such as a sense of incomplete bladder emptying, urinary hesitancy, incontinence, nocturia or urinary tract infections (UTIs) (78). These symptoms may be overlooked or attributed to primary urological disorders, with 61-62% affected by LUTD (79,80). The prevalence of neurological bladder is more significantly associated with the anteroposterior diameter of the dural sac than with its cross-sectional area. Spinal surgery is related to LUTD in 38-60% of patients (81,82). In a series with sacrectomy for sacral chordoma's NLUTD was found in 74% (83).

2.1.12 ***Peripheral neuropathy***

Diabetes: This common metabolic disorder has a prevalence of about 2.5% in the American population, but the disease may be subclinical for many years. No specific criteria exist for secondary neuropathy in this condition, but it is generally accepted that 50% of patients will develop somatic neuropathy, with 75-100% of these patients developing NLUTD (84,85). Diabetic patients suffer from various polyneuropathies, with 'diabetic cystopathy' reported in 43-87% of insulin-dependent diabetics without gender or age differences. It is also described in about 25% of type 2 diabetic patients on oral hypoglycaemic treatment (86).

The prevalence of NLUTD in type 2 diabetes gets higher with increasing severity of cardiac autonomic neuropathy (87) .

Alcohol abuse will eventually cause peripheral neuropathy. This has a reported prevalence that varies widely from 5-15% (88) to 64% (89). NLUTD is probably more likely to be present in patients with liver cirrhosis. The parasympathetic nervous system is attacked more than the sympathetic nervous system (89).

Less prevalent peripheral neuropathies include the following:

- Porphyria: bladder dilatation occurs in up to 12% of patients (90).
- Sarcoidosis: NLUTD is rare (91).
- Lumbosacral zone and genital herpes: incidence of LUT dysfunction is as high as 28% when only lumbosacral dermatome-involved patients are considered. The overall incidence is 4% (92,93). NLUTD is transient in most patients.
- Guillain Barré syndrome: the prevalence of micturition disorders varies from 25% to more than 80% (94,95), but is regressive in most cases (96). The true incidence is uncertain because, during the acute phase, patients are usually managed by indwelling catheter.

2.1.13 ***Other conditions (systematic lupus erythematosus)***

Nervous system involvement occurs in about half of patients with systemic lupus erythematosus (SLE). Symptoms of LUTD can occur, but data on prevalence are rare and give an incidence of 1% (97,98).

In familial amyloidotic polyneuropathy (FAP) approx. 50% of patients present with NLUTD (99).

*2.1.14 **Human immunodeficiency virus***

Voiding problems have been described in 12% of HIV-infected patients, mostly in advanced stages of the disease (100,101).

*2.1.15 **Regional spinal anaesthesia***

This may cause NLUTD but no prevalence figures have been found (102,103).
NLUTD have been described after image guided transforaminal lumbar spine epidural steroid injection (104), and intrathecal methotrexate injection (105).

*2.1.16 **Iatrogenic***

Abdominoperineal resection of the rectum has been described as causing NLUTD in up to 50% of patients (106,107).
One study has reported that NLUTD remains a long-term problem in only 10% (108); however, the study was not clear whether this was because the neurological lesion was cured or bladder rehabilitation was successful. Surgical prevention with nerve preservation was shown to be important (109,110).

NLUTD has been reported following simple hysterectomy (111) and in 8-57% of patients following radical hysterectomy or pelvic irradiation for cervical cancer (112-115). Surgical prevention can be used to prevent it (116). Neurological dysfunction of the pelvic floor has been demonstrated following radical prostatectomy (117).

2.2 Standardisation of terminology

*2.2.1 **Introduction***

Several national or international guidelines have already been published for the care of patients with NLUTD (118-121). The guidelines will evolve as time goes by. The guidelines include definitions of important terms and procedures. The ICS NLUTD standardisation report (119) deals specifically with the standardisation of terminology and urodynamic investigation in patients with NLUTD. Other relevant definitions are found in the general ICS standardisation report (122).

Section 2.2.2 lists the definitions from these references, partly adapted, and other definitions considered useful for clinical practice in NLUTD (Tables 3 and 4). For specific definitions relating to urodynamic investigation, the reader is referred to the appropriate ICS report (119).

*2.2.2 **Definitions***

Table 3: Definitions useful in clinical practice

Acontractility, detrusor	*See below under voiding phase*
Acontractility, urethral sphincter	*See below under storage phase*
Autonomic dysreflexia	Increase of sympathetic reflex due to noxious stimuli with symptoms or signs of headache, hypertension, flushing face and perspiration
Capacity	*See below under storage phase*
Catheterisation, indwelling	Emptying of the bladder by a catheter that is introduced (semi-) permanently
Catheterisation, intermittent (IC)	Emptying of the bladder by a catheter that is removed after the procedure, mostly at regular intervals
• Aseptic IC	The catheters remain sterile, the genitals are disinfected, and disinfecting lubricant is used
• Clean IC	Disposable or cleansed re-usable catheters, genitals washed
• Sterile IC	Complete sterile setting, including sterile gloves, forceps, gown and mask
• Intermittent self-catheterisation (ISC)	IC performed by the patient
Compliance, detrusor	*See below under storage phase*
Condition	Evidence of relevant pathological processes

Diary, urinary	Record of times of micturitions and voided volumes, incontinence episodes, pad usage, and other relevant information
• Frequency volume chart (FVC)	Times of micturitions and voided volumes only
• Micturition time chart (MTC)	Times of micturitions only
Filling rate, physiological	Below the predicted maximum: body weight (kg) / 4 in mL/s (122,123)
Hesitancy	Difficulty in initiating micturition; delay in the onset of micturition after the individual is ready to pass urine
Intermittency	Urine flow stops and starts on one or more occasions during voiding
Leak point pressure (LPP)	*See below under storage phase*
Lower motor neuron lesion (LMNL)	Lesion at or below the S1-S2 spinal cord level
Neurogenic lower urinary tract dysfunction (NLUTD)	Lower urinary tract dysfunction secondary to confirmed pathology of the nervous supply
Observation, specific	Observation made during specific diagnostic procedure
Overactivity, bladder	*See below under symptom syndrome*
Overactivity, detrusor	*See below under storage phase*
Rehabilitation, LUT	Non-surgical non-pharmacological treatment for LUT dysfunction
Sign	To verify symptoms and classify them
Sphincter, urethral, non-relaxing	*See below under voiding phase*
Symptom	Subjective indicator of a disease or change in condition, as perceived by the patient, carer, or partner that may lead the patient to seek help from healthcare professionals
Upper motor neuron lesion (UMNL)	Lesion above the S1-S2 spinal cord level
Voiding, balanced: In patients with NLUTD (< 80 mL or < 20% of bladder volume)	Voiding with physiological detrusor pressure and low residual
Voiding, triggered	Voiding initiated by manoeuvres to elicit reflex detrusor contraction by exteroceptive stimuli
Volume, overactivity	*See below under storage phase*

Table 4: Further definitions useful in clinical practice

Storage phase	
Maximum anaesthetic bladder capacity	Maximum bladder filling volume under deep general or spinal anaesthesia
Increased daytime frequency	Self-explanatory; the normal frequency can be estimated at about 8 times per day (124)
Nocturia	Waking at night one or more times to void
Urgency	The symptom of a sudden compelling desire to pass urine that is difficult to defer
Urinary incontinence	Any involuntary leakage of urine
• Stress urinary incontinence	On effort or exertion, or on sneezing or coughing
• Urge urinary incontinence	Accompanied by or immediately preceded by urgency
• Mixed urinary incontinence	Associated with urgency and also exertion, effort, sneezing, or coughing
• Continuous urinary incontinence	
Bladder sensation	

Normal	
• Symptom and history	Awareness of bladder filling and increasing sensation up to a strong desire to void
• Urodynamics	First sensation of bladder filling, first desire to void, and strong desire to void at realistic bladder volumes
Increased	
• Symptom and history	An early and persistent desire to void
• Urodynamics	Any of the three urodynamic parameters mentioned under 'normal' persistently at low bladder volume
Reduced	
• Symptom and history	Awareness of bladder filling but no definite desire to void
• Urodynamics	Diminished sensation throughout bladder filling
Absent	No sensation of bladder filling or desire to void
Non-specific	Perception of bladder filling as abdominal fullness, vegetative symptoms, or spasticity
Definitions valid after urodynamic confirmation only	
Cystometric capacity	Bladder volume at the end of the filling cystometry
• Maximum cystometric capacity	Bladder volume at strong desire to void
• High-capacity bladder	Bladder volume at cystometric capacity far over the mean voided volume, estimated from the bladder diary, with no significant increase in detrusor pressure under non-anaesthetised condition
Normal detrusor function	Little or no pressure increase during filling: no involuntary phasic contractions despite provocation
Detrusor overactivity	Involuntary detrusor contractions during filling; spontaneous or provoked
• Phasic DO	Characteristic phasic contraction
• Terminal DO	A single contraction at cystometric capacity
• High pressure DO	Maximal detrusor pressure > 40 cm H_2O (119,125)
• Overactivity volume	Bladder volume at first occurrence of DO
• Detrusor overactivity incontinence	Self-explanatory
Leak point pressure	
• Detrusor leak point pressure (DLPP)	Lowest value of detrusor pressure at which leakage is observed in the absence of abdominal strain or detrusor contraction
• Abdominal leak point pressure	Lowest value of intentionally increased intravesical pressure that provokes leakage in the absence of a detrusor contraction
Detrusor compliance	Relationship between change in bladder volume (ΔV) and change in detrusor pressure ($\Delta pdet$):$C=\Delta V/\Delta pdet$ (mL/ cmH_2O)
• Low detrusor	compliance $C=\Delta V/\Delta pdet$ < 20 mL/cm H_2O (106)
Break volume	Bladder volume after which a sudden significant decrease in detrusor compliance is observed
Urethral sphincter acontractility	No evidence of sphincter contraction during filling, particularly at higher bladder volumes, or during abdominal pressure increase
Voiding phase	
• Slow stream	Reduced urine flow rate
• Intermittent stream (intermittency)	Stopping and starting of urine flow during micturition

• Hesitancy	Difficulty in initiating micturition
• Straining	Muscular effort to initiate, maintain, or improve urinary stream
• Terminal dribble	Prolonged final part of micturition when the flow has slowed to a trickle/dribble
Definitions valid after urodynamic confirmation only	
Normal detrusor function	Voluntarily initiated detrusor contraction that causes complete bladder emptying within a normal time span
Detrusor underactivity	Contraction of reduced strength / duration
Acontractile detrusor	Absent contraction
Non-relaxing urethral sphincter	Self-explanatory
Detrusor sphincter dyssynergia (DSD)	Detrusor contraction concurrent with an involuntary contraction of the urethra and/or periurethral striated musculature
Post-micturition phase Feeling of incomplete emptying (symptom only) Post-micturition dribble: involuntary leakage of urine shortly after finishing the micturition Pain, discomfort or pressure sensation in the LUT and genitalia that may be related to bladder filling or voiding, may be felt after micturition, or be continuous	
Symptom syndrome: combination of symptoms • Overactive bladder syndrome: urgency with or without urge incontinence, usually with frequency and nocturia • Synonyms: urge syndrome, urgency-frequency syndrome • This syndrome is suggestive for LUTD

3. DIAGNOSIS

3.1 Introduction

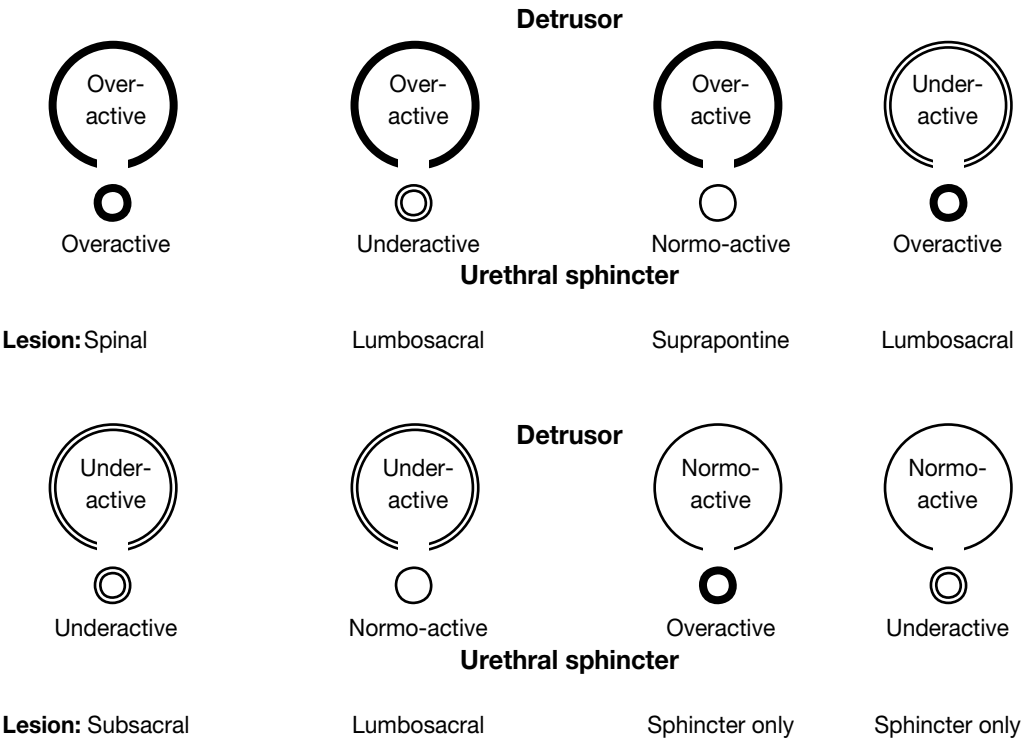
A thorough medical history and physical examination is mandatory, before any additional diagnostic investigations are planned. The clinical assessment of patients with NLUTD includes a detailed history, a

patient voiding diary and systematic physical examination. The initial evaluation is essential to determine the therapeutic scheme for long-term treatment and follow-up.

3.2 Classification

The NLUTD classification provides a standardised terminology. Several classification systems have been proposed. A simple classification focused on therapeutic consequences has been proposed by Madersbacher (1) (LE: 4). This classification describes several NLUTD symptoms on the basis of the contraction state of the bladder and external urethral sphincter during voiding and filling phase (Figure 1).

Figure 1: Madersbacher classification system with typical neurogenic lesions [1]



3.3 Timing of diagnosis and treatment

Early diagnosis and treatment are essential in both congenital and acquired NLUTD. Irreversible changes within the LUT may occur, even with normal neurological reflexes (2,3) (LE: 3). Additionally, NLUTD can be the presenting feature of neurological pathology (4,5) (LE: 3). Early intervention, e.g. intermittent catheterisation (IC), can prevent irreversible deterioration of the lower and upper urinary tract (6) (LE: 3).

3.4 Patient history

History taking is the cornerstone of evaluation and should include past and present symptoms and disorders. The patient's past history should be taken in detail, particularly in cases of non-traumatic neurological bladder dysfunction with a slow insidious onset. Occasionally, this is traceable to childhood or adolescence (7) (LE: 4). Urinary history consists of symptoms related to both storage and evacuation functions of the LUT.

Bowel history is important since patients with NLUTD may suffer from a related neurogenic condition of the lower gastrointestinal tract. This may reflect the neurological condition of the urinary bladder (7) (LE: 4). Sexual function may also be impaired because of the neurogenic condition.

Table 5 gives an overview of the items that should be assessed. These items are important to guide the decision process of diagnostic investigations and treatment options.

Special attention should be paid to possible warning signs and symptoms (e.g. pain, infection, haematuria and fever) that warrant further investigation. However, it is usually difficult for patients with SCI to report accurately symptoms related to urinary tract infections (8-10) (LE: 3).

Table 5: History examination in neurogenic lower urinary tract dysfunction*	
Past history	
	Childhood – adolescence – adult
	Hereditary or familial risk factors
	Menarche (age)*; may suggest metabolic disorder*
	Obstetric history
	History of diabetes; *in some cases correction will resolve the neurological problem*
	Diseases, *e.g. syphilis, Parkinsonism, multiple sclerosis, encephalitis*
	Accidents and operations, *especially those involving the spine and central nervous system*
Present history	
	Present medication
	Lifestyle (smoking, alcohol and drugs); *may influence bowel and urinary function*
	Quality of life
	Life expectancy
Specific urinary history	
	Onset urological history
	Relief after voiding; *to detect the extent of a neurological lesion in the absence of obstructive uropathy*
	Bladder sensation
	Initiation of micturition *(normal, precipitate, reflex, strain, Credé)*
	Interruption of micturition *(normal, paradoxical, passive)*
	Enuresis
	Mode and type of voiding (catheterisation)
	Urinary diary*; (semi)objective information about number of voids, day- and night-time voiding frequency, volumes voided, incontinence, urge episodes*
Bowel history	
	Frequency and faecal incontinence
	Desire to defecate
	Defecation pattern
	Rectal sensation
	Initiation of defecation *(digital rectal stimulation)*
Sexual history	
	Genital or sexual dysfunction symptoms
	Sensation in genital area
	Specific male: erection, (lack of) orgasm, ejaculation
	Specific female: dyspareunia, (lack of) orgasm
Neurological history	
	Acquired or congenital neurological condition
	Mental status and comprehension
	Neurological symptoms (somatic and sensory), with onset, evolution and any treatment
	Spasticity or autonomic dysreflexia (lesion above level Th 6) Mobility and hand function

** Extracted from Bors and Turner ([7] (LE: 4; GR: C) and Stöhrer, et al. [11] (LE: 4; GR: C).*

Voiding diaries offer information on the number of voids, volumes voided, incontinence, and urge episodes. A 24-hour voiding diary was shown to be reliable in women with urinary incontinence (12,13) (LE: 3). However, no such information is available in patients with neurological incontinence. The voiding diary is also useful in patients performing intermittent catheterisation (11) (LE: 4).

3.5 Physical examination

In addition to a detailed patient history and a general examination, attention should be paid to possible physical and mental handicaps with respect to the planned investigation.

Neurological status should be described as completely as possible (Table 4). Patients with very high neurological lesions may suffer from a significant drop in blood pressure when moved in a sitting or standing position. All sensations and reflexes in the urogenital area must be tested. Furthermore, detailed testing of the anal sphincter and pelvic floor functions must be performed (Figure 2). Availability of this clinical information is essential for the reliable interpretation of subsequent diagnostic investigations.

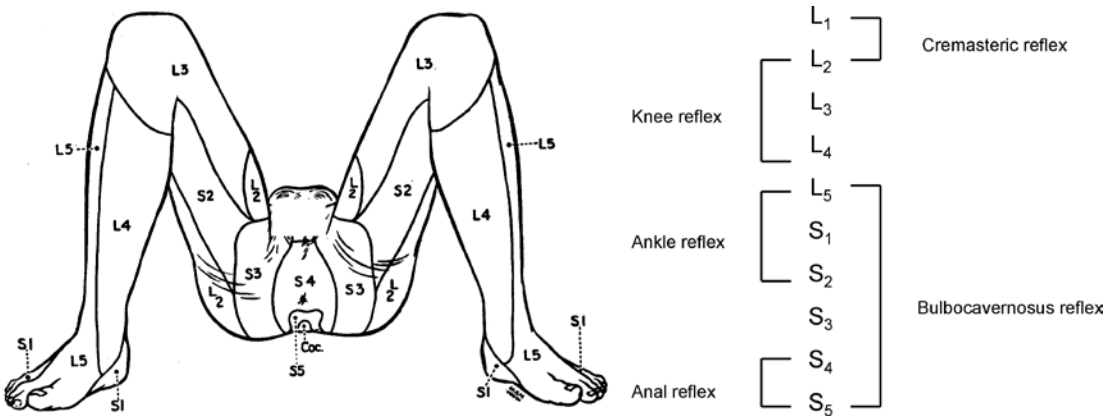


Figure 2: The neurological status of a patient with neurogenic lower urinary tract dysfunction (NLUTD) must be described as completely as possible: (a) dermatomes of spinal cord levels L2-S4; (b) urogenital and other reflexes in the lower spinal cord

Table 6: Neuro-urological items to be specified*

Sensations S2-S5 (both sides)	
	Presence (increased/normal/reduced/absent)
	Type (sharp/blunt)
	Afflicted segments
Reflexes (increased/normal/reduced/absent)	
	Bulbocavernous reflex
	Perianal reflex
	Knee and ankle reflexes
	Plantar responses (Babinski)
Anal sphincter tone	
	Presence (increased/normal/reduced/absent)
	Voluntary contractions of anal sphincter and pelvic muscles (increased/normal/reduced/absent)
Prostate palpation	
Descensus (prolapse) of pelvic organs	

**From Stöhrer, et al. [11] (LE: 4; GR: C).*

Caution

Autonomic dysreflexia (AD) is a sudden and exaggerated autonomic response to stimuli in patients with spinal cord injuries or dysfunction above level Th 5–Th 6. Hypertension is a relatively common manifestation of AD and can have life-threatening results if not properly managed (14-16) (LE: 3; GR: C).

3.5.1 *Recommendations for history taking and physical examination**

History taking	GR
An extensive general history is mandatory, concentrating on past and present symptoms and conditions for urinary, bowel, sexual, and neurological functions, and on general conditions that might impair any of these.	A
Special attention should be paid to the possible existence of alarm signs, such as pain, infection, haematuria, fever, etc, that warrant further specific diagnosis.	A
A specific history should be taken for each of the four mentioned	A
Physical examination	A
Individual patient handicaps should be acknowledged in planning further investigations.	A
The neurological status should be described as completely as possible. Sensations and reflexes in the urogenital area must all be tested.	A
The anal sphincter and pelvic floor functions must be tested extensively.	A
Urinalysis, blood chemistry, voiding diary, residual and free flowmetry, incontinence quantification and urinary tract imaging should be performed.	A

** All grade A recommendations based on panel consensus.*

3.6 Urodynamics

3.6.1 *Introduction*

Urodynamic investigation is the only method that can objectively assess the (dys-)function of the LUT. It is essential to describe the LUT status in patients with NLUTD.
In these patients, particularly when DO might be present, the invasive urodynamic investigation is even more provocative than in other patients. Any technical source of artefacts must be critically considered. The quality of the urodynamic recording and its interpretation must be ensured (17).
In patients at risk for autonomic dysreflexia, it is advisable to measure blood pressure during the urodynamic study.

In many patients with NLUTD, it may be helpful to assess the maximum anaesthetic bladder capacity. The rectal ampulla should be empty of stool before the start of the investigation. Drugs that influence the LUT function should be stopped at least 48 hours before the investigation (if feasible) or otherwise be considered when interpreting the data obtained.

All urodynamic findings must be reported in detail and performed according to the ICS technical recommendations and standards (17-19).

3.6.2 *Urodynamic tests*

A bladder diary is a semi-objective qualification of the LUT. It is a highly advisable diagnostic tool. For reliable interpretation, it should be recorded over at least 2-3 days (18,20). Possible pathological findings: high voiding frequency, very low or very high voided volumes, nocturnal voidings, urgency, incontinence.

Free uroflowmetry and assessment of residual urine gives a first impression of the voiding function. It is mandatory before planning any invasive urodynamics. For reliable information, it should be repeated at least 2-3 times (18,21,22). Possible pathological findings: low flow rate, low voided volume, intermittent flow, hesitancy, residual urine.

Care must be taken when assessing the results in patients who are not able to void in a normal position. Both the flow pattern and the flow rate may be modified by inappropriate positions and by any constructions to divert the flow.

Filling cystometry: The only method to quantify the filling function has limited significance as a solitary procedure. It is much more powerful if combined with bladder pressure measurement during micturition and even more in video-urodynamics. This investigation is necessary to document the status of the LUT function during the filling phase. The bladder should be empty at the start of filling. A physiological filling rate should be used with body-warm saline, as fast filling and room-temperature saline are provocative (18).

Possible pathological findings include DO, low detrusor compliance, abnormal bladder and other sensations, incontinence, incompetent or relaxing urethra.

Detrusor leak point pressure (DLPP): This specific investigation may estimate the risk for the upper urinary tract or for secondary bladder damage (18,23). The DLPP is a screening test only, because it gives no impression of

the duration of the high pressure during the filling phase, which can be expected to have even more impact on the upper urinary tract (24). A high DLPP thus warrants further testing by video-urodynamics.

Pressure flow study: This measurement reflects the co-ordination between detrusor and urethra or pelvic floor during the voiding phase. It is even more powerful in combination with filling cystometry and with video urodynamics. It is necessary to document the function of the LUT function during the voiding phase. Possible pathological findings: Detrusor underactivity/acontractility, DSD, non-relaxing urethra, residual urine.

Most types of obstruction caused by NLUTD are due to DSD (25,26), non-relaxing urethra, or nonrelaxing bladder neck (18,27,28). Pressure-flow analysis mostly assesses the amount of mechanical obstruction caused by the urethra's inherent mechanical and anatomical properties and has limited value in patients with NLUTD.

Electromyography (EMG): Registration of the activity of the external urethral sphincter, the peri-urethral striated musculature, the anal sphincter, or the striated pelvic floor muscles. The correct interpretation may be difficult due to artefacts introduced by other equipment used. In the urodynamic setting an EMG is useful as a gross indication of the patient's ability to control the pelvic floor. Possible pathological findings: Inadequate recruitment on specific stimuli (bladder filling, hyperreflexive contractions, onset of voiding, coughing, Valsalva, etc.). More detailed analysis (motor unit potentials, single-fibre EMG) is only possible as part of a neurophysiological investigation.

Urethral pressure measurement: This investigation has only a very limited place in NLUTD. There exists no basic consensus on parameters indicating pathological findings (29).

Video-urodynamics: This combination of filling cystometry and pressure flow study with imaging is the gold standard for urodynamic investigation in NLUTD (18,30,31). Possible pathological findings: All as described under cystometry and pressure flow study, plus morphological pathology of the LUT and the upper urinary tract.

Ambulatory urodynamics: Functional investigation of the urinary tract utilising predominantly natural filling of theurinary tract and reproducing normal subject activity (32).

This type of study should be considered when office urodynamics do not reproduce the patient's symptoms and complaints. Possible pathological findings include those found under filling cystometry and pressure flow study, provided the flow is measured also. It should be kept in mind that during this study the actual bladder volume is unknown.

Provocative tests during urodynamics: The LUT function can be provoked by coughing, triggered voiding, or anal stretch.

Fast-filling cystometry with cooled saline (the 'ice water test') is considered a discriminative test between upper motor neuron lesion (UMNL) and lower motor neuron lesion (LMNL) (33-38). Patients with UMNL will develop a detrusor contraction if the detrusor muscle is intact, while patients with lower lesions will not. The test gives false-positive results in young children (35) and does not seem to be fully discriminative in other patients (36,37).

It was thought that a positive bethanechol test (39) (detrusor contraction > 25 cm H_2O) provided proof of a detrusor denervation hypersensitivity and the muscular integrity of an acontractile detrusor; however, in practice, the test has given equivocal results. Recently, a variation of this method was reported using intravesical electromotive administration of the bethanechol (40); this test turned out to be both selective and predictive for successful oral bethanechol treatment.

3.6.3 ***Specific uro-neurophysiological tests***

These tests are advised as part of the neurological work-up of the patient. They comprise:

- EMG (in a neurophysiological setting) of pelvic floor muscles, urethral sphincter and/or anal sphincter;
- nerve conduction studies of pudendal nerve;
- reflex latency measurements of bulbocavernosus and anal reflex arcs;
- evoked responses from clitoris or glans penis;
- sensory testing on bladder and urethra.

Other elective tests may be asked for specific conditions that became obvious during patient work-up and urodynamic investigations. Possible pathological findings are dependent on the type of the test.

3.6.4 *Recommendations for urodynamics and uro-neurophysiology*

Recommendations	GR
Urodynamic investigation is necessary to document the (dys-)function of the LUT.	A
The recording of a bladder diary is advisable.	B
Non-invasive testing is mandatory before invasive urodynamics is planned.	A
Video-urodynamics is the gold standard for invasive urodynamics in patients with NLUTD. If this is available, then a filling cystometry continuing into a pressure flow study should be performed.	A
A physiological filling rate and body-warm saline must be used.	A
Specific uro-neurophysiological tests are elective procedures.	C

3.7 *Typical manifestations of neurogenic lower urinary tract dysfunction*

Typical findings in NLUTD are listed below:

Filling phase

- hyposensitivity or hypersensitivity;
- vegetative sensations;
- low compliance;
- high capacity bladder;
- detrusor overactivity, spontaneous or provoked;
- sphincter acontractility.

Voiding phase

- detrusor acontractility;
- dsd;
- non-relaxing urethra;
- non-relaxing bladder neck.

These signs warrant further neurological evaluation, as LUTD may be the presenting symptom of NLUTD (41-45).

4. TREATMENT

4.1 Introduction

The primary aims for treatment of NLUTD and their priorities are (1-4):

1. Protection of the upper urinary tract;
2. Improvement of urinary continence;
3. Restoration of (parts of) the LUT function;
4. Improvement of the patient's QoL.

Further considerations are the patient's disability, cost-effectiveness, technical complexity, and possible complications (4).

Preservation of the upper tract function is of paramount importance (1-7). Renal failure was the main factor for mortality in the SCI patient surviving the trauma (5-7). This has led to the golden rule in treatment of NLUTD: ensure that the detrusor pressure remains within safe limits during both the filling phase and the voiding phase (1-4). This approach has indeed significantly reduced the mortality from urological causes in this patient group (8).

The therapy of urinary incontinence is important for social rehabilitation of the patient and thus contributes substantially to the QoL. It is also pivotal in preventing UTI (6,7). If complete continence cannot be achieved, methods to attain a socially acceptable control of incontinence can be used.

The patient's QoL is an essential part of any treatment decision.

In patients with high detrusor pressure during the filling phase (DO, low detrusor compliance) or during the voiding phase (DSD, other causes of bladder outlet obstruction), treatment is aimed primarily at 'conversion of an active, aggressive high-pressure bladder into a passive low-pressure reservoir' despite the resulting residual urine (1).

4.2 Non-invasive conservative treatment

*4.2.1 **Assisted bladder emptying***

Incomplete bladder emptying is a serious risk factor for UTI, developing a high intravesical pressure during the filling phase, and incontinence. Methods to improve the voiding process are practised in patients with NLUTD.

Third party bladder expression (Credé): Regretfully, this method is still applied, foremost in infants and young children with myelomeningocele and sometimes in tetraplegics. Because of the high pressures that may be created during this procedure, it is potentially hazardous for the urinary tract (9).

Voiding by abdominal straining (Valsalva): The considerations mentioned under Credé above also apply to the Valsalva manoeuvre (1,9-11). For both methods of emptying, long-term complications are hardly avoidable (9,10) and the already weak pelvic floor function may be further impaired, thus exacerbating the existing incontinence (11).

Triggered reflex voiding: Stimulation of the sacral or lumbar dermatomes in patients with UMNL can elicit reflex contraction of the detrusor (1,11). Morbidity occurs more often during the first decades of treatment (12-16). Strict urodynamic control is therefore required (1,11).

Behavioural modification techniques: These are used to improve continence and include prompted voiding, timed voiding (bladder training), and lifestyle modification (17-20).

Pelvic floor muscle exercises: These aim to improve continence. They may be helpful in selected patients with NLUTD (21-23).

Biofeedback: This method can be used for supporting the voiding pattern modification (24,25).

*4.2.2 **Lower urinary tract rehabilitation***

4.2.2.1 Bladder rehabilitation including electrical stimulation

4.2.2.1.1 Introduction

The term bladder rehabilitation summarises treatment options that aim to re-establish bladder function in patients with NLUTD. Regaining voluntary control over LUTD has been described in individuals with non-neurogenic bladder dysfunction, using behavioural treatment in patients with urge incontinence and biofeedback training for stress urinary incontinence. However, evidence for bladder rehabilitation using electrical stimulation in neurogenic patients is lacking and mainly based on pilot studies with small patient numbers.

A strong contraction of the urethral sphincter and/or pelvic floor, but also anal dilatation, manipulation of the genital region, and physical activity reflexly inhibit the micturition (11,26). Whereas the first mechanism is affected by activation of efferent fibres, the latter ones are produced by activation of afferents (14). Electrical stimulation of the pudendal nerve afferents produces a strong inhibition of the micturition reflex and of the detrusor contraction (27). This stimulation might then support the restoration of the balance between excitatoryand inhibitory inputs at the spinal or supraspinal level (11,28,29). It might also imply that patients with incomplete lesions will benefit (11,29,30), but patients with complete lesions will not (31).

4.2.2.1.2 Peripheral temporary electrostimulation
Posterior tibial nerve stimulation and external temporary electrical stimulation (e.g. penile/clitoral or intracavital) suppress neurogenic DO during acute stimulation (32). Both techniques have also demonstrated sustained prolonged effects (3 months and 1 year, respectively) in patients with neurogenic bladder dysfunction due to MS (33.34).

In MS patients, combining active neuromuscular electrical stimulation with pelvic floor muscle training and electromyography biofeedback achieved a substantial reduction of LUTD (35). Furthermore, this treatment combination was significantly superior ($p = 0.0028$) to electrostimulation alone.

Biofeedback: This method can be used for supporting the voiding pattern modification (24,25).

4.2.2.1.3 Intravesical electrostimulation
Intravesical electrostimulation can increase bladder capacity, improve bladder compliance as well as the sensation of bladder filling in patients with incomplete SCI or meningomyelocele (36). In patients with neurogenic detrusor hypocontractility, intravesical electrostimulation may also improve voiding and reduce residual urine volume (37).

4.2.2.1.4 Chronic peripheral pudendal stimulation
The results of a pilot study showed that chronic peripheral pudendal stimulation (chronic, defined as a period of 2 weeks) in patients with incomplete SCI produced significant neuromodulatory effects in the brain which led to changes in urodynamic parameters (38).

4.2.2.1.5 Repetitive transcranial magnetic stimulation
Although repetitive transcranial magnetic stimulation improved voiding symptoms in patients with PD or MS, the duration of the effect, stimulation parameters and the appropriate patient selection are still under investigation (39,40).

4.2.2.1.6 Summary
To date, bladder rehabilitation techniques are mainly based on electrical or magnetic stimulation. However, there is a lack of well-designed studies for all techniques. The different techniques of external temporary electrostimulation, possibly combined with biofeedback training, may be useful, especially in patients with MS or incomplete spinal cord injury. Further studies are necessary to evaluate the usefulness of these techniques.

4.2.3 ***Drug treatment***
A single, optimal, medical therapy for NLUTD is not yet available. Currently, a combination of therapies is the best way to maximise outcomes (41-50) (LE: 1a).

4.2.3.1 Antimuscarinic drugs
Antimuscarinic drugs are the first-line choice for treating NLUTD. They are the most useful medications available for NLUTD and provide an established approach to managing neurogenic detrusor overactivity (NDO) (41-47, 51-53) (LE: 1a). Previously, these drugs were known as ‘anticholinergic’, but they are now described as muscarinic receptor antagonists because of their action in binding to muscarinic receptors. Antimuscarinic drugs are used to stabilise the detrusor muscle, which reduces its overactivity and makes it moderately refractory to parasympathetic stimulation. This results in improved bladder compliance and reduced symptoms of overactive bladder (47,51), which in turn helps to prevent renal and bladder damage and potentially improve long-term outcomes (54) (LE: 1a).

Neurogenic patients may need a higher dose of antimuscarinic agents than patients with idiopathic DO (47,48,55-57) (LE: 1b). However, adverse events due to the higher dosage may lead to early discontinuation of therapy (19,21,56.58.59) (LE: 1b).

4.2.3.1.1 Choice of antimuscarinic agent

Oxybutynin chloride (47) (LE: 1a) (48-51,57-59), trospium chloride (47,55,56,60), tolterodine tartrate (61-63) and propiverine (47,58,64,65) (LE: 1a) are established, effective, medical treatments. These antimuscarinic agents are known to be well tolerated and safe, even during long-term treatment. They have diverse tolerance profiles, so that a different antimuscarinic agent may be prescribed if a patient experiences adverse effects or if the therapeutic effect is not sufficient (66).

Darifenacin has recently been evaluated in neurogenic overactive bladder secondary to MS (67,68), with results similar to other muscarinic drugs. Solifenacin has also been introduced, even though to date there has been no published clinical evidence of the use of solifenacin in NDO. Data is awaited from an ongoing trial.

4.2.3.1.1.1 Side effects

Antimuscarinic agents have some minor side-effects, e.g. dry mouth. It has been suggested that different ways of administration may help to reduce side effects. In a selected group of patients, transdermal oxybutynin was found to be well tolerated and effective (69,70), while intravesical oxybutynin led to abolishment of the bladder-cooling reflex (71). However, further research is needed into the use of alternative methods of administration, particularly long-term results (LE: 2a).

4.2.3.2 Other agents

4.2.3.2.1 Phosphodiesterase inhibitors (PDE5I)

These have demonstrated significant effects upon DO in pilot studies and in the future may become an alternative or adjunct to antimuscarinic treatment (72).

4.2.3.3 Adjunct desmopressin

Additional treatment with desmopressin might improve the efficacy of treatment (73-75) (LE: 3).

4.2.3.4 Drugs with different mechanisms of action

4.2.3.4.1 Detrusor underactivity

Cholinergic drugs, such as bethanechol chloride and distigmine bromide, have been considered to enhance detrusor contractility and promote bladder emptying, but are not routinely used in clinical practice. The available studies do not support the use of parasympathomimetic agents, especially when frequent and/or serious possible side-effects are considered (76) (LE: 1a).

Combination therapy with an antimuscarinicdrug and alpha-blocker appears to be more useful than monotherapy with either agent (77). In conclusion, there is no drug with evidence of efficacy for underactive detrusor (11,78-81) (LE: 2a).

4.2.3.4.2 Decreasing bladder outlet resistance

Alpha-blockers (non-selective and selective) have been partially successful for decreasing bladder outlet resistance, residual urine and autonomic dysreflexia (11,82-86) (LE: 2a).

4.2.3.4.3 Increasing bladder outlet resistance

Several drugs have shown efficacy in selected cases of mild stress urinary incontinence, but there have been very few publications in patients with NLUTD (11,87).

4.2.3.4.4 Conclusions and recommendations on drug treatments

Conclusions	**LE**
Long-term efficacy and safety of antimuscarinic therapy for NDO is well documented.	1a
A combination of antimuscarinic agents is now used more frequently and is often considered to maximise outcomes for NDO.	1a
Alternative ways of administration of antimuscarinic agents, such as transdermally and intravescically, should now be considered.	2a
There is no drug with evidence of efficacy for underactive detrusor.	2a
Alpha-blockers have been partly successful in decreasing bladder outlet resistance and autonomic dysreflexia prophylaxis in spinal cord injury.	2a
There is a lack of prospective, randomised, controlled studies in the medical management of NLUTD.	

Recommendations on drug treatments	GR
Antimuscarinic therapy for NDO is effective and safe to use, including long term.	A
Outcomes for NDO can be maximised by considering a combination of antimuscarinic agents.	A
Alternative ways of administration of antimuscarinic agents, such as transdermally and intravescically, should be considered with the aim of reducing side effects.	B
Alpha-blockers may help to decrease bladder outlet resistance and may be a preventive measure in spinal cord injury to prevent autonomic dysreflexia.	B

*4.2.4 **External appliances***

As an ultimate remedy, social continence may be achieved by collecting urine during incontinence (1,11). Condom catheters with urine collection devices are a practical method for men. Otherwise, incontinence pads may offer a reliable solution. In both cases, the infection risk must be closely observed (11). Because of the risk of developing high intravesical pressure, the penile clamp is absolutely contraindicated.

*4.2.5 **Statements & guidelines on non-invasive conservative treatment***

Statements	LE
The first aim of any therapy is the protection of the upper urinary tract.	1
A condom catheter or pads may reduce urinary incontinence to a socially acceptable situation.	

Recommendations	GR
The mainstay of treatment for overactive detrusor is anticholinergic drug therapy.	A
Lower urinary tract rehabilitation may be effective in selected cases (patients that do not suffer from a complete spinal cord lesion).	
Any method of assisted bladder emptying should be used with the greatest caution.	A

4.3 Minimal invasive treatment

*4.3.1 **Catheterisation***

Intermittent self- or third-party catheterisation (88,89) is the gold standard for the management of NLUTD (1,11). It is effective in patients with:

- Detrusor underactivity or acontractility (1).
- With DO, provided the overactivity can be controlled (1,11,90-95).

Sterile IC, as originally proposed by Guttmann and Frankel (67), significantly reduces the risk of UTI and/or bacteriuria (1,11,96,97), compared with clean IC introduced by Lapides, et al. (89). However, it cannot be considered a routine procedure (11,97). Aseptic IC is an alternative (1,98), which provides a significant benefit in reducing the potential for external contamination of an intermittent urinary catheter (99). Insufficient patient education and the inherent greater risk of UTI in patients with NLUTD are contributing factors (11,100-104).

The average frequency of catheterisations per day is 4-6 times and the catheter size should be 12-14 Fr.

Less frequent catheterisation results in higher catheterisation volumes and a higher risk of UTI (1,100-103). More frequent catheterisation increases the risk of cross-infections and other complications (1,100-103).

Bladder volume at catheterisation should be lower than 400 mL.

The prevalence of complications can be limited by adequate patient education, use of nontraumatising techniques and adequate precautions to prevent infections (11,104).

Indwelling transurethral catheterisation and, to a lesser extent, suprapubic cystostomy are significant and early risk factors for UTI and other complications (11,16,105-114). Silicone catheters are preferred because they are less susceptible to encrustation and because of the high incidence of latex allergy in the NLUTD population.

4.3.2 ***Recommendations for catheterisation***

Recommendations	GR
Intermittent catheterisation is the standard treatment for patients who are unable to empty their bladder.	A
Patients should be well instructed in the technique and risks of IC.	
Aseptic IC is the method of choice.	B
The catheter size should be 12-14 Fr.	B
The frequency of IC is 4-6 times per day.	B
The bladder volume should remain below 400.	B
Indwelling transurethral and suprapubic catheterisation should be used only exceptionally, under close control, and the catheter should be changed frequently. Silicone catheters are preferred and should be changed every 2-4 weeks, while (coated) latex catheters need to be changed every 1-2 weeks.	A

4.3.3 ***Intravesical drug treatment***

To reduce DO, anticholinergics can also be applied intravesically (115-121). This approach may reduce adverse effects because the anticholinergic drug is metabolised differently (119) and a greater amount is sequestered in the bladder, even more than with electromotive administration (120,121).

The vanilloids, capsaicin and resiniferatoxin, desensitise the C-fibres and thereby decrease DO for a period of a few months until the sensation of these fibres has been restored (122-127).
The dosage is 1-2 mMol capsaicin in 100 mL 30% alcohol, or 10-100 nMol resiniferatoxin in 100 mL 10% alcohol for 30 minutes. Resiniferatoxin has about a 1,000-fold potency compared to capsaicin, with less pain during the instillation, and is effective in patients refractory to capsaicin. Clinical studies have shown that resiniferatoxin has limited clinical efficacy compared to botulinum toxin A injections in the detrusor (127).

4.3.4 ***Intravesical electrostimulation***

Intravesical electrostimulation (128) enhances the sensation for bladder filling and urge to void and may restore the volitional control of the detrusor (11,129,130). Daily stimulation sessions of 90 minutes with 10 mApulses of 2 ms duration at a frequency of 20 Hz (130,131) are used for at least 1 week (131). It appears that patients with peripheral lesions are the best candidates, that the detrusor muscle must be intact, and that at least some afferent connection between the detrusor and the brain must still be present (11,130,131). Also, the positioning of the stimulating electrodes and bladder filling are important parameters (132). With these precautions, the results in the literature are still not unequivocal: both positive (129,131,133,134) and negative (LE: 3) (135,136) results have been reported.

4.3.5 ***Botulinum toxin injections in the bladder***

Botulinum toxin causes a long-lasting but reversible chemical denervation that lasts for about 9 months (137-143). The toxin injections are mapped over the detrusor in a dosage that depends on the preparation used. Botulinum toxin A has been proven effective in a randomised placebo-controlled trial in NLUTD (144). Repeated injections seem to be possible without loss of efficacy (143,145,146). Generalised muscular weakness is an occasional adverse effect (141,143,146). Histological studies have not found ultrastructural changes after injection (147).

4.3.6 ***Bladder neck and urethral procedures***

Reduction of the bladder outlet resistance may be necessary to protect the upper urinary tract. This can be achieved by surgical interventions (bladder neck or sphincter incision or urethral stent) or by chemical denervation of the sphincter. Incontinence may result and can be managed by external devices (see Section 4.2.5).

Botulinum toxin sphincter injection can be used to treat detrusor sphincter dyssynergia effectively by injection in a dosage that depends on the preparation used. The dyssynergia is abolished for a few months, necessitating repeat injections. The efficacy of this treatment is high and there are few adverse effects (148-150).

Balloon dilatation: although favourable immediate results were reported (151), no further reports since 1994 have been found. Consequently, this method is no longer recommended.

Sphincterotomy: by staged incision, bladder outlet resistance can be reduced without completely losing the closure function of the urethra (1,11,144). The laser technique appears to be advantageous (1,152).

Sphincterotomy also needs to be repeated at regular intervals in a substantial proportion of patients (153), but is efficient and without severe adverse effects (1,9,151-154). Secondary narrowing of the bladder neck may occur, for which combined bladder neck incision might be considered (1,155).

Bladder neck incision: This is indicated only for secondary changes at the bladder neck (fibrosis) (1,9,152,155). When the detrusor is hypertrophied and causes thickening of the bladder neck, this procedure makes no sense (1).

Stents: Implantation of urethral stents causes the continence to be dependent on the adequate closure of the bladder neck only (1,4). Although the results are comparable with sphincterotomy and the stenting procedure has a shorter surgery time and reduced hospital stay (156,157), the costs (1) and possible complications or re-interventions (156,158,159) are limiting factors in its use.

Increasing bladder outlet resistance: This can improve the continence condition. Despite early positive results with urethral bulking agents, a relative early loss of continence is reported in patients with NLUTD (4,16,160-164).

Urethral inserts: Urethral plugs or valves for management of (female) stress incontinence have not been applied in patients with NLUTD. The experience with active pumping urethral prosthesis for treatment of the underactive or acontractile detrusor was disappointing (165).

4.3.7 ***Recommendations for minimal invasive treatment****

Recommendations	GR
Botulinum toxin injection in the detrusor is the most effective minimally invasive treatment to reduce neurogenic detrusor overactivity.	A
Sphincterotomy is the standard treatment for DSD.	A
Bladder neck incision is effective in a fibrotic bladder neck.	B

**Guidelines for catheterisation are listed separately under Section 4.3.2.*

4.4 Surgical treatment

4.4.1 ***Urethral and bladder neck procedures***

Increasing the bladder outlet resistance has the inherent risk of causing high intravesical pressure during the filling, which may become even higher during the voiding phase. Procedures to treat sphincteric incontinence are suitable only when the detrusor activity is, or can be, controlled, when no significant reflux is present.

Moreover, these procedures require the urethra and bladder neck to be in good condition and mostly result in intermittent catheterisation being performed after the procedure (4).

Urethral sling: Various materials have been used for this procedure with enduring positive results (4,166-179). The procedure is established in women; for men, the artificial sphincter is obviously the first choice (4).

Artificial urinary sphincter: This device has stood the test of time in patients with NLUTD (4). It was introduced by Light and Scott (180) for this patient group and the need for revisions (181) has decreased significantly with new generations of devices (172,182-185).

Functional sphincter augmentation: By transposing the gracilis muscle to the bladder neck (186) or to the proximal urethra (187), the possibility exists for creating a functional autologous sphincter by electrical stimulation (186,187). This would open the possibility of restoring control over the urethral closure.

Bladder neck and urethra reconstruction: The classical Young-Dees-Leadbetter (188) procedure for bladder neck reconstruction in children with bladder exstrophy and the Kropp urethral lengthening (189) improved by Salle (190) are established methods to restore continence provided that intermittent catheterisation is practiced and/or bladder augmentation is performed (172,181,189-200).

4.4.2 ***Detrusor myectomy (auto-augmentation)***

The idea of enlarging a shrunken bladder by removing lateral detrusor tissue to free the entrapped ureter in a non-functional fibrotic detrusor was put forward by Couvelaire (201). Since its clinical introduction by

Cartwright and Snow (202) in children and by Stöhrer (203) in adults, this procedure for reducing DO or improving low detrusor compliance has gained popularity because of its acceptable long-term results, its low surgical burden, its low rate of long-term adverse effects, its positive effect on the patient's QoL, and because it does not preclude further interventions (1,4,202-221).

The procedure is performed extraperitoneally under general anaesthesia and consists of the dissection of about 20% of the detrusor tissue around the umbilicus, leaving the mucosa intact (1,202,203). A diverticulum will develop, but this may take 1-2 years in adults (1,191,192). A laparoscopic procedure (205,209,213,222), covering of the mucosa at the detrusor defect (transperitoneal) (24,212,214,218), supporting the bladder (202,218), or simple incision of the detrusor muscle (detrusor myotomy) (220,221) are proposed variations of the procedure but offer no essential advantages.

*4.4.3 **Denervation, deafferentation, neurostimulation, neuromodulation***

Various procedures estimated to destroy the peripheral detrusor innervation have been abandoned because of poor long-term results and severe complications (4). These procedures include bladder distension, cystolysis, transvaginal denervation (Ingelman-Sundberg procedure) and subtrigonal phenol injections.

Sacral rhizotomy, also known as sacral deafferentation (SDAF), has achieved some success in reducing DO (16,223-227), but it is used nowadays mostly as an adjuvant to sacral anterior root stimulation (228-239). Alternatives for rhizotomy are sought in this treatment combination (240-242).

Sacral anterior root stimulation (SARS) is aimed at producing a detrusor contraction. The technique was developed by Brindley (243) and is applicable only in complete lesions above the implant location because of its stimulation amplitude over the pain threshold. The urethral sphincter efferents are also stimulated, but as the striated muscle relaxes faster than the smooth muscle of the detrusor, a so-called 'post-stimulus voiding' will occur. This approach has been successful in highly selected patients (228-239). By changing the stimulation parameters, this method can also induce defecation or erection.

The sacral nerve stimulation or sacral neuromodulation is based on the research by Schmidt and Tanagho (244). This technique stimulates the afferents and thereby probably restores the correct balance between excitatory and inhibitory impulses from and to the pelvic organs at a sacral and supra-sacral level, thus reducing the DO (28,245). It is used either as a temporary procedure using foramen electrodes with an external stimulator, with the expectation that the changes will persevere after treatment, or as a chronic procedure with an implanted stimulator. In the latter case, a test procedure, the percutaneous nerve evaluation (PNE), with an external stimulator is performed before the implant to judge the patient's response. This procedure also has considerable success in selected patients (210,246-250).

On the basis of the successful application of these systems, future developments towards a device that may be more integrated in the body are under research (251).

*4.4.4 **Bladder covering by striated muscle***

When the bladder is covered by a (part of) striated muscle that can be stimulated electrically, or ideally could be contracted volitionally, an acontractile bladder could be restored to perform a voiding function. The rectus abdominis (252) and the latissimus dorsi (253) have been used successfully in patients with NLUTD.

*4.4.5 **Bladder augmentation or substitution***

Replacing or expanding the bladder by intestine or other passive expandable coverage will reduce detrusor compliance and at least reduce the pressure effect of DO. The inherent complications associated with these procedures include recurrent infection, stone building, perforation or diverticula, possible malignant changes, and for intestine metabolic abnormality, mucus production and impaired bowel function (4,254-256). Since the age of the NLUTD patient population, when the surgery is performed, is generally much lower than that of patients with bladder malignancy, who are elected for this surgery, it is important that any possible, very long-term, complications in particular are appraised. Thus, the procedures should be used with caution in NLUTD patients, but may become necessary if all less-invasive treatment methods have failed.

Bladder augmentation, by procedures such as clam cystoplasty, is a valid option to decrease detrusor pressure and increase bladder capacity, whenever more conservative approaches have failed. A number of different techniques have been published. The results of the various procedures are very good and comparable (208,210-212,215-217,255-258). Bladder substitution to create a low pressure reservoir may be indicated in patients with severely thick and fibrotic bladder wall. Scaffolds, probably of tissue-engineered material for bladder augmentation or substitution or alternative techniques, are promising future options (216,259-264).

*4.4.6 **Urinary diversion***

When no other therapy has been successful urinary diversion must be considered for the protection of the upper tract and for the patient's QoL (4,265).

Continent diversion: This should be the first choice for diversion. In patients for whom indwelling catheterisation or suprapubic catheterisation is the only feasible treatment option, change to a continent stoma may be a better prospect (4). Some patients with limited dexterity prefer a stoma to using the urethra for catheterisation (4). The continent stoma is created following various techniques. All of them, however, do show frequent complications, including leakage or stenosis (4,266). The short-term continence rates are over 80% and good protection of the upper urinary tract is achieved (4,13,264-278). For cosmetic reasons, the umbilicus is often used for the stoma site, but this may have a higher risk of stenosis (269,271,276).

Incontinent diversion: If catheterisation is impossible, incontinent diversion with a urine collecting devic eis indicated. Fortunately, nowadays, this indication is seldom because many appropriate alternatives can be offered (4). Ultimately, it could be considered in patients who are wheelchair bound or bed-ridden with intractable and untreatable incontinence, in devastated LUTs, when the upper urinary tract is severely compromised, and in patients who refuse other therapy (4). An ileal segment is used for the deviation in most cases (4,279-283). The rather poor long-term results and the expected complications warrant a permanent follow-up (4).

Undiversion: Long-standing diversions may be successfully undiverted or an incontinent diversion changed to a continent one with the emergence of new and better techniques for control of the detrusor pressure and the incontinence (4). Also, in young patients, body image may play a role (273). The patient must be carefully counselled and must comply meticulously with the instructions (4). Successful undiversion can then be performed (284).

4.5 Recommendations for surgical treatment

Recommendations			**GR**
Detrusor	Overactive	Detrusor myectomy is an acceptable option for the treatment of overactive bladder when more conservative approaches have failed. It is limited invasive and has minimal morbidity	B
		Sacral rhizotomy with SARS in complete lesions and sacral neuromodulation in incomplete lesions are effective treatments in selected patients	B
		Bladder augmentation is an acceptable option for decreasing detrusor pressure whenever less invasive procedures have failed. For the treatment of a severely thick or fibrotic bladder wall, a bladder substitution might be considered	B
	Underactive	SARS with rhizotomy and sacral neuromodulation are effective in selected patients	B
		Restoration of a functional bladder by covering with striated muscle is still experimental	
Urethra	Overactive (DSD)	refer to guidelines for minimal invasive treatment (see Section 4.3.6)	
	Underactive	The placement of a urethral sling is an established procedure	B
		The artificial urinary sphincter is very effective	B
		Transposition of the gracilis muscle is still experimental

5. URINARY TRACT INFECTION IN NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

5.1 Introduction

Complicated UTI is the name given to urinary tract infection (UTI) in neurogenic lower urinary tract dysfunction (NLUTD). A detailed discussion of the clinical presentation, diagnosis, microbiological considerations and treatment strategies of complicated UTI can be found in the *EAU Guidelines on Urological Infections* (1). As stated in these guidelines, bacteriuria in patients with SCI should not be treated, even in cases of intermittent catheterisation. Generally, most knowledge concerning UTI in neurogenic patients comes from studies of patients with SCI and is therefore not directly transferable to other populations, such as MS, stroke, or PD.

5.2 Recurrent urinary tract infection in neurogenic patients

Recurrent UTI in patients with NLUTD may indicate a suboptimal management of the underlying functional problem, e.g. high bladder pressure during storage and voiding, incomplete voiding or bladder stones. The improvement of bladder function and the removal of bladder stones or other direct supporting factors are mandatory. Additionally, UTI prevention strategies can be applied (1).

5.3 Prevention

It is generally agreed that the best prevention of UTI in neurogenic patients is a well-balanced management of the LUTD, including low-pressure urine storage, maintaining a periodical, low resistance and ensuring complete voiding. If clean, intermittent catheterisation (CIC) is used for emptying, aseptic technique and sterile lubricated (2) or hydrophilic catheters (3,4) should be used. Regular voiding and a minimal daily fluid intake of 30 mL/kg body weight are considered to be supportive factors in UTI prevention.

Various approaches have been tried to minimise UTIs in neurogenic bladder. Randomised controlled trials have shown that cranberry extracts have no benefit (5-7). Research has also shown that both methenamine hippurate (8) and bladder irrigation are ineffective (9). Although urine acidification therapy using drugs, such as L-methionine, is widely used in neurogenic patients in an attempt to prevent UTIs, there is little scientific evidence to support its use. Low-dose, long-term, antibiotic prophylaxis may be an option for patients with recurrent UTI (10), but has the disadvantage of possibly increasing bacterial resistance (11). Vaccination therapy for UTI prevention has not been tested in neurogenic patients.

5.3.1 Recommendations for the treatment of urinary tract infection

Recommendations	GR
Bacteriuria in patients with spinal cord injury (SCI) should not be treated, even in cases of intermittent catheterisation.	
As in the general population, the use of long term antibiotics in recurrent UTIs may cause bacterial resistance and caution is advised.	
Protection of the urinary tract is the main focus.

6. TREATMENT OF VESICO-URETERAL REFLUX

6.1 Treatment options

The treatment options for vesico-ureteral reflux in patients with NLUTD do not differ essentially from those in other reflux patients. They become necessary when the high intravesical pressure during the filling phase or during the voiding phase have been treated successfully, but where the reflux did not resolve (1-4). Subtrigonal injections with bulking agents or ureteral re-implantation are the standard procedures.

Subtrigonal injections of bulking agents: This minimal invasive procedure has a relatively good effect with complete success in about 65% of patients (5-12). It can also be easily repeated if not effective and thereby the success rate can be increased to about 75% after the second or third session.

Ureteral re-implantation: This technique has an immediate and long-lasting result in over 90% of the patients (11-13). In deciding which procedure will be offered to the patient, the relative risks of more invasive surgery and of less successful therapy should be considered.

7. SEXUAL (DYS)FUNCTION AND FERTILITY

7.1 Spinal cord injury and sexuality - introduction

Neurological diseases and injuries have a distinct impact on sexual health, but guidelines for their management are still lacking (1). Periodical check-ups using validated questionnaires will help to assess and therefore improve sexual rehabilitation and response (2) (LE: 3).

7.2 Male erectile dysfunction

7.2.1 Medical treatment - Phosphodiesterase type 5 inhibitors

Phosphodiesterase type 5 inhibitors (PDE5Is) are recommended as first-line treatment in men with SCI and ED. They are safe and effective for long-term use. The most common side-effects in men with SCI are headache and flushing, while men with tetraplegia or high-level paraplegia may have postural hypotension for several

hours after using a PDE5I.

Phosphodiesterase type 5 inhibitors are currently the first-line treatment option for ED in patients with SCI because of their high efficacy and safety rates (3-5) (LE: 1b). However, little is known about the effect on erectile function in neurological patients. Tadalafil and sildenafil citrate are effective and safe long-term treatments for patients with MS and PD, respectively (8-11) (LE: 1b).

The great majority of neurogenic patients require long-term therapy for ED. However, some patients have a low compliance rate or they stop therapy because of side-effects (3). In addition, some patients with severe neurological damage may be resistant to PDE5Is (12).

7.2.2 Mechanical devices

Mechanical devices (vacuum tumescence devices and penile rings) may be effective but are less popular (6,7).

7.2.3 Intracavernosal injections

Patients not responding to oral drugs may be offered intracavernosal injections. Intracavernosal penile injectable medications (ICI) are very effective for the treatment of ED in men with SCI, but their use requires careful dose titration and some precautions. The reported complications of intracavernous drugs include priapism and corpora cavernosa fibrosis.

An intracavernosal injection of vasoactive medication is the first therapeutic option to consider in patients taking nitrate medications, for whom there are concerns about drug interactions with PDE5Is, or in patients for whom PDE5Is are ineffective.

Topical agents for penile smooth muscle relaxation (prostaglandin) or intraurethral preparation of prostaglandin E1 (MUSE) were found to be less effective in SCI patients suffering from ED (13).

7.2.4 Penile prostheses

Penile prostheses may be effective for treatment of ED in men with SCI and should be offered when all conservative treatments have failed. Serious complications, including infection and prosthesis perforation, may occur in about 10% of patients, depending on implant type (14-16).

7.2.5 Recommendations sexual dysfunction

Recommendations	GR
Oral PDE5Is are the first-line treatment for erectile dysfunction in men with SCI.	A
Intracavernosal injections of vasoactive drugs (alone or in combination) are the second-line treatment when oral medications have failed.	A
Mechanical devices such as vacuum devices and rings may be effective but are not as popular.	C
Surgical prostheses should be reserved for selected patients who have not responded to conservative therapies.	B

7.3 Male fertility

Reproductive dysfunction in men with SCI is a common condition and is due to a combination of ED, ejaculatory failure, and abnormal semen parameters, even if the definitive causal mechanism is unknown (17) (LE: 3). Assisted reproductive technologies may be needed.

Pregnancy rates are lower than in the general population. But since the advent of intracytoplasmic sperm injection (ICSI) men with SCI now have a good chance of becoming biological fathers (18-20).

In men with retrograde ejaculation, the use of a balloon catheter to obstruct the bladder neck may be effective in obtaining antegrade ejaculation (21). More comparative trials are needed to evaluate the impact of intracavernosal injections on ejaculation and orgasmic function, their early use for increasing the recovery rate of a spontaneous erection, and their effectiveness and tolerability in the long-term (3). Prostatic massage is a safe and easy method to use for obtaining semen in men with lesions above T10 (22).

The two most commonly used methods of sperm retrieval are vibrostimulation (VS) and transrectal electroejaculation (EEJ) (23-25). Semen retrieval is more likely with VS in men with lesions above T10 (26-28).

Midodrine may be combined with VS in men not responding to VS alone. However, EEJ is the second choice for sperm retrieval when repeated tries at VS have failed (29).

Surgical procedures, such as epididymal (MESA) or testicular (TESE) sperm retrieval, may be used if VS and EEJ are not successful (30,31).

*7.3.1 **Sperm quality and motility***

The following has been reported about sperm quality and motility:

- Vibratory stimulation produces samples with better sperm motility than electrostimulation (24,32).
- Antegrade samples have better sperm motility than retrograde samples.
- EEJ with interrupted current produces better sperm motility than does continuous current (33).
- Bladder management with clean intermittent catheterisation may improve semen quality compared to indwelling catheterisation, reflex voiding or bladder expression (34).
- Sperm quality in patients with SCI is enhanced by processing in able-bodied seminal plasma (35).

There are no relevant publications about fertility in other neurological pathologies.

7.4 Female sexuality

Studies have shown that most women (65–80%) continue to be sexually active after SCI, but to a much lesser extent than before injury. In addition, about 25% of women with an SCI report a decreased satisfaction with their sexual life (37-39).

Studies show that the greatest physical barrier to sexual activity is urinary leakage. Problems with positioning and spasticity affect mainly tetraplegics. Peer support may help to optimise the sexual adjustment of women with SCI in achieving a more positive self-image, self-esteem and feelings of being attractive to themselves and others (40-43).

The use of specific drugs for sexual dysfunctions is indicated to treat inadequate lubrication. Sildenafil may partially reverse subjective sexual arousal difficulties, while manual and vibratory clitoral stimulation may increase genital responsiveness (44,45).

Neurophysiological studies have shown that women with the ability to perceive T11-L2 pinprick sensations may have psychogenic genital vasocongestion, while reflex lubrication and orgasm is more prevalent in women with SCI who have preserved the sacral reflex arc (S2-S5). These findings are true, even when it has not been shown in an individual woman that a specific level and degree of lesion is the cause of a particular sexual dysfunction. In SCI women with a complete lesion of the sacral reflex, arousal and orgasm may be evoked through stimulation of other erogenous zones above the level of lesions (46-48).

Studies have reported dissatisfaction with the quality and quantity of sexuality related rehabilitation services for women with SCI and that affected women were less likely to receive sexual information than men (48-50).

7.5 Female fertility

The reproductive capacity of women with SCI is only temporarily affected by SCI with cessation of menstruation for approximately 6 months post-SCI (51). About 70% of sexually active women use some form of contraception after injury, but fewer women use the birth control pill compared to before their injury (52).

Although pregnancy is usually normal, women with SCI are more likely to suffer complications during pregnancy, labour and delivery compared to able-bodied women. Complications of labour and delivery include bladder problems, spasticity, pressure sores, and anaemia autonomic dysreflexia (53,54). Obstetric outcomes include higher rates of caesarean sections and an increased incidence of low birth-weight babies (55).

Epidural anaesthesia is chosen and effective for most patients with autonomic dysreflexia during labour and delivery (56,57).

There is very little published data on women's experience of the menopause following an SCI (58). There are no relevant publications about sexuality and fertility in other neurological pathologies.

8. QUALITY OF LIFE

8.1 Introduction

Quality of life (QoL) is a very important aspect of the global management of NLUTD patients (1). The type of bladder management may influence the health-related QoL (HRQoL) in patients with SCI (2). The effectiveness of urological treatment and the urodynamic functionality of the neurogenic bladder have become increasingly determinant of patient QoL (3). QoL is a reflection of the individual's ability to cope with the new life situation (4). Despite the limitations associated with neurological pathology, adequate treatment is possible in most patients and should not interfere with social independence. QoL can be influenced by several factors including family support, adjustment and coping ability, productivity, self-esteem, financial stability, education, and the physical and social environment (5) (LE: 3). Age, sex, ethnicity, and the patient's acceptance of the condition should also be taken into consideration when assessing QoL (6) (LE: 3).

8.2 Quality of life assessment

There are no specific QoL questionnaires for neurogenic bladder dysfunction or NLUTD. The only validated tools are a generic Visual Analogue Scale (VAS) for symptom bother, and Qualiveen® which is a specific tool for QoL in spinal cord lesion and multiple sclerosis patients. Qualiveen appears to be a discriminative evaluation instrument (3,7-9) and a short form is now available (10).

More commonly, QoL is assessed secondarily by generic HRQL questionnaires such as the Incontinence Quality of Life Instrument (I-QOL), King's Health Questionnaire (KHQ), Short Form 36 Health Survey Questionnaire (SF-36), Euro Quality of Life-5 Domains (EQ-5D), Short Form 6D Health Survey Questionnaire (SF-6D), or the Health Utilities Index (HUI).

Furthermore, the quality-adjusted life year (QALY) metric quantifies patient outcomes, by weighting years of life spent in a specified health state by a factor representing the value that society or patients place on that health state (11) (LE: 3).

8.3 Therapy influence on quality of life

Appropriate therapies should manage symptoms, improve urodynamic parameters, functional abilities and QoL, and avoid secondary complications (8,12). Changes in NLUTD appear to be a major determinant of patient QoL (13,14) (LE: 2a).

8.4 Conclusions and recommendations

Conclusions	LE
One of the main aims of therapy is to improve qualify of life.	1
There is a lack of disease-specific outcome measures assessing HRQoL in patients with NLUTD.	

Recommendations	GR
Quality of life should be assessed when evaluating lower urinary tract symptoms in neurogenic patients and when treating neurogenic bowel dysfunction.	B
The available validated tools are Qualiveen, a specific long- and short-form tool for spinal cord lesion and multiple sclerosis patients and VAS for symptom bother. In addition, generic (SF-36) or specific tools for incontinence (I-QOL) questionnaires can be used.	B

9. FOLLOW-UP

9.1 Introduction

NLUTD is an unstable condition and can vary considerably, even within a relatively short period. Meticulous follow-up and regular checks are necessary (1-20). Depending on the type of the underlying neurological pathology and on the current stability of the NLUTD, the interval between the detailed investigations should not exceed 1-2 years. In patients with multiple sclerosis and in acute SCI, this interval is of course much smaller. Urine dip sticks should be available for the patient and urinalysis should be performed at least every second month. The upper urinary tract, the bladder shape, and residual urine should be checked every 6 months. Physical examination and blood and urine laboratory should take place every year. Any sign indicating a risk factor warrants specialised investigation.

9.2 Guidelines for follow-up

Possible UTI checked by the patient (dip stick).
Urinalysis every second month.
Upper urinary tract, bladder morphology, and residual urine every 6 months (ultrasound).
Physical examination, blood chemistry, and urine laboratory every year.
Detailed specialistic investigation every 1-2 years and on demand when risk factors emerge. The investigation is specified according to the patient's actual risk profile, but should in any case include a video-urodynamic investigation and should be performed in a leading neuro-urological centre.
All of the above should be more frequent if the neurological pathology or the NLUTD status demand this.

10. CONCLUSIONS

NLUTD is a multi-faceted pathology. It requires an extensive and specific diagnosis before we can embark on an individualised therapy, which takes into account the medical and physical condition of the patient and the patient's expectations about his future social and physical situation with respect to the NLUTD.

The urologist or paediatric urologist can select from a wealth of therapeutical options, each with its own pros and cons. Notwithstanding the success of any therapy embarked upon, a close surveillance is necessary for the patient's entire life.

With these guidelines, we offer you expert advice on how to define the patient's NLUTD condition as precisely as possible and how to select, together with the patient, the appropriate therapy. This last choice, as always, is governed by the golden rule: as effective as needed, as less invasive as possible.

11. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

CVA	cerebrovascular
DLPP	detrusor leak point pressure
DO	detrusor overactivity
DSD	detrusor sphincter dyssynergia
EMG	electromyography, electromyogram
FVC	frequency volume chart
HIV	human immunodeficiency virus
HRQoL	health-related quality of life
IC	intermittent catheterisation
ISC	intermittent self-catheterisation
ICS	international Continence Society
LPP	leak point pressure
LMNL	lower motor neuron lesion
LUT	lower urinary tract
LUTD	lower urinary tract dysfunction
LUTS	lower urinary tract symptoms
MTC	micturition time chart
NDO	neurogenic detrusor overactivity
NLUTD	neurogenic lower urinary tract dysfunction
PNE	percutaneous nerve evaluation test
QoL	quality of life
SARS	sacral anterior root stimulation
SCI	spinal cord injury
SDAF	sacral deafferentation
SLE	systemic lupus erythematosus
UMNL	upper motor neuron lesion
UTI	urinary tract infection
VAS	visual analogue scale
VS	vibrostimulation

Conflict of interest

All members of the Neurogenic Lower Urinary Tract Dysfunction guidelines working group have provided disclosure statements of all relationships which they have and which may be perceived as a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on Urolithiasis

of Urology

TABLE OF CONTENTS PAGE

1. METHODOLOGY

1.1 Introduction

The European Association of Urology (EAU) Urolithiasis Guidelines Panel have prepared these guidelines to help urologists assess evidence-based management of stones/calculi and incorporate recommendations into clinical practice.

The document covers most aspects of the disease, which is still a cause of significant morbidity despite technological and scientific advances. The Panel is aware of the geographical variations in healthcare provision.

1.2 Data identification

For this 2012 (limited) update of the Urolithiasis guidelines, a scoping search, covering all content, was performed. Time frame of the search was November 2010 to August 10th, 2011. This search was limited to level 1 evidence (systematic reviews [SRs] and meta-analyses of randomised controlled trials [RCTs]) and English language publications in peer-reviewed journals. Animal studies were excluded.

For this limited update 124 unique records were identified of which 28 new references were selected for inclusion in this document. For a number of sections which included recommendations upgraded following panel consensus (High-risk stone formers and familiar risk [2.6], Patient evaluation [3.1.2] and Decompression of obstructed kidney [4.2.1]) additional verification searches were done to assess whether additional evidence has become available over the past year. These searches were not limited to level 1 data. Only in two instances could a higher level of evidence (not influencing the grade of recommendation) be found (3.2.2 Recommendations for repeat analysis of stone composition and 5.7.2.1 Indications for laparoscopic stone surgery). A more detailed summary of changes can be found below.

Annual scoping searches will be repeated as a standard procedure.

1.3 Evidence sources

Searches were carried out in the Cochrane Library Database of Systematic Reviews, Cochrane Library of Controlled Clinical Trials, and Medline and Embase on the Dialog-Datastar platform. The searches used the controlled terminology and the use of free text ensured search sensitivity.

Randomised controlled trial strategies were based on Scottish Intercollegiate Guidelines Network (SIGN) and Modified McMaster/Health Information Research Unit (HIRU) filters for RCTs, systematic reviews and practice guidelines on the OVID platform and then translated into Datastar syntax.

For the 2011 full text update, 4,013 papers were identified and 688 were included in the 2011 print, which also included key publications from other sources were proposed by panel members. Initial assessment and selection were based on citation and abstract only, and when in doubt, full-text papers were consulted. Meta-analysis of the stone-free rates for the section on ureteral calculi was updated. An overall scoping search was conducted to ensure that the individual searches met the minimum requirement of identification of all level 1 evidence. There is a need for ongoing re-evaluation of the current guidelines by an expert panel. It must be emphasised that clinical guidelines present the best evidence available but following the recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients - also taking personal values and preferences/individual circumstances of patients into account.

1.4 Level of evidence and grade of recommendation

References in the text have been assessed according to their level of scientific evidence (Table 1), and guideline recommendations have been graded (Table 2) according to the Oxford Centre for Evidence-based Medicine Levels of Evidence (1). Grading aims to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence (LE)*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised controlled trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

** Modified from Sackett et al. (1).*

When recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of RCTs may not translate into a grade A recommendation when there are methodological limitations or disparity in published results.

Absence of high-level evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. There may be exceptions where corroborating studies cannot be performed, perhaps for ethical or other reasons, and unequivocal recommendations are considered helpful. Whenever this occurs, it is indicated in the text as "upgraded based on panel consensus". The quality of the underlying scientific evidence must be balanced against benefits and burdens, values and preferences and cost when a grade is assigned (2-4).

The EAU Guidelines Office does not perform cost assessments, nor can it address local/national preferences systematically. The expert panels include this information whenever it is available.

Table 2: Grade of recommendation (GR)*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without RCTs
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett et al. (1).*

1.5 Publication history

The current guidelines present a limited update following a complete update of the 2011 print version. The first EAU Guidelines on Urolithiasis were published in 2000. Subsequent updates were in 2001 (partial), 2005 (comprehensive), 2008 (comprehensive), and 2009 and 2010 (limited). Several summaries have been published in scientific journals; the first in 2001 (5) and subsequently in 2007 (6,7).

A quick reference document presenting the main findings of the urolithiasis guidelines is also available with several scientific publications in the EAU journal European Urology and Journal of Urology (5-7). All texts can be viewed and downloaded for personal use at the EAU website:
http://www.uroweb.org/guidelines/online-guidelines/.

This document was peer-reviewed prior to publication.

1.5.1 Summary of changes

New literature included

Section	Title
2.3	X-ray characteristics
2.6	Risk groups for stone formation (Table 6)
5.3.4	Factors affecting success of MET
5.5.3	Best clinical practice

5.6.1.5.4	Puncture
5.6.1.5.7	Management of complications following PNL (new Table 14)
5.6.2.2.1	Pre-operative work up and preparations
5.6.2.2.6	Stone extraction new data added
5.6.2.2.8	Stenting prior to, and after URS
5.7.2	Laparoscopic surgery
6.4	Selection of procedure for active removal of kidney stones

New literature resulting in a change of LE in the recommendation sections

3.1	Diagnostic imaging: Patient evaluation (3.1.2) for patients in whom treatment of renal stones is planned (NCCT recommended in favour of IVU)
3.2	Recommendations for repeat stone analysis in patients: (LE:2 - old listing LE:3)
5.7.2.1	Indications for laparoscopic stone surgery - recommendations (LE: 3 - old listing LE: 4)

New literature has been including in the following sections resulting in new recommendations or a change in ranking (GR)

5.7.2.1	Indications for laparoscopic stone surgery - New recommendation on large impact stones or when endoscopic lithotripsy or SWL have failed.
6.4.2	Selection of procedure for active removal of kidney stones.

2. CLASSIFICATION OF STONES

Urinary stones can be classified according to size, location, X-ray characteristics, aetiology of formation, composition, and risk of recurrence.

2.1 Stone size

Stone size is usually given in one or two dimensions, and stratified into those measuring up to 5, > 5-10, > 10-20, and > 20 mm in largest diameter.

2.2 Stone location

Stones can be classified according to anatomical position: upper, middle or lower calyx; renal pelvis; upper, middle or distal ureter; and urinary bladder. Treatment of bladder stones is not discussed here.

2.3 X-ray characteristics

Stones can be classified according to plain X-ray appearance (kidney-ureter-bladder radiography; KUB) (Table 3), which varies according to mineral composition. Non-contrast-enhanced computer tomography (NCCT) can be used to classify stones according to density, inner structure and composition, which can affect treatment decisions (Section 6.3.4) (1,2).

Table 3: X-ray characteristics

Radiopaque	Poor radiopacity	Radiolucent
Calcium oxalate dihydrate	Magnesium ammonium phosphate	Uric acid
Calcium oxalate monohydrate	Apatite	Ammonium urate
Calcium phosphates	Cystine	Xanthine
		2,8-dihydroxyadenine
		'Drug-stones' (Section 11.11)

2.4 Aetiology of stone formation

Stones can be classified into those caused by: infection, or non-infectious causes (infection and non-infection stones); genetic defects; or adverse drug effects (drug stones) (Table 4).

Table 4: Stones classified by aetiology*

Non-infection stones • Calcium oxalate • Calcium phosphate (including brushite and carbonate apatite) • Uric acid
Infection stones • Magnesium ammonium phosphate • Carbonate apatite • Ammonium urate
Genetic causes • Cystine • Xanthine • 2,8-dihydroxyadenine
Drug stones

*Section 11.4.2

2.5 Stone composition

Metabolic aspects are important in stone formation, and metabolic evaluation is required to rule out any disorders. Analysis in relation to metabolic disorders is the basis for further diagnostic and management decisions. Stones are often formed from a mixture of substances, and that comprising the largest part is the most important. Table 5 lists the clinically most relevant substances and their mineral components.

Table 5: Stone composition

Chemical composition	Mineral
Calcium oxalate monohydrate	whewellite
Calcium oxalate dihydrate	wheddelite
Uric acid dihydrate	uricite
Ammonium urate	
Magnesium ammonium phosphate	struvite
Carbonate apatite (phosphate)	dahllite
Calcium hydrogenphosphate	brushite
Cystine	
Xanthine	
2,8-dihydroxyadenine	
'Drug stones'	

2.6 Risk groups for stone formation

The risk status of stone formers is of particular interest because it defines the probability of recurrence or regrowth, and is imperative for pharmacological treatment.

About 50% of recurrent stone formers have just one lifetime recurrence (3,4). Highly recurrent disease is observed in slightly more than 10% of patients. Stone type and disease severity determine low or high risk of recurrence (Table 6) (5-7).

Table 6: High-risk stone formers (7-12)

General factors
Early onset of urolithiasis (especially children and teenagers)
Familial stone formation
Brushite-containing stones (calcium hydrogen phosphate; $CaHPO_4 . 2H_2O$)
Uric acid and urate-containing stones
Infection stones
Solitary kidney (the solitary kidney itself does not particularly increase risk of stone formation, but prevention of stone recurrence is of more importance)
Diseases associated with stone formation
Hyperparathyroidism
Nephrocalcinosis
Gastrointestinal diseases (i.e. jejuno-ileal bypass, intestinal resection, Crohn's disease, malabsorptive conditions, enteric hyperoxaluria after urinary diversion)
Sarcoidosis
Genetically determined stone formation
Cystinuria (type A, B, AB)
Primary hyperoxaluria (PH)
Renal tubular acidosis (RTA) type I
2,8-dihydroxyadenine
Xanthinuria
Lesch-Nyhan syndrome
Cystic fibrosis
Drugs associated with stone formation (Section 11.11)
Anatomical abnormalities associated with stone formation

Medullary sponge kidney (tubular ectasia)
Ureteropelvic junction (UPJ) obstruction
Calyceal diverticulum, calyceal cyst
Ureteral stricture
Vesico-uretero-renal reflux
Horseshoe kidney
Ureterocele

3. DIAGNOSIS

3.1 Diagnostic imaging

Patients with urinary stones usually present with loin pain, vomiting, and sometimes fever, but may also be asymptomatic. Standard evaluation includes detailed medical history and physical examination. Clinical diagnosis should be supported by appropriate imaging.

If available, ultrasonography should be used as the primary diagnostic imaging tool although pain relief, or any other emergency measures should not be delayed by imaging assessments. It is safe (no risk of radiation), reproducible and inexpensive. It can identify stones located in the calices, pelvis, and pyelo-ureteric and vesicoureteric junctions, as well as upper urinary tract dilatation. For stones > 5 mm, ultrasound has a sensitivity of 96% and specificity of nearly 100% (1). For all stone locations, sensitivity and specificity of ultrasound reduces to 78% and 31%, respectively (1).

The sensitivity and specificity of KUB is 44-77% and 80-87%, respectively (2). KUB should not be performed if NCCT is considered (3), however, it is helpful in differentiating between radiolucent and radiopaque stones and for comparison during follow-up.

Recommendation	LE	GR
With fever or solitary kidney, and when diagnosis is doubtful, immediate imaging is indicated.	4	A*

**Upgraded following panel consensus.*

3.1.1 Evaluation of patients with acute flank pain

Non-contrast-enhanced computer tomography has become the standard for diagnosing acute flank pain, and has replaced intravenous urography (IVU), which was the gold standard for many years. NCCT can determine stone diameter and density. When stones are absent, the cause of abdominal pain should be identified. Compared with IVU, NCCT shows higher sensitivity and specificity for identifying urinary stones (Table 7) (4-8).

Table 7: Comparison of non-contrast-enhanced computer tomography (NCCT) and intravenous urography (IVU)

Reference	NCCT		IVU	
	Sensitivity	Specificity	Sensitivity	Specificity
Miller (5)	96%	100%	87%	94%
Niall (7)	100%	92%	64%	92%
Sourtzis (4)	100%	100%	66%	100%
Yilmaz (6)	94%	97%	52%	94%
Wang (8)	99%	100%	51%	100%

Recommendation	LE	GR
NCCT should be used to confirm stone diagnosis in patients with acute flank pain, because it is superior to IVU (9,10).	1a	A

NCCT can detect uric acid and xanthine stones, which are radiolucent on plain films, but not indinavir stones (11).

NCCT can determine stone density, inner structure of the stone and skin-to-stone distance; both of which affect extracorporeal shock wave lithotripsy (SWL) outcome (12-15). The advantage of non-contrast imaging must be balanced against loss of information about renal function and urinary collecting system anatomy, as well as higher radiation dose (Table 8).

Radiation risk can be reduced by low-dose CT (16). In patients with body mass index (BMI) < 30, low-dose CT was 86% sensitive for detecting ureteric stones < 3 mm and 100% sensitive for detecting calculi > 3 mm (17). A meta-analysis of prospective studies (18) showed that low-dose CT diagnosed urolithiasis with a pooled sensitivity of 96.6% (95% CI: 95.0-97.8) and specificity of 94.9% (92.0-97.0).

Table 8: Radiation exposure of imaging modalities (19-22)

Method	Radiation exposure (mSv)
KUB	0.5-1
IVU	1.3-3.5
Regular-dose NCCT	4.5-5
Low-dose NCCT	0.97-1.9
Enhanced CT	25-35

Recommendation	LE	GR
In patients with BMI < 30, low-dose NCCT should be used.	1b	A

3.1.2 Evaluation of patients for whom further treatment of renal stones is planned

A contrast study is recommended if stone removal is planned and the renal collecting system anatomy is not known. Enhanced CT is preferable because it enables 3D-reconstruction of the collecting system, as well as measurement of stone density and skin-to-stone distance. IVU may also be used.

Recommendation	LE	GR
A renal contrast study (enhanced CT or IVU) is indicated when planning treatment for renal stones.	3	A*

** Upgraded based on panel consensus.*

3.2 Diagnostics - metabolism-related

Each emergency patient with urolithiasis needs a succinct biochemical work-up of urine and blood besides imaging. At that point, no distinction is made between high- and low-risk patients.

Table 9: Recommendations: basic analysis - emergency stone patient (1-4)

Urine	**GR**
Urinary sediment/dipstick test of spot urine sample • red cells • white cells • nitrite • approximate urine pH	A*
Urine culture or microscopy	A
Blood	

Serum blood sample • creatinine • uric acid • ionized calcium • sodium • potassium	A*
Blood cell count CRP	A*
If intervention is likely or planned: Coagulation test (PTT and INR)	A*

** Upgraded based on panel consensus.*
CPR = C-reactive protein; INR = international normalised ratio; PTT = partial thromboplastin time.

*3.2.1 **Basic analysis - non-emergency stone patients***

Biochemical work-up is similar for all stone patients. However, examination of sodium, potassium, CRP, blood coagulation time can be omitted for non-emergency cases.

Only patients at high risk for stone recurrence should undergo a more specific analytical programme (4). Stone-specific metabolic evaluation is described in Chapter 11.

The easiest means to achieve correct diagnosis is by analysis of a passed stone using a valid method. Once mineral composition is known, the potential metabolic disorders can be identified.

*3.2.2 **Analysis of stone composition***

Stone analysis should be performed in all first-time stone formers.
In clinical practice, repeat stone analysis is needed in case of:

- recurrence under pharmacological prevention;
- early recurrence after interventional therapy with complete stone clearance;
- late recurrence after a prolonged stone-free period (6).

The patient should be instructed to filter the urine to retrieve a concrement for analysis. Stone passage and restoration of normal renal function should be confirmed.

The preferred analytical procedures are infrared spectroscopy (IRS) or X-ray diffraction (XRD) (5, 7-10).
Equivalent results can be obtained by polarisation microscopy, but only in centres with expertise.
Chemical analysis (wet chemistry) is generally deemed to be obsolete (5).

Table 10: Accuracy of substance identification in stone analysis (5)

Accuracy of identification of substance (%)	Chemical analysis	Infrared spectroscopy	X-ray diffraction
Uric acid	81.0	97.6	97.9
Ammonium urate	83.1	95.0	96.0
Cystine	93.5	99.1	98.5
Xanthine	28.4	96.3	93.2
2,8-Dihydroxyadenine	6.0	80.0	69.6
Whewellite	85.6	97.8	98.7
Struvite	89.5	97.9	98.0
Brushite	69.6	97.4	100.0
Apatite	79.4	93.9	100.0
Calcite	66.0	98.5	98.2
Cholesterol	38.9	98.6	82.4
Silicium dioxide	21.6	95.6	98.1
Gypsum	38.6	96.0	77.1

Recommendations	LE	GR
Always perform stone analysis in first-time formers using a valid procedure (XRD or IRS).	2	A
Repeat stone analysis in patients: • presenting with reccurent stones despite drug therapy; • with early recurrence after complete stone clearance; • with late recurrence after a long stone-free period because stone composition may change (3).	2	B

4. TREATMENT OF PATIENTS WITH RENAL COLIC

4.1 Renal colic

*4.1.1 **Pain relief***

Pain relief is the first therapeutic step in patients with an acute stone episode (1,2).

Non-steroidal anti-inflammatory drugs (NSAIDs) are effective in patients with acute stone colic (3-6), and have better analgesic efficacy than opioids. Patients receiving NSAIDs are less likely to require further analgesia in the short term.

Opioids, particularly pethidine, are associated with a high rate of vomiting compared with NSAIDs, and carry a greater likelihood of further analgesia being needed (7,8) (see Section 4.1.3). If an opioid is used, it is recommended that it is not pethidine.

Recommendations	GR
In acute stone episodes, pain relief should be initiated immediately.	A
Whenever possible, an NSAID should be the first drug of choice.	A

4.1.2 ***Prevention of recurrent renal colic***

Most ureteral stones pass spontaneously (Section 5.1.1), and facilitation of passage is discussed in Section 5.3.

For patients with ureteral stones that are expected to pass spontaneously, NSAID tablets or suppositories (e.g. diclofenac sodium, 100-150 mg/day, 3-10 days) may help reduce inflammation and risk of recurrent pain (8-10). Although diclofenac can affect renal function in patients with already reduced function, it has no effect in patients with normal kidney function (LE: 1b) (11).

In a double-blind, placebo-controlled trial, recurrent pain episodes of stone colic were significantly fewer in patients treated with NSAIDs (as compared to no NSAIDs) during the first 7 days of treatment (10).

Daily α-blockers reduce recurrent colic (LE: 1a) (Section 5.3) (12,13).

If analgesia cannot be achieved medically, drainage, using stenting or percutaneous nephrostomy, or stone removal, should be performed.

4.1.3 ***Recommendations for analgesia during renal colic***

	LE	GR	Refs.
First choice: start with an NSAID, e.g. diclofenac*, indomethacin or ibuprofen.	1b	A	1-4
Second choice: hydromorphine, pentazocine and tramadol.	4	C	
*Recommended to counteract recurrent pain after ureteral colic.	1b	A	7

**Affects glomerular filtration rate (GFR) in patients with reduced but not normal renal function (LE: 2a) (14).*

Although NSAIDs constitute the first choice for medical management of acute renal colic pain, spasmolytics may be given when parenteral administration of a non-narcotic agent is mandatory (third-line treatment) (15,16).

4.2 Management of sepsis in obstructed kidney

Obstructed, infected kidney is a urological emergency. Urgent decompression is necessary to prevent further complications in infected hydronephrosis secondary to a stone-induced, either unilateral or bilateral renal obstruction.

The optimal method of decompression has yet to be established (1-3). However, it is known that compromised delivery of antibiotics into the obstructed kidney means that the collecting system must be drained to encourage resolution of infection.

*4.2.1 **Decompression***

Currently, there are two options for urgent decompression of obstructed collecting systems:

- placement of an indwelling ureteral catheter under general anaesthesia;
- percutaneous placement of a nephrostomy catheter.

There is little evidence to support the superiority of percutaneous nephrostomy over retrograde stenting as primary treatment of infected hydronephrosis. There is no good-quality evidence to suggest that ureteric stenting under general anaesthesia has more complications than percutaneous nephrostomy. However, the latter has the advantage of avoiding general anaesthesia and instrumentation in the urinary tract (1,4-6).

Only two RCTs (2,5) have assessed decompression of acute infected hydronephrosis. The complications of percutaneous nephrostomy insertion have been reported consistently, but those of ureteric stent insertion are less well described (1).

A “stent first where possible” approach may reduce the requirement for out-of-hours nephrostomy placement in patients with infected hydronephrosis, although it does not eliminate the demand for nephrostomy (1-8).

Definitive treatment of the stone should be delayed until the infection is cleared following a complete course of antimicrobial therapy (9).

Exceptionally, emergency nephrectomy may become necessary for severe sepsis and/or abscess formation.

Statement	LE
For decompression of the renal collecting system, ureteral stents and percutaneous nephrostomy catheters are equally effective.	1b

Recommendation	LE	GR
For sepsis with obstructing stones, the collecting system should be urgently decompressed, using percutaneous drainage or ureteral stenting. Definitive treatment of the stone should be delayed until sepsis is resolved.	1b	A

*4.2.2 **Further measures***

Following urgent decompression of the obstructed and infected system, urine samples should be sent for culture-antibiogram sensitivity testing, and antibiotics should be initiated immediately thereafter. The regimen should be revisited in the light of the culture-antibiogram test. Intensive care might become necessary.

Recommendations	GR
Collect urine for antibiogram test following decompression.	A*
Start antibiotics immediately thereafter (+ intensive care if necessary).	
Revisit antibiotic treatment regimen following antibiogram findings.	

** Upgraded based on panel consensus.*

5. STONE RELIEF

When deciding between active stone removal and conservative treatment with medical expulsive therapy (MET), it is important to consider all the circumstances of a patient that may affect treatment decisions.

5.1 Observation of ureteral stones

5.1.1 Stone-passage rates

There are only limited data about spontaneous stone passage according to size (1,2). A meta-analysis of 328 patients harbouring ureteral stones < 10 mm investigated the likelihood of ureteral stone passage (Table 11) (1). These studies had limitations including non-standardisation of stone size measurement, and lack of analysis of stone position, stone-passage history, and time to stone passage.

Table 11: Likelihood of ureteral stone passage of ureteral stones (1)

Stone size	passage	CI
< 5 mm (n = 224)	68%	(95% CI 46-85%)
> 5 mm (n = 104)	47%	(95% CI 36-58%)
< 2 mm	31 days	
2-4 mm	40 days	
> 4-6 mm	39 days	

95% of stones up to 4 mm pass within 40 days (2).

Recommendations	LE	GR
In patients with newly diagnosed ureteral stones < 10 mm, and if active removal is not indicated (Chapter 6), observation with periodic evaluation is optional initial treatment.	1a	A
Such patients may be offered appropriate medical therapy to facilitate stone passage during observation.*		

**see also Section 5.3, Medical expusive therapy (MET).*

5.2 Observation of kidney stones

Observation of kidney stones, especially in calices, depends on their natural history (Section 6.2.1).

Statement	LE
It is still debatable whether kidney stones should be treated, or whether annual follow-up is sufficient for asymptomatic caliceal stones that have remained stable for 6 months.	4

Recommendations	GR
Kidney stones should be treated in case of growth, formation of de novo obstruction, associated infection, and acute or chronic pain.	A
Comorbidity and patient preference need to be taken into consideration when making treatment decisions.	C
If kidney stones are not treated, periodic evaluation is needed.	A

** Upgraded based on panel consensus.*

5.3 Medical expulsive therapy (MET)

Drugs that expel stones might act by relaxing ureteral smooth muscle through inhibition of calcium channel pumps or α-1 receptor blockade (3,4).

MET should only be used in patients who are comfortable with this approach and when there is no obvious advantage from immediate active stone removal.

Meta-analyses have shown that patients with ureteral stones treated with α-blockers or nifedipine are more likely to pass stones with less episodes of colic than those not receiving such therapy (3,5).

Statement	LE
There is growing evidence that MET accelerates spontaneous passage of ureteral stones and fragments generated with SWL, and limits pain (3-15).	1a

*5.3.1 **Choice of medical agent***

5.3.1.1 Alpha-blockers

Tamsulosin is one of the most commonly used alpha-blockers (3,5,16-19). However, one small study has suggested that tamsulosin, terazosin and doxazosin are equally effective, indicating a possible class effect (20). This is also indicated by several trials demonstrating increased stone expulsion using doxazosin (4,20,21) terazosin (20,22) alfuzosin (23-26) and naftopidil (27,28).

Statement	LE
Several trials have demonstrated increased stone expulsion using tamsulosin, doxazosin, terazosin, alfuzosin and naftopidil.	1b

5.3.1.2 Calcium-channel blockers

With regard to the class effect of calcium-channel blockers, only nifedipine has been investigated (LE = 1a) (3,8-10, 29,30).

5.3.1.2.1 Tamsulosin versus nifedipine

Administration of tamsulosin and nifedipine is safe and effective in patients with distal ureteral stones with renal colic. However, tamsulosin is significantly better than nifedipine in relieving renal colic and facilitating and accelerating ureteral stone expulsion (10,29,30).

5.3.1.3 Corticosteroids

Based on studies with a limited number of patients (31,32: LE 1b), no recommendation for the use of corticosteroids in combination with alpha-blockers in MET can be made.

Statement	LE
There is no evidence to support the use of corticosteroids as monotherapy for MET. Insufficient data exist to support the use of corticosteroids in combination with alpha-blockers as an accelerating adjunct (3,20,31,32).	1b

Recommendations for MET	LE	GR
For MET, alpha-blockers or nifedipine are recommended.		A
Patients should be counselled about the attendant risks of MET, including associated drug side effects, and should be informed that it is administered as 'off-label' use.†		A*
Patients, who elect for an attempt at spontaneous passage or MET, should have well-controlled pain, no clinical evidence of sepsis, and adequate renal functional reserve.		A
Patients should be followed once between 1 and 14 days to monitor stone position and to assess for hydronephrosis.	4	A*

† It is not known if tamsulosin harms the human foetus or if it is found in breast milk.
** Upgraded based on panel consensus.*

*5.3.2 **Factors affecting success of medical expulsive therapy (Tamsulosin)***

5.3.2.1 Stone size

Due to the high likelihood of spontaneous passage of stones up to ~5 mm, MET is less likely to increase the stone-free rate (4,33-36) (LE: 1b). However, MET does reduce the need for analgesics (3,5) (LE: 1a).

5.3.2.2 Stone location

The vast majority of trials have investigated distal ureteral stones (3). One RCT has assessed the effect of tamsulosin on spontaneous passage of proximal ureteral calculi 5-10 mm. The main effect was to encourage stone migration to a more distal part of the ureter (37) (LE: 1b).

5.3.2.3 Medical expulsive therapy after extracorporeal shock wave lithotripsy (SWL)

Clinical studies and several meta-analyses have shown that MET after SWL for ureteral or renal stones can

expedite expulsion and increase stone-free rates and reduce analgesic requirements (6,11,38-46) (LE: 1a).

5.3.2.4 Medical expulsive therapy after ureteroscopy

MET following holmium:YAG laser lithotripsy increases stone-free rates and reduces colic episodes (47) (LE: 1b).

5.3.2.5 Medical expulsive therapy and ureteral stents (section 5.6.2.2.8)

5.3.2.6 Duration of medical expulsive therapy treatment

Most studies have included a duration of 1 month or 30 days. No data is currently available to support other time-intervals.

*5.3.3 **Medical expulsive therapy in the paediatric population***

A recent study has investigated the expulsion rate and time to expulsion of ureteral stones ≤ 10 mm in children aged 2-14 years receiving doxazosin or ibuprofen, but failed to demonstrate the effectiveness of doxazosin (48) (LE: 2a).

Statements	**LE**
MET has an expulsive effect also on proximal ureteral stones.	1b
After SWL for ureteral or renal stones, MET seems to expedite and increase stone-free rates, reducing additional analgesic requirements.	1a
MET in children cannot be recommended due to the limited data in this specific population.	4

5.4 Chemolytic dissolution of stones

Oral or percutaneous irrigation chemolysis of stones or their fragments can be useful first-line therapy. It may also be an adjunct to SWL, percutaneous nephrolithotomy (PNL), URS or open surgery to support elimination of small residual fragments. However, because its use as first-line therapy may take weeks to be effective, it is mainly used as an adjunct to endourological therapy.

Combined treatment with SWL and chemolysis is a minimal invasive option for patients with partial or complete infection staghorn stones who are not suitable for PNL. Stone fragmentation leads to increased stone surface area and improved efficacy of chemolitholysis.

Chemolysis is possible only for the stone compositions listed below, therefore, knowledge of stone composition is mandatory before treatment.

*5.4.1 **Percutaneous irrigation chemolysis***

Recommendations	GR
In percutaneous chemolysis, at least two nephrostomy catheters should be used to allow irrigation of the renal collecting system, while preventing chemolytic fluid draining into the bladder and reducing the risk of increased intrarenal pressure*.	A
Pressure- and flow-controlled systems should be used if available.	

** Alternatively, one nephrostomy catheter with a JJ stent and bladder catheter can serve as a through-flow system preventing high pressure.*

Table 12: Methods of percutaneous irrigation chemolysis

Stone composition	Refs.	Irrigation solution	Comments
Struvite Carbon apatite	1-6	10% hemiacidrin, pH 3.5-4 Suby's G	Combination with SWL for staghorn stones
			Risk of cardiac arrest due to hypermagnesaemia
Brushite	7	Hemiacidrin Suby's G	Can be considered for residual fragments
Cystine	8-13	Trihydroxymethyl aminomethane (THAM; 0.3 or 0.6 mol/L), pH 8.5-9.0 N-acetylcysteine (200 mg/L)	Takes significantly longer time than for uric acid stones
			Used for elimination of residual fragments
Uric acid	10,14-18	THAM (0.3 or 0.6 mol/L), pH 8.5-9.0	Oral chemolysis is the preferred option

*5.4.2 **Oral chemolysis***

Oral chemolitholysis is efficient only for uric acid calculi, and is based on alkalinisation of urine by application of alkaline citrate or sodium bicarbonate (14,16,18,19).

When chemolitholysis is planned, the pH should be adjusted to 7.0-7.2. Addition of allopurinol may support chemolysis and prevention of recurrent stones. No formal recommendation on allopurinol use can be given.

In case of uric acid obstruction of the collecting system, oral chemolysis in combination with urinary drainage is indicated (6).

Recommendations	GR
The dosage of alkalising medication must be modified by the patient according to urine pH, which is a direct consequence of alkalising medication.	A
Dipstick monitoring of urine pH by the patient is required at regular intervals during the day. Morning urine must be included.	A
The physician should clearly inform the patient of the significance of compliance.	A

5.5 Extracorporeal shock wave lilthotripsy (SWL)

Introduction of SWL in the early 1980s dramatically changed the management of urinary tract stones. The development of new lithotripters, modified indications and treatment principles has also completely changed urolithiasis treatment. Modern lithotripters are smaller and usually included in uroradiological tables. They ensure application of SWL and other associated diagnostic and ancillary procedures.

More than 90% of stones in adults might be suitable for SWL treatment (1-3). However, success depends on efficacy of the lithotripter and the following factors:

- size, location (ureteral, pelvic or calyceal), and composition (hardness) of the stones (Chapter 6);
- patient's habitus (Chapter 6);
- performance of SWL (best practice, see below).

Each of these factors has an important influence on retreatment rate and final outcome of SWL.

*5.5.1 **Contraindications of extracorporeal shock wave lithotripsy***

There are several contraindications to the use of extracorporeal SWL, including:

- pregnancy, due to the potential effects on the foetus (4);
- bleeding diatheses, which should be compensated for at least 24 h before and 48 h after treatment (5);
- uncontrolled urinary tract infections (UTIs);
- severe skeletal malformations and severe obesity, which prevent targeting of the stone;
- arterial aneurysm in the vicinity of the stone (6);
- anatomical obstruction distal to the stone.

*5.5.2 **Stenting before carrying out extracorporeal shock wave lithotripsy***

5.5.2.1 Stenting in kidney stones

Routine use of internal stents before SWL does not improve stone-free rate (LE: 1b) (7). A JJ stent reduces the risk of renal colic and obstruction, but does not reduce formation of steinstrasse or infective complications (8).

However, stone particles may pass along stents while urine flows in and around the stent. This usually prevents obstruction and loss of ureteral contractions. Occasionally, stents do not efficiently drain purulent or mucoid material, increasing the risk of obstructive pyelonephritis. If fever occurs and lasts for a few days despite correct stent position, the stent must be removed and replaced by a new JJ stent or a percutaneous nephrostomy tube, even when ultrasound does not reveal any dilatation.

5.5.2.2 Stenting in ureteral stones

The 2007 AUA/EAU Guideline on the management of ureteral calculi states that routine stenting is not recommended as part of SWL (9). When the stent is inserted, patients often suffer from frequency, dysuria, urgency, and suprapubic pain (10).

Recommendation	LE	GR
Routine stenting is not recommended as part of SWL treatment of ureteral stones.	1b	A

5.5.3 ***Best clinical practice***

5.5.3.1 Pacemaker

Patients with a pacemaker can be treated with SWL, provided that appropriate technical precautions are taken; patients with implanted cardioverter defibrillators must be managed with special care (firing mode temporarily reprogrammed during SWL treatment). However, this might not be necessary with new-generation lithotripters (11).

5.5.3.2 Shock wave rate

Lowering shock wave frequency from 120 to 60-90 shock waves/min improves stone-free rate (12-16). Tissue damage increases with shock wave frequency (17,18).

Statement	LE	GR
The optimal shock wave frequency is 1.0-1.5 Hz (16).	1a	A

5.5.3.3 Number of shock waves, energy setting and repeat treatment sessions

The number of shock waves that can be delivered at each session depends on the type of lithotripter and shock wave power. There is no consensus on the maximum number of shock waves.

Starting SWL on a lower energy setting with stepwise power (and SWL sequence) ramping can achieve vasoconstriction during treatment (19), which prevents renal injury (20). Animal studies (21) and a prospective randomised study (22) have shown better stone-free rate (96% vs. 72%) using stepwise power ramping, but no difference has been found for fragmentation or evidence of complications after SWL, irrespective of whether ramping was used (23).

There are no conclusive data on the intervals required between repeated SWL sessions. However, clinical experience indicates that repeat sessions are feasible (within 1 day for ureteral stones).

Statement	LE
Clinical experience has shown that repeat sessions are feasible (within 1 day for ureteral stones).	4

5.5.3.4 Improvement of acoustic coupling

Proper acoustic coupling between the cushion of the treatment head and the patient's skin is important. Defects (air pockets) in the coupling gel reflect 99% of shock waves. Only a 2% defect in the gel layer covering the cushion reduces stone fragmentation by 20-40% (24). Ultrasonography gel is probably the optimum agent available for use as a lithotripsy coupling agent (25). To reduce air pockets, ultrasonography gel should be applied to the water cushion straight from the container, rather than by hand (26).

Recommendation	LE	GR
Ensure correct use of the coupling gel because this is crucial for effective shock wave transportation (24).	2a	B

5.5.3.5 Procedural control

Results of treatment are operator dependent, and better results are obtained by urologists who treat larger numbers of patients. During the procedure, careful imaging control of localisation contributes to outcome quality (27).

Recommendation	LE	GR
Maintain careful fluoroscopic and/or ultrasonographic monitoring during the procedure.	4	A*

** Upgraded based on panel consensus.*

5.5.3.6 Pain control

Careful control of pain during treatment is necessary to limit pain-induced movements and excessive respiratory excursions (28-30).

Recommendation	LE	GR
Use proper analgesia because it improves treatment results by limiting induced movements and excessive respiratory excursions.	4	C

5.5.3.7 Antibiotic prophylaxis

No standard prophylaxis before SWL is recommended. However, prophylaxis is recommended in case of internal stent placement ahead of anticipated treatments and in the presence of increased bacterial burden (e.g. indwelling catheter, nephrostomy tube, infectious stones) (31,32).

Recommendation	LE	GR
In case of infected stones or bacteriuria, antibiotics should be given prior to SWL.	4	C

5.5.3.8 Medical expulsive therapy after extracorporal shock wave lithotripsy

MET after SWL for ureteral or renal stones can expedite expulsion and increase stone-free rates, as well as reduce additional analgesic requirements (33-43) (Section 5.3.2.3).

*5.5.4 **Complications of extracorporeal shock wave lithotripsy***

Compared to PNL and ureteroscopy, there are fewer overall complications with SWL (44,45) (Table 13).

Table 13: SWL-related complications (1,4,44-46)

Complications			%	Refs.
Related to stone fragments		Steinstrasse	4-7	47-49
		Regrowth of residual fragments	21-59	50
		Renal colic	2-4	46
Infectious		Bacteriuria in non-infection stones	7.7-23	50,51
		Sepsis	1-2.7	50,51
Tissue effect	Renal	Haematoma, symptomatic	< 1	1,52
		Haematoma, asymptomatic	4 - 19	1,52
	Cardiovascular	Dysrhythmia	11-59	50,53
		Morbid cardiac events	Case reports	50,53
	Gastrointestinal	Bowel perforation	Case reports	54-56
		Liver, spleen haematoma	Case reports	56-58

The relationship between SWL and hypertension or diabetes is unclear. Published data are contradictory and no conclusion can be reached (9,59-61).

5.6 Endourology techniques

*5.6.1 **Percutaneous nephrolithotomy (PNL)***

Since Goodwin et al. first punctured the kidney in 1955 and Harris et al. used a bronchoscope for nephroscopy in 1975, rapid technological advances have revolutionised endourological procedures. Currently, percutaneous nephrolithothomy (PNL) is a minimally invasive surgical procedure for removal of kidney stones (1,2). Rigid and flexible nephroscopes of different sizes have been developed.

5.6.1.1 Rigid nephroscopes

Rigid nephroscopes are available in diameters up to 28 Ch [Charrière (French) gauge], allowing maximal working and irrigation channels. Thinner nephroscopes are available for Mini-PNL (also known as Mini-perc), which uses nephroscopes of diameter 11-18 Ch. The term Mini-PNL (Mini-perc), although not precisely defined, indicates the use of smaller diameter nephroscopes compared with standard PNL. The smaller diameter results in smaller working channels.

Mini-PNL is associated with less morbidity than standard PNL. However, the benefit of using a smaller-calibre nephroscope to preserve renal parenchyma has not been confirmed (3-5). The use of Mini-PNL in adult patients is controversial, but Mini-PNL is the standard procedure for percutaneous stone removal in children (3,4) (Section 9.2.3).

5.6.1.2 Flexible nephroscopes

In complex cases, such as multiple or staghorn stones, or difficult anatomy, such as horseshoe kidneys, the use of rigid nephroscopes may require multiple access procedures. However, the use of flexible nephroscopes, or combination of retrograde flexible ureteroscopy with standard nephroscopy, reduces the need for multiple-access procedures. New 'chip-on-the-tip' endoscopes are equipped with a camera on the tip of the instrument and a light-emitting diode to improve visibility and handling. Complete stone clearance is viewed endoscopically and by X-ray.

5.6.1.3 Intracorporeal lithotripsy

Intracorporeal lithotripsy can be performed in several different ways (devices are discussed in Section 5.6.2.2.7). During PNL procedures, ultrasonic or pneumatic lithotripters are most commonly used. Electrohydraulic intracorporeal lithotripsy is effective even for hard kidney stones; however, due to potential damage to surrounding tissue, it should only be used in carefully selected cases, such as hard cystine stones.

With the increase in the use of flexible nephroscopes, the holmium:yttrium-aluminium-garnet (Ho:YAG) laser is becoming more important in ureteroscopy and PNL. It can be used for lithotripsy in parts of the calyceal system that are only accessible with flexible nephroscopes. Where flexible devices are used for PNL, the Ho:YAG laser has become the preferred intracorporeal lithotripter (5).

Recommendations	**GR**
Ultrasonic, ballistic and Ho:YAG devices are recommended for intracorporeal lithotripsy using rigid nephroscopes.	A*
When using flexible instruments, the Ho:YAG laser is currently the most effective device.	

** Upgraded based on panel consensus.*

5.6.1.4 Extraction tools

Stones or stone fragments are extracted from the kidney through the access sheath of the nephroscope using forceps or baskets, washing out with irrigation fluid, or using a suction device. New baskets made of nitinol (nickel-titanium alloy) provide additional advantages compared with steel wire baskets. Tipless versions of nitinol baskets are also available for use in calices.

5.6.1.5 Best clinical practice

5.6.1.5.1 Contraindications

All contraindications for general anaesthesia apply. Patients receiving anticoagulant therapy must be monitored carefully pre- and postoperatively. Anticoagulant therapy must be discontinued before PNL (6).

Other important contraindications include:

- untreated UTI;
- atypical bowel interposition;
- tumour in the presumptive access tract area;
- potential malignant kidney tumour;
- pregnancy (see Section 8.2).

5.6.1.5.2 Preoperative imaging

Preprocedural evaluations are summarised in Chapter 3. In particular for PNL, ultrasonography or CT of the kidney and the surrounding structures can provide information about interpositioned organs within the planned percutaneous path (e.g. spleen, liver, large bowel, pleura, lung) (7,8).

Recommendation	GR
Preprocedural imaging, including contrast medium where possible or retrograde study when starting the procedure, is mandatory to assess stone comprehensiveness, view the anatomy of the collecting system, and ensure safe access to the kidney stone.	A*

** Upgraded based on panel consensus.*

5.6.1.5.3 Positioning of the patient

Traditionally, the patient is positioned prone for PNL. Supine position is also possible, with or without flank upholstering. Both positions are equally safe. The advantages of the supine position for PNL are (9,10):

- shorter operating time;
- possibility of simultaneous retrograde transurethral manipulation;
- more convenient position for the operator;
- easier anaesthesia.

Although the supine position confers some advantages (9,10), it depends on appropriate equipment being available to position the patient correctly, e.g. X-ray devices and operating table. The supine position can limit the manoeuvrability of instruments (11).

5.6.1.5.4 Puncture

After the insetion of a ureteric catheter, balloon or otherwise, the appropriate calyx is punctured, using fluoroscopy or ultrasonography guidance. Ultrasonography guidance is associated with decreased radiation hazards (12).

Colon interposition in the access tract of PNL can lead to colon injuries. Although rare, such injuries are more likely when operating on the left kidney. The colon is not reliably detectable with ultrasound, so preprocedural imaging is recommended. In particular, preoperative CT provides further information (13,14). However, ultrasound-guided puncture will allow identification of the tissue between the skin and kidney and lower the incidence of bowel injury (15).

5.6.1.5.5 Dilatation

Dilatation of the percutaneous access tract can be achieved using a metallic telescope, single (serial) dilators, or a ureteral balloon dilatator. Use of balloon dilatation can reduce blood transfusion rates (16). One-stage dilatation has been shown to be safe and effective, even in patients with a history of open surgery on the same kidney (17,18).

5.6.1.5.6 Nephrostomy and stents

The decision about whether or not to place a nephrostomy tube at the end of the PNL procedure depends on several factors, including:

- presence of residual stones;
- likelihood of a second-look procedure;
- significant intraoperative blood loss;
- urine extravasation;

- ureteral obstruction;
- potential persistent bacteriuria due to infected stones;
- solitary kidney;
- bleeding diathesis;
- planned percutaneous chemolitholysis.

Ureteral stenting at the end of the procedure is common procedure using antegrade placement of a JJ stent. They are usually placed using the antegrade approach at the end of the procedure. The most important criteria for ureteral stenting are residual stone fragments, inadequate transureteral drainage, or alterations to the pyeloureteral junction. An external ureteral catheter can be used instead of a JJ stent (19).

Tubeless PNL is performed without a nephrostomy tube. When neither a nephrostomy tube nor a ureteral stent is introduced, the procedure is known as totally tubeless PNL. In uncomplicated cases, the latter procedure results in a shorter hospital stay, with no disadvantages reported (20-24).

Recommendation	LE	GR
In uncomplicated cases, tubeless (without nephrostomy tube) or totally tubeless (without nephrostomy tube and without ureteral stent) PNL procedures provide a safe alternative.	1b	A

5.6.1.5.7 Management of complications
The most common postoperative complications associated with PNL are fever and bleeding, urinary leakage and problems due to residual stones. A recent review on complications following PNL used the validated Dindo-modified Clavien system and showed a normal (uncomplicated) postoperative course in 76.7% of patients (Clavien 0) (25) (Table 14). See also the EAU Guidelines on Reporting and Grading of Complications after Surgical Procedures (26).

Table 14: Complications following PNL

Complications	Transfusion	Embolisation	Urinoma	Fever	Sepsis	Thoracic complication	Organ injury	Death	LE
(Range)	(0-20%)	(0-1.5%)	(0-1%)	(0-32.1%)	(0.3-1.1%)	(0-11.6%)	(0-1.7%)	(0-0.3%)	1a
N = 11,929	7%	0,4%	0,2%	10,8%	0,5%	1,5%	0,4%		

Urinary leakage and stone clearance can be viewed endoscopically and by X-ray. In doubtful cases, complications can be minimised by performing standard rather than totally tubeless PNL.

Perioperative fever can occur, even with a sterile preoperative urinary culture and perioperative antibiotic prophylaxis, because the kidney stones themselves may be a source of infection. Intraoperative kidney stone culture may therefore help to select postoperative antibiotics (27,28). Intraoperative irrigation pressure < 30 mm Hg and unobstructed postoperative urinary drainage may be important factors in preventing postoperative sepsis. Well-positioned or specially designed access sheaths can prevent high intrapelvic irrigation pressure (29-31).

Bleeding after PNL may be due to intraparenchymal haemorrhage or acquired intrarenal aneurysm. With the former, brief clamping of the nephrostomy may stem bleeding. The latter may be marked by intense bleeding, and it can be treated by super-selective embolic occlusion of the artery supplying the aneurysm (32).

5.6.2 ***Ureterorenoscopy (URS) (including retrograde access to renal collecting system)***

During the past 20 years, ureterorenoscopy (URS) has dramatically changed the management of ureteral calculi. Major technical improvements include endoscope miniaturization, enhanced optical quality and tools, and introduction of disposables. URS has had a great impact on active stone removal and is performed increasingly worldwide.

5.6.2.1 Instruments

5.6.2.1.1 Rigid scopes

Semi-rigid ureteroscopy for urinary stone removal became a standard procedure in the 1990s. Today, small endoscopes with tip diameters < 8 Ch are mainly used. In Europe, rigid URS is used for proximal and distal ureteral calculi, but an increasing number of urologists prefer flexible endoscopes for proximal calculi. However, rigid URS is safe even for proximal ureteral calculi (1-11).

5.6.2.1.2 Flexible endoscopes

Technological advances have been responsible for the evolution of flexible URS (12), especially for improved deflection mechanisms, which have reached almost 300° in the latest generation, facilitating intrarenal manoeuvrability (13,14). The latest endoscopes have also made it possible to visualise the lower pole in almost all kidneys. Although a secondary active deflection mechanism has been introduced, it has not yet demonstrated its superiority over conventional flexible URS (15,16).

The durability of the latest generation of flexible scopes has been improved by stiffer shaft construction (17,18).

As with rigid scopes, the tip diameters of flexible scopes usually do not exceed 8.7 Ch.

5.6.2.1.3 Digital scopes
The miniaturisation of flexible scopes has significantly improved their effectiveness (19-21), but it has also reduced the number of fibreoptics, and therefore, the optical quality and durability.

Digital URS eliminates the need for fragile low-resolution fibreoptics. The tips of digital ureteroscopes contain digital camera chips (complementary metal-oxide semiconductors or charge-coupled devices), which produce superior image resolution. The tips also have light-emitting-diode-driven light carriers, which provide a substitute for an external light source (22).

Initial experience with digital scopes has demonstrated marked improvement in image quality, with efficacy comparable to that achieved with analogue URS (23,24). To prevent damage to the camera chip, ballistic lithotripsy can no longer be used.

5.6.2.2 Best clinical practice in ureterorenoscopy (URS)
5.6.2.2.1 Preoperative work-up and preparations
Before the procedure, the following information should be sought and actions taken (LE: 4):

- patient history;
- physical examination because anatomical and congenital abnormalities may complicate or prevent retrograde stone manipulation;
- thrombocyte aggregation inhibitors/anticoagulation (anti-platelet drugs) should be discontinued if possible, however URS can be performed in patients with bleeding disorders,with a moderate increase in complications (25,26);
- imaging.

Recommendation	LE	GR
Short-term antibiotic prophylaxis should be administered (27).	4	A*

** Upgraded based on panel consensus.*

5.6.2.2.2 Contraindications
Apart from general problems, e.g. with general anaesthesia or untreated urinary infections, URS can be performed in all patients without any specific contraindications. Specific problems such as ureteral strictures may prevent successful retrograde stone management.

5.6.2.2.3 Access to the upper urinary tract
Most interventions are performed under general anaesthesia, although local anaesthesia or spinal anaesthesia are possible. Instrument miniaturisation means that intravenous sedation can be used to achieve the same outcome (28,29).

Intravenous sedation with miniaturised instruments is especially suitable for female patients with distal ureteral stones. However, kidney movement is more pronounced with local or intravenous anaesthesia, which may hinder flexible URS.

Antegrade URS is an option for large, impacted proximal ureteral calculi (5,30) (see Section 6.5.3).

5.6.2.2.4 Safety aspects
Fluoroscopic equipment must be available in the operating room. We recommend placement of a safety wire, even though some groups have demonstrated that URS can be performed without it (31,32). A safety wire prevents false passage in case of perforation, and ensures that a JJ stent can be inserted in difficult situations, thus avoiding more significant complications.

Retrograde access to the upper urinary tract is usually obtained under endoscopic guidance.

Balloon and plastic dilators are available if necessary. If insertion of a flexible URS is difficult, prior rigid ureteroscopy can be helpful for optical dilatation. If ureteral access is not possible, insertion of a JJ stent followed by URS after 7-14 days offers an alternative procedure.

Recommendation	GR
Placement of a safety wire is recommended.	A*

** Upgraded based on panel consensus.*

5.6.2.2.5 Ureteral access sheaths
Hydrophilic-coated ureteral access sheaths, which are available in different calibres (usual inner diameter of 9 or 12/13 Ch), can be inserted via a guide wire, with the tip placed in the proximal ureter.

Ureteral access sheaths allow easy multiple access to the upper urinary tract and therefore significantly facilitate URS. The use of ureteral access sheaths improves vision by establishing a continuous outflow, decrease intrarenal pressure and potentially reduce operating time (19,33-36).

Ureteral access sheaths allow continuous outflow of irrigation fluid, which improves visual quality and maintains a low-pressure system (36,37).

Ureteral access sheaths are widely accepted and used regularly, despite ongoing debate about potential hazards, including increased ureteral stricture, which has not yet been demonstrated (33).

5.6.2.2.6 Stone extraction
The aim of endourological intervention is complete stone removal (especially in ureteric stones). “Smash and go” strategies might have a higher risk of stone regrowth and postoperative complications (38).

Stones can be extracted by endoscopic forceps or baskets. Forceps allow safe release of stone fragments if they become stuck within the ureter, but extraction takes longer than when using baskets. Only baskets made of nitinol (nickel-titanium alloy) can be used for flexible URS (39-42).

Recommendations	LE	GR
Stone extraction using a basket without endoscopic visualisation of the stone (blind basketing) should not be performed.	4 3	A* B
Nitinol baskets preserve the tip deflection of flexible ureterorenoscopes, and the tipless design reduces the risk of mucosal injury.		
Nitinol baskets are most suitable for use in flexible URS.		

** Upgraded based on panel consensus.*

Stones that cannot be extracted directly must be disintegrated. If it is difficult to access stones that need disintegration within the lower renal pole, it may help to displace them into a more accessible calyx (*see* Section 6.4.2) (43).

5.6.2.2.7 Intracorporeal lithotripsy
Intracorporeal lithotripsy is usually necessary before stone extraction.

5.6.2.2.7.1 Electrohydraulic systems
Flexible electrohydraulic lithotripsy probes are available for semi-rigid and flexible ureterorenoscopes. If lasers are unavailable, electrohydraulic lithotripsy can disintegrate all types of stones (even cystine or hard stones, such as calcium oxalate monohydrate), even though there is an increased risk of surrounding tissue damage (44-46).

5.6.2.2.7.2 Pneumatic systems
Pneumatic or ballistic lithotripters are often used with 2.4 Ch probes for safe rigid URS and can achieve > 90% disintegration (47-49). Proximal stone migration is a common occurrence (50,51), but can be avoided by using a basket or special tools (6,52-56).

5.6.2.2.7.3 Ultrasound
Ultrasound can be used alone or in combination with pneumatic lithotripsy. However, ultrasound can only be used in larger but not in flexible endoscopes (57,58).

5.6.2.2.7.4 Laser systems

The most efficient laser system for treatment of all types of stones in all locations is the Ho:YAG system (59-70) (LE: 3), which is the gold standard for rigid and flexible URS (65). Compared with the Nd-YAG laser, its rapid absorption in water (3 mm) and minimal tissue penetration (0.4 mm) reduces thermal damage and improves safety (69). Contact with the surface of the stone is required. Other laser systems are being evaluated, but have yet to prove superior in efficacy or safety.

Recommendation	LE	GR
Ho:YAG laser lithotripsy is the preferred method for (flexible) URS.	3	B

5.6.2.2.8 Stenting before and after URS

Routine stenting is no longer necessary before URS. However, pre-stenting facilitates ureteroscopic management of stones, improves the stone-free rate, and reduces complications (71-73).

Most urologists routinely insert a JJ stent following URS, although several randomised prospective trials have found that routine stenting after uncomplicated URS (complete stone removal) is no longer necessary (71,74-85). Ureteric stenting can be associated with lower urinary tract symptoms and pain reducing quality of life (86).

Stents should be inserted in patients who are at increased risk of complications (e.g. residual fragments, bleeding, perforation, urinary tract infections or pregnancy), and in all doubtful cases, to avoid stressful emergencies.

The ideal duration of stenting is not known. Most urologists favour 1-2 weeks after URS (71,74). Patients should be followed up with a plain abdominal film (kidney-ureter-bladder), CT or ultrasound.

Alpha-blockers reduce the morbidity of ureteral stents and increase tolerability (87-90). A recently published meta-analysis provides evidence for improvement of ureteral stent tolerability with tamsulosin (91).

Recommendation	LE	GR
Stenting is optional after uncomplicated URS.	1a	A

5.6.2.2.9 Complications

The overall complication rate after URS is 9-25% (1,9,33,35,66,92) (Table 15). Most are minor and do not require intervention. Ureteral avulsion and strictures used to be greatly feared, but nowadays are rare in experienced hands (< 1%). Previous perforations are the most important risk factor for complications.

Table 15: Complications of URS*

	Rate (%)
Intraoperative complications	3.6
Mucosal injury	1.5
Ureteral perforation	1.7
Significant bleeding	0.1
Ureteral avulsion	0.1
Early complications	6.0
Fever or urosepsis	1.1
Persistent haematuria	2.0
Renal colic	2.2
Late complications	0.2
Ureteral stricture	0.1
Persistent vesicoureteral reflux	0.1

5.7 Open and laparoscopic surgery for removal of renal stones

*5.7.1 **Open surgery***

Advances in SWL and endourological surgery (URS and PNL) have significantly decreased the indications for open stone surgery, which is now often a second- or third-line treatment option needed in 1.0-5.4% of cases only (1-5). The incidence of open stone surgery is ~1.5% of all stone removal interventions in developed countries, and in developing countries, it has dropped from 26% to 3.5 % in recent years (3,5).

However, open surgery is still needed for the most difficult stones, which supports the importance of maintaining proficiency, skills and expertise in open renal and ureteral surgical techniques such as extended pyelolithotomy, pyelonephrolithotomy, anatrophic nephrolithotomy, multiple radial nephrotomy, partial nephrectomy and renal surgery under hypothermia (6-10) (Table 16).

Recently, intraoperative B-mode scanning and Doppler sonography (11,12) have been used to identify avascular areas in the renal parenchyma that are close to the stone or dilated calices. This allows removal of large staghorn stones by multiple small radial nephrotomy, without loss of kidney function.

The efficacy of open surgery and less-invasive therapy, in terms of stone-free rates, is based on historical data, but no comparative studies are available (13-16).

5.7.1.1 Indications for open surgery

There is a consensus that most complex stones, including partial and complete staghorn stones, should be approached primarily with PNL or combined PNL and SWL. If a reasonable number of percutaneous approaches are not likely to be successful, or if multiple, endourological approaches have been performed unsuccessfully, open surgery may be a valid treatment option.

Table 16: Indications for open surgery

Complex stone burden
Treatment failure of SWL and/or PNL, or failed ureteroscopic procedure
Intrarenal anatomical abnormalities: infundibular stenosis, stone in the calyceal diverticulum (particularly in an anterior calyx), obstruction of the ureteropelvic junction, stricture if endourologic procedures have failed or are not promising
Morbid obesity
Skeletal deformity, contractures and fixed deformities of hips and legs
Comorbidity
Concomitant open surgery
Non-functioning lower pole (partial nephrectomy), non-functioning kidney (nephrectomy)
Patient choice following failed minimally invasive procedures; the patient may prefer a single procedure and avoid the risk of needing more than one PNL procedure
Stone in an ectopic kidney where percutaneous access and SWL may be difficult or impossible
For the paediatric population, the same considerations apply as for adults

*5.7.2 **Laparoscopic surgery***

Laparoscopic urological surgery is increasingly replacing open surgery as a result of accumulated surgical experience. Laparoscopy is associated with lower postoperative morbidity, shorter hospital stay and time to convalescence, and better cosmetic results with comparably good functional results (17-24).

Laparoscopic surgery is now used to remove renal and ureteric stones in certain situations, including complex stone burden, failed previous SWL and/or endourological procedures, anatomical abnormalities or morbid obesity, and planned nephrectomy of a stone-containing non-functioning kidney.
Surgical pyelolithotomy is rarely indicated (see Table 16) and feasible laparoscopically, e.g. stone removal from an anterior caliceal diverticulum (34).

Laparoscopic ureterolithotomy is relatively easy, with stone-free rates up to 100% provided expertise is available (25-28). It can replace open surgery in most situations (15,16). Retroperitoneal and transperitoneal laparoscopic access to all portions of the ureter have been reported (28-33,35) although laparoscopic ureterolithotomy in the distal ureter is less successful than in the middle and proximal ureter, but the size of the

stone does not appear to influence outcome. Although highly effective, laparoscopic ureterolithotomy is not first-line therapy in most cases because of its invasiveness, longer recovery time, and greater risk of associated complications compared to SWL and URS (25-28) (Table 17).

5.7.2.1 Indications for laparoscopic stone surgery (Table 17)

Indications for laparoscopic kidney-stone surgery include: • Complex stone burden • Failed previous SWL and/or endourological procedures • Anatomical abnormalities • Morbid obesity • Nephrectomy in case of non-functioning kidney
Indications for laparoscopic ureteral stone surgery include: • Large impacted stones • Multiple ureteral stones • In cases of concurrent conditions requiring surgery • When other non-invasive or low-invasive procedures have failed • If indicated, for upper ureteral calculi, laparoscopic urolithomy has the highest stone free rate compared to URS and SWL (LE: 1a)

Recommendations	**LE**	**GR**
Laparoscopic or open surgical stone removal may be considered in rare cases where SWL, URS, and percutaneous URS fail or are unlikely to be successful.	3	C
When expertise is available, laparoscopic surgery should be the preferred option before proceeding to open surgery. An exception is complex renal stone burden and/or stone location.	3	C
For ureterolithotomy, laparoscopy is recommended for large impact stones or when endoscopic lithotripsy or SWL have failed.	2	B

Skolarikos, et al. have tried to identify the level of evidence and grade of recommendation, according to the evidence-based medicine criteria, in studies supporting laparoscopic stone extraction. The highest level of evidence (2a) was found for laparoscopic ureterolithotomy.

6. INDICATION FOR ACTIVE STONE REMOVAL AND SELECTION OF PROCEDURE

Although kidney stones might be asymptomatic, ureteral stones cause acute renal colic in most cases. Treatment decisions for upper urinary tract calculi are based on several general aspects such as stone composition, stone size, and symptoms.

6.1 Indication for active removal of ureteral stones (1,2)

- Stones with low likelihood of spontaneous passage;
- persistent pain despite adequate pain medication;
- persistent obstruction;
- renal insufficiency (renal failure, bilateral obstruction, single kidney).

6.2 Indication for active removal of kidney stones (2)

- stone growth;
- stones in high-risk patients for stone formation;
- obstruction caused by stones;
- infection;
- symptomatic stones (e.g., pain, haematuria);
- stones > 15 mm;
- stones < 15 mm if observation is not the option of choice;
- patient preference;
- comorbidity;
- social situation of the patient (e.g. profession, travelling);
- > 2-3 years stone persistence.

The suspected stone composition might influence the choice of treatment.

6.2.1 Natural history of caliceal stones

Natural history of small, non-obstructing asymptomatic lower pole calculi is not well defined, and the risk of progression is unclear. There is still no consensus on the follow-up duration, timing and type of intervention.

Statement	LE
Although the question of whether caliceal stones should be treated is still unanswered, stone growth, *de novo* obstruction, associated infection, and acute and/or chronic pain are indications for treatment (1-3).	3

Glowacki et al. have reported that the risk of a symptomatic episode or need for intervention was ~10% per year, with a cumulative 5-year event probability of 48.5% (4). In a recent retrospective study, 77% of asymptomatic patients with renal stones experienced disease progression, with 26% requiring surgical intervention (5).

In a retrospective study, Hubner and Porpaczy have reported that infection developed in 68% of patients with asymptomatic caliceal stones, and 45% had increased stone size after 7.4 years follow-up. They have suggested that 83% of caliceal calculi require intervention within the first 5 years of diagnosis (6). Inci et al. have investigated lower pole caliceal stones, and observed that no patient required intervention during 24 months follow-up. In addition, an increase in stone size without any need for intervention was observed in eight of 27 renal units (29.6%). When the follow-up period was increased to 52.3 months, nine (33.3%) patients had increased stone size, but only three (11%) required intervention (7).

However, in a prospective RCT with 2.2 years clinical follow-up, Keeley et al. have reported no significant difference between SWL and observation when they compared asymptomatic caliceal stones < 15 mm in terms of stone-free rate, symptoms, requirement for additional treatment, quality of life, renal function, or hospital admission (10). Although some have recommended prophylaxis for these stones to prevent renal colic, haematuria, infection or stone growth conflicting data have been reported (4,6,11).

Statement	LE
SWL has been increasingly used for treatment of caliceal stones to reduce the risk of complications and the need for invasive procedures.	4

Excellent stone-free rates and pain relief have been reported after removal of small caliceal stones by SWL, PNL or URS, which indicates the need for removal of symptomatic caliceal stones (12-14).

Recommendations	GR
For asymptomatic caliceal stones in general, active surveillance with annual follow-up of symptoms and stone status [KUB, ultrasonography (US), NCCT] is an option for 2-3 years, whereas intervention should be considered after this period provided patients are adequately informed.	C
Observation might be associated with a greater risk of necessitating more invasive procedures.

6.3 General recommendations and precautions for stone removal

*6.3.1 **Infections***

Urinary infections should always be treated if stone removal is planned. In patients with clinically significant infection and obstruction, drainage should be performed for several days, via a stent or percutaneous nephrostomy, before starting stone removal.

Recommendation	GR
Urine culture or urinary microscopy is mandatory before any treatment is planned.	A*

**Upgraded following panel consensus.*

*6.3.2 **Anticoagulation and stone treatment***

Patients with a bleeding diathesis, or receiving anticoagulation, should be referred to an internist for appropriate therapeutic measures before and during stone removal (1-3). In patients with an uncorrected bleeding diathesis, the following are contraindicated:

- SWL;
- PNL;
- percutaneous nephrostomy;
- open surgery (4-6).

Although SWL is feasible and safe after correction of underlying coagulopathy (7-9), URS might offer an alternative approach and is associated with less morbidity. The problem of coagulation disorder is less pronounced in URS than in SWL and PNL.

Recommendations	LE	GR
Anticoagulation therapy including salicylates should be stopped before stone removal, in particular if SWL is planned.	3	B
If intervention for stone removal is essential and salicylate therapy should not be interrupted, retrograde URS is the preferred treatment of choice.		

*6.3.3 **Obesity***

Obesity can cause a higher risk due to anaesthesiological measurements, and a lower success rate after SWL and PNL (see Section 5.5).

Statement	LE
In case of severe obesity, URS is a more promising therapeutic option than SWL.	2b

6.3.4 *Hard stones*

Stones composed of brushite or calcium oxalate monohydrate are particularly hard. Percutaneous removal of these stones might be appropriate, particularly if they are large. Chemolytic treatment of brushite stone fragments is possible. Cystine stones respond well or poorly to SWL (10). PNL or retrograde intrarenal surgery (RIRS) are alternatives for removal of large SWL-resistant stones.

Recommendation	LE	GR
Consider the stone composition before deciding on the method of removal (former stone analysis of the patient, HU in unenhanced CT). Stones with medium density > 1,000 HU on NCCT are less likely to be disintegrated by SWL.	2a	B

6.3.5 *Radiolucent stones*

Uric acid concrements can be localised using US or intravenous or retrograde administration of contrast medium. Stones composed of uric acid, but not sodium or ammonium urate, can be dissolved by oral chemolysis. Differentiation is done by urinary pH measurement (see Section 5.4.2). Postoperative monitoring of radiolucent stones during chemolysis or after SWL is the domain of ultrasound, however repeat NCCT might be necessary.

Recommendation	GR
Careful monitoring of radiolucent stones during/after therapy is imperative.	A*

** Upgraded based on panel consensus.*

6.3.6 *Steinstrasse*

Steinstrasse is an accumulation of stone fragments or stone gravel in the ureter, which does not pass within a reasonable period of time, and interferes with the passage of urine (11,12). Steinstrasse occurs in 4-7% cases of SWL (13-15), and the major factor in steinstrasse formation is stone size (14).

Insertion of a ureteral stent before SWL prevents formation of steinstrasse only in stones > 15 mm in diameter (16). Symptoms include flank pain, fever, nausea and vomiting, bladder irritation, or it may asymptomatic. A major problem of steinstrasse is ureter obstruction, which can be silent in 23% of cases (14) and lead to kidney failure (17). Anuria occurs in 5% of cases of steinstrasse in treatment of solitary kidneys (14).

When steinstrasse is asymptomatic, conservative treatment is an initial option, depending on patient preference and willingness to comply with close surveillance. Medical expulsion therapy significantly increases stone expulsion and reduces the need for endoscopic intervention (18,19).

Statement	LE
Medical expulsion therapy increases stone expulsion rate of steinstrasse (16).	1b

When spontaneous passage is unlikely, further treatment of steinstrasse is indicated.

SWL is indicated in asymptomatic and symptomatic cases, with no evidence of UTI, when large stone fragments are present (19). There is an 80% chance of clearance of the steinstrasse (13).

Ureteroscopy is equally effective as SWL for treatment of steinstrasse (13,20,21). Placement of a percutaneous nephrostomy tube is indicated for symptomatic ureteric obstruction with/without UTI, and it is effective in 83% of cases (13).

Table 18: Treatment of steinstrasse

Asymptomatic	LE		Symptomatic		LE		Symptomatic + fever	LE
1. MET	1b		1. URS		3		1. PCN	1a
2. SWL	3		1. PCN		3		2. Stent	
3. URS	3		1. SWL		3			
			2. Stent		3			

Numbers 1,2, and 3 indicate first, second and third choice.

Recommendations	LE	GR
PCN is indicated for steinstrasse associated with UTI/fever.	4	C
SWL is indicated for steinstrasse when large stone fragments are present.	4	C
Ureteroscopy is indicated for symptomatic steinstrasse and treatment failure.	4	C

6.4 Selection of procedure for active removal of kidney stones

*6.4.1 **Stones in renal pelvis or upper/middle calices***

SWL, PNL or flexible URS are available treatment modalities for renal calculi. Although PNL efficacy is hardly affected by stone size, the stone-free rates (SFRs) after SWL or URS are inversely proportional to stone size (1-4). SWL achieves excellent SFRs for stones up to 20 mm, except for those at the lower pole (3,5). Therefore, SWL remains the first method of choice for such stones. Larger stones > 20 mm should be treated by PNL primarily, because SWL often requires multiple treatments, and has the risk of ureteral obstruction (colic, steinstrasse) with the need for adjunctive procedures (Figure 1) (6). Flexible URS cannot be recommended as first-line treatment, especially for stones > 15 mm, for which SFR is decreasing, and staged procedures have become necessary (7,8).

*6.4.2 **Stones in the lower renal pole***

The stone clearance rate after SWL seems to be lower for stones in the inferior calyx than for other intrarenal locations. Although the disintegration efficacy of SWL is not limited compared to other locations, the fragments often remain in the calyx and cause recurrent stone formation. The reported SFR of SWL for lower pole calculi is 25-85%. The preferential use of endoscopic procedures is under discussion (1-6).

The following can impair successful stone treatment by SWL:

- steep infundibular-pelvic angle;
- long calyx;
- narrow infundibulum (Table 19) (7-13).

Further anatomical parameters cannot yet be established. The value of supportive measures such as inversion, vibration or hydration remains under discussion (7,8).

Table 19: Unfavourable factors for SWL success (9-15)

Factors that make SWL less likely
Shockwave-resistant stones (calcium oxalate monohydrate, brushite, cystine)
Steep infundibular-pelvic angle
Long lower pole calyx (> 10 mm)
Narrow infundibulum (< 5 mm)

SWL for the lower pole is often disappointing, therefore, endourological procedures (PNL, flexible URS) are recommended for stones > 15 mm. If there are negative predictors for SWL, PNL and flexible URS might be a reasonable alternative even for smaller calculi.

Flexible URS seems to have comparable efficacy to SWL (5,6). Recent clinical experience with last-generation ureterorenoscopes suggests an advantage of URS over SWL, by paying the price of greater invasiveness (16,17). Depending on operator skills, stones up to 3 cm can be treated efficiently by flexible URS (16,18-20). However, staged procedures are frequently required.

Recommendations	GR
SWL remains the method of first choice for stones < 2 cm within the renal pelvis and upper or middle calices. Larger stones should be treated by PNL.	B*
Flexible URS cannot be recommended as first-line treatment, especially for stones > 1.5 cm in renal pelvis and upper or middle calices, for which SFR after flexible URS is decreasing, and staged procedures become necessary.	B*
For the lower pole, PNL or flexible URS are recommended even for stones > 1.5 cm because the efficacy of SWL is limited (depending on favourable and unfavourable factors for SWL).	B*

Figure 1: Treatment algorithm for renal calculi within the renal pelvis or upper and middle calices

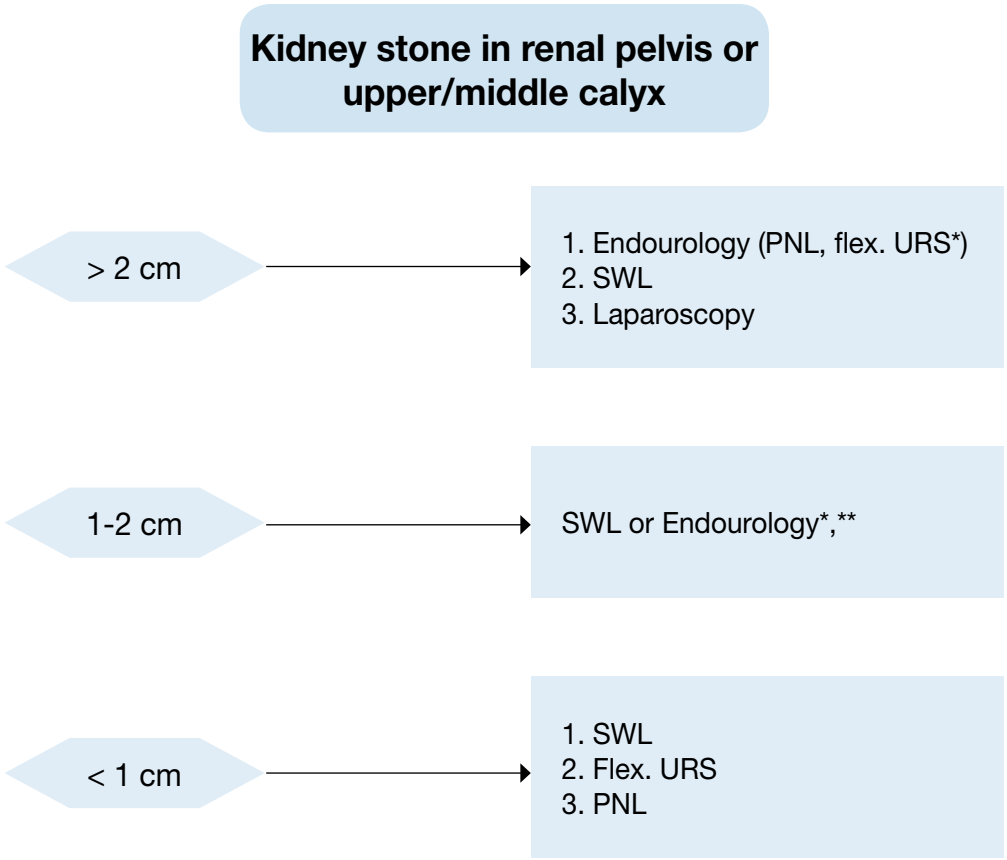

Figure 2: Treatment algorithm for renal calculi in the inferior calyx

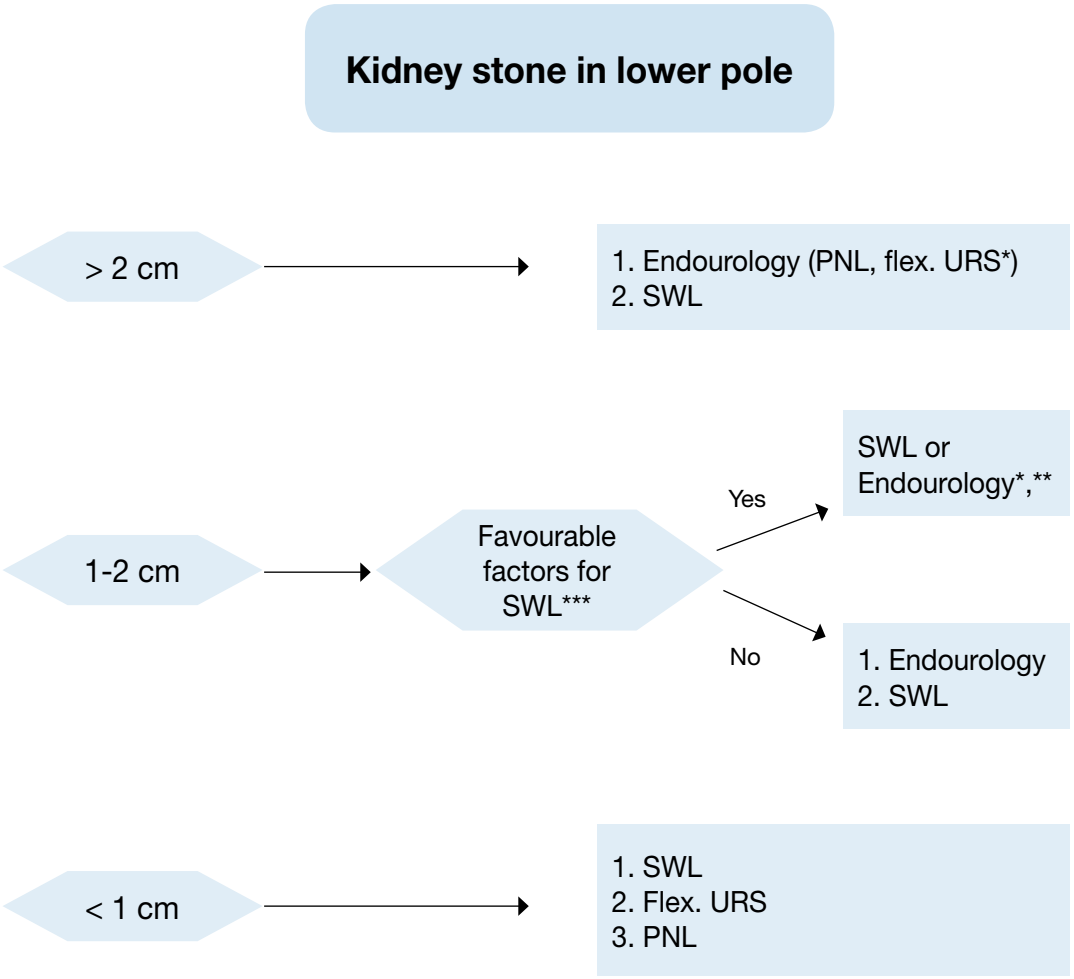

*Flexible URS is used less as first-line therapy for renal stones > 1.5 cm, although some expert centers have reported such for renal stones > 1.5 cm.
The high number of staged procedures of URS underline the superiority of PNL. A combined approach (PNL+flexible URS) might be an option in specialised centres.
** The ranking of the recommendations reflects a panel majority vote.

6.5 Selection of procedure for active removal of ureteral stones

*6.5.1 **Methodology***

Stone free rates were analysed for SWL and URS. If the study reported the SFR after all primary procedures, that number was used. If not, and the study reported the SFR after the first procedure, then that number was used. The Panel aimed to present an estimate of the number of primary procedures and the associated SFRs. There is a lack of uniformity in reporting the time to stone-free status, thereby limiting the ability to comment on the timing of this parameter.

*6.5.2 **Extracorporeal shock wave lithotripsy and ureteroscopy***

For proximal stones, no difference in overall SFRs between SWL and URS was detected. However, after stratifying for stone size, in proximal ureteral stones < 10 mm (n = 1,285), SWL had a higher SFR than URS. For stones > 10 mm (n = 819), URS had superior SFRs. This can be attributed to the fact that proximal ureteral stones treated with URS did not vary significantly with size, whereas the SFR following SWL negatively correlated with stone size.

For all mid-ureteral stones, URS appears superior to SWL, but after stratification for stone size, the small number of patients limits the significance. For all distal stones, URS yields better SFRs overall, compared to other methods for active stone removal, independent of stone size.

6.5.2.1 Stone free rates (SFRs)

Table 20 shows the results of a meta-analysis of SFRs. The results are presented as medians of the posterior distribution (best central estimate) with 95% Bayesian Credible Intervals (CIs). This represents an update of the EAU/AUA collaborative guidelines project (1). Outcomes show no significant changes.

Table 20: SFRs after primary treatment with SWL and URS in the overall population (1-5)

	SWL		URS	
	Number of patients	**SFR/95% CI**	**Number of patients**	**SFR/95% CI**
Distal ureter	7217	74% (73-75)	10372	93% (93-94)
< 10 mm	1684	86% (80-91)	2013	97% (96-98)
> 10 mm	966	74% (57-87)	668	93% (91-95)
Mid ureter	1697	73% (71-75)	1140	87% (85-89)
< 10 mm	44	84% (65-95)	116	93% (88-98)
> 10 mm	15	76% (36-97)	110	79% (71-87)
Proximal ureter	6682	82% (81-83)	2448	82% (81-84)
< 10 mm	967	89% (87-91)	318	84% (80-88)
> 10 mm	481	70% (66-74)	338	81% (77-85)

Unfortunately, RCTs comparing these treatments have been lacking. However, the posterior distributions from the meta-analysis can be subtracted, which yields a distribution for the difference between the treatments. If the CI does not include zero, then the result can be considered to be significantly different. This operation is mathematically justifiable but operationally risky: if the patients receiving different treatments or the outcome measures are different, the results might be meaningless. Nonetheless, the SFRs for URS remained significantly better than those for SWL for distal ureteral stones < 10 mm and > 10 mm and for proximal ureteral stones > 10 mm. The SFRs for mid-ureteral stones did not differ significantly between URS and SWL.

Although there are not sufficient data to compare statistically flexible and rigid URS for proximal ureteral stones, favourable SFRs have been reported using flexible URS (87%) compared with rigid or semi-rigid URS (77%) (1). SFRs probably continue to improve as the distribution and technical improvement of flexible URS continue.

6.5.2.2 Complications

Although URS is effective for ureteric calculi, it has greater potential for complications. In the current endourological era, with access to newer, smaller rigid and flexible instruments and use of small-calibre intracorporeal lithotripsy devices, the complication rate and morbidity of ureteroscopy have been significantly reduced (6).

Patients should be informed that URS has a better chance of achieving stone-free status with a single procedure, but has higher complication rates [Sections 5.5.4 (Complications of SWL) and 5.6.2.2.9 (Complications of URS)].

6.5.3 Percutaneous antegrade ureteroscopy

Percutaneous antegrade removal of ureteral stones is a consideration in selected cases, for example, for very large (> 15 mm diameter) impacted stones in the proximal ureter between the ureteropelvic junction and the lower border of the fourth lumbar vertebra (7-10). With SFRs of 85-100%, its superiority to standard techniques has been evaluated (7,10-13). The complication rate is low, acceptable, and not different from any other percutaneous procedure. However, percutaneous antegrade removal of ureteral stones is associated with longer operative times, hospital stay, and time to return to normal activities (10).

Recommendations	GR
Percutaneous antegrade removal of ureteral stones is an alternative when SWL is not indicated or has failed, and when the upper urinary tract is not amenable to retrograde URS (13-15).	A
A patient must be informed about the existing active treatment modalities, including the relative benefits and risks associated with each modality.	A

Table 21: Recommended treatment options (if indicated for active stone removal) (GR A*)

	First choice	Second choice
Proximal ureter < 10 mm	SWL	URS
Proximal ureter > 10 mm	URS (retrograde or antegrade) or SWL	
Distal ureter < 10 mm	URS or SWL	
Distal ureter > 10 mm	URS	SWL

**Upgraded following panel consensus.*

Recommendation	GR
Treatment choices should be based on stone size and location and available equipment for stone removal.	A

6.5.4 Other methods for ureteral stone removal

Few studies have reported laparoscopic stone removal (see Section 5.7.2), and open surgery (see Section 5.7.1). These procedures are usually reserved for special cases, therefore, the reported data could not be used to compare procedures with each other or with SWL or URS. These more invasive procedures have yielded high SFRs.

7. RESIDUAL STONES

7.1 Clinical evidence

Residual fragments are commonly seen after SWL and sometimes after intracorporeal lithotripsy, and mostly in the lower calix.

Reports on residual fragments vary between institutions, according to imaging method. However, the clinical value of detecting very small concretions remains debatable.

The clinical problem of residual kidney stones is related to the risk of developing:

- new stones from such nidi (heterogeneous nucleation);
- persistent UTI;
- dislocation of fragments with/without obstruction and symptoms (1-5).

Recommendations	LE	GR
Identification of biochemical risk factors and appropriate stone prevention is particularly indicated in patients with residual fragments or stones (3-5).	1b	A
Patients with residual fragments or stones should be followed up regularly to monitor disease course.	4	C

Recurrence risk in patients with residual fragments after treatment of infection stones is higher than for other stones. In a 2.2-year follow-up of 53 patients, 78% with stone fragments at 3 months after treatment

experienced stone progression. The SFR was 20%, and the remaining 2% had stable disease (6). For all stone compositions, 21-59% of patients with residual stones require treatment within 5 years. Fragments > 5 mm are more likely than smaller ones to require intervention (2,3,5,7).

Table 22: Recommendations for the treatment of residual fragments

Residual fragments, stones (largest diameter)	Symptomatic residuals	Asymptomatic residuals	LE	GR
< 4-5 mm	Stone removal	Reasonable follow-up (dependent on risk factors)	4	C
> 6-7 mm	Stone removal			

7.2 Therapy

To avoid residual fragments or facilitate further clearance, medical and physical adjunctive therapy can be suggested:

Recommendations	LE	GR
After SWL and URS, MET is recommended using an alpha-blocker to improve fragment clearance and reduce probability of residual stones (Chapter 7).	1a	A
For well-disintegrated stone material in the lower calix, inversion therapy during high diuresis and mechanical percussion facilitate clearance (8).	1a	B

The indication for active stone removal and selection of the procedure are based on the same criteria as for primary stone treatment (Chapter 6) and includes repeat SWL (9).

If intervention is not required, medical therapy according to stone analysis, patient risk group, and metabolic evaluation might help to prevent regrowth of residual fragments (10-13).

8. MANAGEMENT OF URINARY STONES AND RELATED PROBLEMS DURING PREGNANCY

Urolithiasis during pregnancy is a diagnostic and therapeutic challenge. In most cases, it becomes symptomatic in the second or third trimester (1-4).

8.1 Diagnostic options

Diagnostic options are limited in pregnant women due to the possible teratogenic, carcinogenic, and mutagenic risk of foetal radiation exposure. The risk depends crucially on gestational age and amount of radiation delivered. Clinicians must consider carefully the risk-benefit ratio of an examination that involves radiation during the first trimester (1,2,5,6).

Currently, when evaluating pregnant patients suspected of renal colic, US (using change in resistive index and transvaginal ultrasound when necessary) has become the primary radiological diagnostic tool, with a limited excretory urogram only necessary in complicated cases. NCCT results in an even higher dose of radiation exposure. However, US is limited by poor sound transmission through gas and bone and its operator-dependent nature. Similarly, it can be difficult to differentiate physiological dilation of pregnancy from ureteral obstruction, and US is therefore of limited value in acute obstruction (7,8).

Transvaginal/endoluminal US might be important for evaluation of possible stones at the vesicoureteral junction. An endoluminal ultrasound probe can help to elucidate the level of obstruction and facilitate subsequent endoscopic ureteral stent placement.

Among other modalities, magnetic resonance urography (MRU) can be used to evaluate the urinary tract, thus avoiding ionising radiation and iodinated contrast medium, which is important in pregnancy. Magnetic resonance imaging can define the level of obstruction, and stones can be seen as a filling defect. However, these findings are non-specific. There is little experience with using this imaging modality during pregnancy (9-11).

Statements	LE	GR
US is the method of choice for practical and safe evaluation of pregnant women.	1a	A
In symptomatic patients with suspicion of ureteral stones during pregnancy, limited IVU, MRU, or isotope renography is a possible diagnostic method.		

8.2 Management

Management of pregnant urolithiasis patients poses significant multiple challenges to the patient, obstetrician and urologist, but many symptomatic stones (70-80%) pass spontaneously. Conservative management with analgesia can result in spontaneous passage.

If spontaneous passage does not occur, or if complications develop (e.g. induction of premature labour),

placement of an internal stent or percutaneous nephrostomy tube, or ureteroscopy is an alternative treatment (12-19). However, the temporising therapies (e.g. ureteral stenting or percutaneous nephrostomy) are often associated with poor tolerance, and they require multiple exchanges of stents or nephrostomy tubes during pregnancy, due to the potential for rapid encrustation of these devices (20-23).

Improvements in diagnostic technology, as well as experience in endoscopic instrumentation have made the endoscopic approach feasible and safe for diagnosis and treatment of ureteral stones. Nevertheless, one cannot overemphasise the necessity for care during URS, which should be performed only in centres with sufficient experience (20,22-24). When intracorporeal lithotripsy is necessary during URS in pregnant patients, the holmium laser has the advantage of minimal tissue penetration, thereby theoretically limiting risk of foetal injury.

Although percutaneous stone removal in the early stages of pregnancy has been reported in a few studies (21), SWL is still experimental, and pregnancy remains an absolute contraindication.

Recommendation	GR
Following correct diagnosis, conservative management should be the first-line treatment for all non-complicated cases of urolithiasis in pregnancy (except those that have clinical indications for intervention).	A

Statements	LE
If intervention becomes necessary, placement of a internal stent, percutaneous nephrostomy, or ureteroscopy are options.	3
Regular follow-up until final stone removal is necessary due to higher encrustation tendency of stents during pregnancy.

9. MANAGEMENT OF STONE PROBLEMS IN CHILDREN

Rates of urolithiasis have increased in developed countries, and there has been a shift in the age group experiencing a first stone episode (1-3). More than 1% of all urinary stones are seen in patients aged < 18 years. As a result of malnutrition and racial factors, paediatric urolithiasis remains an endemic disease in some areas (e.g. Turkey and Far East); elsewhere, the rates are similar to those observed in developed countries (4-11).

9.1 Investigations

Paediatric patients with urinary stones have a high risk of recurrence, therefore, standard diagnostic procedures for high-risk patients apply (see Chapters 2.6 and 11).

Statement	LE
In paediatric patients, the most common non-metabolic disorders are vesicoureteral reflux, ureteropelvic junction obstruction, neurogenic bladder, or other voiding difficulties (11,12).	4

Recommendation	GR
In all paediatric patients, complete metabolic stone evaluation based on stone analysis (if available) is necessary.	A

*9.1.1 **Imaging***

When selecting diagnostic procedures to identify urolithiasis in paediatric patients, it should be remembered that these patients might be uncooperative, require anaesthesia, or are sensitive to ionising radiation (13).

9.1.1.1 Ultrasound

Ultrasound is the most popular and practical imaging technique (13). In paediatrics, its advantages are absence of irradiation and no need for anaesthesia. US can be used to obtain information about the presence, size and location of a stone, and the grade of dilatation and obstruction of the urinary collecting system. It also indicates signs of abnormalities that facilitate stone formation.

Colour Doppler US shows differences in the ureteric jet (14) and resistive index of the arciform arteries of both kidneys, which are indicative of the grade of obstruction (15). Nevertheless, US fails to identify stones in > 40% of paediatric patients (16-19) (LE: 4), and provides no information about renal function. Ultrasound is part of the metaphylactic work-up in these cases.

Statement	LE
Ultrasound evaluation is the first choice for imaging in children and should include the kidney, filled bladder, and adjoining portions of the ureter (14,20).	2a

9.1.1.2 Plain films (KUB)

KUB can help to identify stones and their radio-opacity, and facilitate follow-up.

9.1.1.3 Intravenous urography (IVU)

IVU is an important diagnostic tool. However, the need for contrast medium injection is a major drawback. The radiation dose for IVU is comparable to that for voiding cystourethrography (0.33 mSV) (21).

9.1.1.4 Helical computed tomography (CT)

Recent CT protocols have been shown to reduce radiation exposure significantly (22). The principle of ALARA (As Low As Reasonable Achievable) should always be observed. like in adults it has a sensitivity of 94-100% and specificity of 92-100% (23).

In children, only 5% of stones escape detection by NCCT (14,23,24). Sedation or anaesthesia is rarely needed with modern high-speed CT apparatus (11).

9.1.1.5 Magnetic resonance urography (MRU)

MRU cannot be used to detect urinary stones. However, it might provide detailed anatomical information about the urinary collecting system, the location of an obstruction or stenosis in the ureter, and renal parenchymal morphology (25).

9.1.1.6 Nuclear imaging

^{99m}Tc-dimercaptosuccinyl acid scanning provides information about cortical abnormalities such as scarring, but does not aid primary diagnosis of urolithiasis. Diuretic renography with injection of a radiotracer (MAG3 or DPTA) and furosemide can be used to demonstrate renal function, identify obstruction in the kidney after injection of furosemide, and indicate the anatomical level of the obstruction (11,14).

9.2 Stone removal

Several factors must be considered when selecting treatment procedures for children. Compared to adults, children pass fragments more rapidly after SWL, and all stones should be evaluated for further metaphylactic measures (26). For endourological procedures, the smaller organs in children must be considered when selecting instruments for PNL or URS. To eliminate radiation exposure, US can be used for localisation during SWL or endourological procedures. Anticipation of the expected stone composition helps with selection of the appropriate procedure for removal (cystine stones are more resistant to SWL).

Statement	LE
Spontaneous passage of a stone is more likely in children than adults (6,11,12).	4

*9.2.1 **Medical expulsive therapy (MET) in children***

MET in children has already been discussed in Section 5.3.2.6. Although the use of nifedipine or α-blockers is very common in adults, there are insufficient data to demonstrate their safety and efficacy in children (27).

*9.2.2 **Extracorporeal shock wave lithotripsy***

Despite increasing application of PNL, and development of smaller-diameter flexible ureteroscopes and ancillary instruments, SWL is still the least-invasive procedure for stone management in children (28-36).

Stone free rates of 67-93% in short-term and 57-92% in long-term follow-up studies have been reported. In children, compared with adults, SWL can achieve more effective disintegration of large stones, together with swifter and uncomplicated discharge of large fragments (32-34). Stones located in calices, as well as abnormal kidneys, and large stones, are more difficult to disintegrate and clear. The likelihood of urinary obstruction is higher in such cases, and children should be followed closely for the prolonged risk of urinary tract obstruction. The retreatment rate is 13.9-53.9%, and the need for ancillary procedures and/or additional interventions is 7-33% (32-34,36).

The need for general anaesthesia during SWL depends on patient age and the lithotripter used. General or dissociative anaesthesia is administered in most children aged < 10 years, to avoid patient and stone motion and the need for repositioning (32,36). With modern lithotriptors, intravenous sedation or patient-controlled analgesia has been used in selected cooperative older children (37) (LE: 2b). There are concerns regarding the safety and potential biological effects of SWL on immature kidneys and surrounding organs in children. However, during short- and long-term follow-up, no irreversible functional or morphological side effects of high-energy shock waves have been demonstrated. In addition, when the potential deterioration of renal function is taken into account (although transient), restricting the number of shock waves and the energy used during each treatment session helps protect the kidneys (38-41).

Compared to adults, children pass stone fragments easily, and stenting is rarely needed. If the stone burden requires a ureteral stent, alternative procedures should be considered. Although internal stents are seldom needed following SWL of upper tract stones, ureteral pre-stenting decreases the SFR after initial treatment (28,30-32).

Statements	LE
In children, the indications for SWL are similar to those in adults, however they pass fragments more easily.	3
Children with renal stones of a diameter up to 20 mm (~300 mm^2) are ideal for SWL.	1b

*9.2.3 **Endourological procedures***

Improvement in intracorporeal lithotripsy devices and development of smaller instruments facilitate PNL and URS in children.

9.2.3.1 Percutaneous nephrolithotripsy (PNL)

Preoperative evaluation and indications for PNL in children are similar to those in adults. Although PNL is performed as monotherapy in most cases, it can be used as an adjunctive procedure. Availability of appropriate-size instruments and ultrasound guidance mean that age is not a limiting factor, and PNL can now be performed safely by experienced operators, with less radiation exposure even for large and complex stones (42-46). SFRs are between 68% and 100% after a single session, and increase with adjunctive measures, such as second-look PNL, SWL and URS (42,43).

Statement	LE
For paediatric patients, the indications for PNL are similar to those in adults.	1a

Recommendation	GR
In children, PNL is recommended for treatment of renal pelvic or caliceal stones with a diameter > 20 mm (~300 mm^2).	A

9.2.3.2 Ureteroscopy

While SWL still is the first-line treatment for most ureteral stones it is unlikely to be successful for stones > 10 mm in diameter, or for impacted, calcium oxalate monohydrate or cystine stones, or stones in children with unfavourable anatomy and in whom localisation is difficult. The success rate of SWL decreases for stones in the more distal parts of the ureter. Overall SFRs after SWL range from 75 to 100% (47-50).
If SWL is not promising ureteroscopy can be used. With the clinical introduction of smaller-calibre instruments, this modality has become the treatment of choice in middle and larger distal ureteric stones in children (48-50).

Different lithotripsy techniques, including ultrasonic, pneumatic and laser lithotripsy, are all safe and effective. As a result of the smaller size of the probes, laser energy is easier to use in smaller instruments and is more useful for paediatric cases (53,54) (see Section 5.6.2.2.7).

Statements	LE	GR
For intracorporeal lithotripsy, the same devices as in adults can be used (Ho:Yag laser, pneumatic and ultrasound lithotriptors).	3	C

Finally, flexible ureteroscopy has become an efficacious treatment for paediatric upper urinary tract stones. It might be particularly effective for treatment of proximal ureteral calculi and for stones < 1.5 cm in the lower pole calices (56-58).

9.2.4 ***Open or laparoscopic surgery***

Most stones in children can be managed by SWL and endoscopic techniques (59). Therefore the rate of open procedure has dropped significantly (60-64). In some situations, open surgery is inevitable. Indications for surgery include failure of primary therapy for stone removal, very young children with complex stones, congenital obstruction that requires simultaneous surgical correction, severe orthopaedic deformities that limit positioning for endoscopic procedures, and abnormal kidney position (29,31,44,45). Open surgery can be replaced by laparoscopic procedures in experienced hands (62-64).

9.3 Special considerations on recurrence prevention

It should be kept in mind that, in addition to stone removal procedures, treatment of paediatric urolithiasis requires a thorough metabolic and environmental evaluation on an individual basis. In case of obstructive pathologies along with the established metabolic abnormalities treatment should not be delayed. Children are in the high-risk group for stone recurrence (see Chapter 11).

10. STONES IN URINARY DIVERSION AND OTHER VOIDING PROBLEMS

10.1 Management of stones in patients with urinary diversion

*10.1.1 **Aetiology and preventive measures***

Patients with urinary diversion are at risk for stone formation in the renal collecting system, ureters, and conduit or continent reservoir (1-3). Metabolic factors such as hypercalciuria and hypocitraturia, infection with urease-producing organisms, foreign bodies, mucus secretion, and urinary stasis could be involved in stone formation in these cases (4).

These patients are also at high risk for stone recurrence, which warrants close follow-up for effective prevention. Preventive measures include medical management of metabolic abnormalities, appropriate therapy of urinary infections, and regular irrigation of continent reservoirs (5). One study showed that the risk for recurrent upper-tract stones in patients with urinary diversion subjected to PNL was 63% at 5 years (6).

*10.1.2 **Management***

Although patients with smaller upper-tract stones can be treated effectively with SWL (7,8) other well-established endourological techniques might be necessary to achieve stone-free status.

Some patients with small- or large-bowel conduits can be treated with URS under fluoroscopic guidance. Although identification of the targeted ureteral orifice is difficult, it can be localised by flexible cystoscopy and/or administration of intravenous indigo carmine. and a hydrophilic guidewire can be placed followed by regular flexible ureteroscopy. Stone removal and fragmentation are then undertaken using standard techniques. This approach might be difficult or impossible in individuals with long, tortuous conduits; percutaneous placement of an antegrade guidewire may facilitate stone removal procedures.

PNL is the preferred treatment alternative for removal of large renal stones in patients with urinary diversion, as well as ureteral stones that cannot be accessed via a retrograde approach or are not amenable to SWL (9).

Stones can form in the conduits after urinary diversion procedures, which is typically associated with a foreign body. A trans-stomal approach can be used to remove all stone material (along with the foreign body) using standard techniques, including intracorporeal lithotripsy. However, for calculi in continent urinary diversion, although a trans-stomal approach might be successful in some patients, there is a risk of disturbing the continence mechanism. A success rate of 89% has been reported for trans-stomal management of patients with stones in Kock reservoirs with afferent nipples (10). Patients with relatively larger stones are the best candidates for percutaneous removal. Before considering any percutaneous approach in these cases, CT should be undertaken to assess the presence of an overlying bowel, which could make this approach unsafe (11), and if present, an open surgical approach should be considered. In patients with no overlying viscera, ultrasound- or CT-guided access is recommended to facilitate safe placement of a sheath into the reservoir followed by standard PNL. Jarrett and colleagues have described an approach in which a 12-mm laparoscopic trocar is placed in the continent reservoir, through which a specimen retrieval bag is inserted (12). Trans-stomal flexible endoscopy facilitates manipulation of the stones into the entrapment bag. The stones are then fragmented in the bag using a rigid nephroscope and standard intracorporeal lithotripsy. This technique allows total stone removal without dispersal of fragments in a capacious reservoir. At the end of the procedure, a large-calibre catheter is placed in the reservoir through the trocar or sheath, and left in place for at least 2-3

weeks to allow tract maturation.

10.2 Management of stones in patients with neurogenic bladder

*10.2.1 **Aetiology and clinical presentation***

Patients with neurogenic bladder can develop urinary calculi because of additional risk factors such as urinary stasis and infection. Indwelling catheters and surgical interposition of bowel segments for treatment of bladder dysfunction can facilitate the introduction of foreign bodies and infection. Although calculi can form at any level of the urinary tract, they occur more frequently in the bladder, especially if bladder augmentation has been performed (1,2). Rare cases have been reported of vaginal calculi secondary to urinary stasis (3) or vesicovaginal fistulae (4). Bacteriuria, pelvicalicectasis, vesicoureteral reflux, renal scarring, lower urinary tract reconstruction, and thoracic spinal defect are risk factors for renal stone formation in patients with neurogenic bladder (5).

Kondo has found that bladder lithiasis is 10 times more prevalent in patients with myelomeningocele (MMC) treated with enterocystoplasy (2). The risk of stone formation after augmentation cystoplasty in immobile patients with sensory impairment can be significantly reduced by irrigation protocols (6). Diagnosis is more difficult because of the absence of clinical expression and difficult visualisation by imaging. As a result of their sensory impairment and vesicourethral dysfunction, these patients generally do not report troublesome symptoms until their calculi become large (7). Difficulty in self-catheterisation should lead to suspicion of possible bladder calculi.

10.2.2 ***Management***

Management of calculi in patients with neurogenic bladder is similar to that described above (see Section 10.1). Regardless of the treatment used, latex allergy is common in patients with MMC and appropriate measures need to be taken (8). Any surgery in these patients must be performed under general anaesthesia because of the impossibility of using spinal anaesthesia. Bone deformities often complicate positioning on the operating table and the necessary venous access. These deformities can even prevent general anaesthesia (9), which makes early diagnosis of lithiasis essential.

Statements	LE
Patients undergoing urinary diversion and/or suffering from neurogenic bladder dysfunction are at risk for recurrent stone formation.	3
Careful patient follow-up, utilisation of the appropriate stone-removal approach, and implementation of effective preventive strategies are the cornerstones of successful management.	3

10.3 Management of stones in transplanted kidneys

10.3.1 ***Aetiology and clinical presentation***

Transplant patients depend on their solitary kidney for renal function, therefore, any impairment causing urinary stasis requires immediate intervention. Although immunosuppression renders these patients more vulnerable to infection, they also have conditions that predispose them to urolithiasis, for example, hyperfiltration, excessively alkaline urine, renal tubular acidosis, recurrent UTIs, and increased serum calcium caused by persistent tertiary hyperparathyroidism (1). Stones in kidney allografts have a incidence of 0.2-1.7% (2-4). Unexplained fever, graft rejection, or unexplained failure to thrive requires US or NCCT to rule out calculi (5).

10.3.2 ***Management***

Treatment of renal calculi in the transplant patient is difficult, however, management principles are similar to those applied in other single renal units (6-9).

Conservative treatment under close surveillance is only possible for small asymptomatic stones. Although SWL for small calyceal stones is appealing because of minimal complications, localisation can be difficult and SFRs are poor (10,11). However, for large or ureteral stones, percutaneous and antegrade endoscopic techniques are more favourable, but concerns exist about potential injury to adjacent organs (12-14).

The introduction of small flexible ureteroscopes and holmium laser has made ureteroscopy another treatment option for transplant calculi. Retrograde access to transplanted kidneys is difficult owing to the anterior location of the ureteral anastamosis and ureteral tortuosity (15-17).

Recommendations	GR
All contemporary endoscopic treatment modalities, including SWL, (flexible) ureteroscopy and percutaneous nephrolithotomy are management options in patients with transplanted kidneys.	B
Metabolic evaluation should be completed after stone removal.	A*

**Upgraded following panel consensus.*

10.4 Special problems in stone removal

Table 23: Special problems in stone removal

Caliceal diverticulum stones	•SWL, PNL (if possible) or RIRS • Can also be removed using laparoscopic retroperitoneal surgery (1-5) • Patients may become asymptomatic due to stone disintegration (SWL) whilst well-disintegrated stone material remains in the original position due to narrow caliceal neck
Horseshoe kidneys	• Can be treated in line with the options described above (6) • Passage of fragments after SWL might be poor
Stones in pelvic kidneys	• SWL, RIRS or laparoscopic surgery • For obese patients, the options are SWL, PNL, RIRS or open surgery
Stones formed in a continent reservoir	• See 10.1 • Each stone problem must be considered and treated individually
Patients with obstruction of the ureteropelvic junction	• When outflow abnormality requires correction, stones can be removed by PNL together with percutaneous endopyelotomy (15-35) or open/ laparoscopic reconstructive surgery • URS together with endopyelotomy with Ho:YAG • Incision with an Acucise balloon catheter might be considered, provided the stones can be prevented from falling into the pelvi-ureteral incision (7-10)

11. METABOLIC EVALUATION AND RECURRENCE PREVENTION

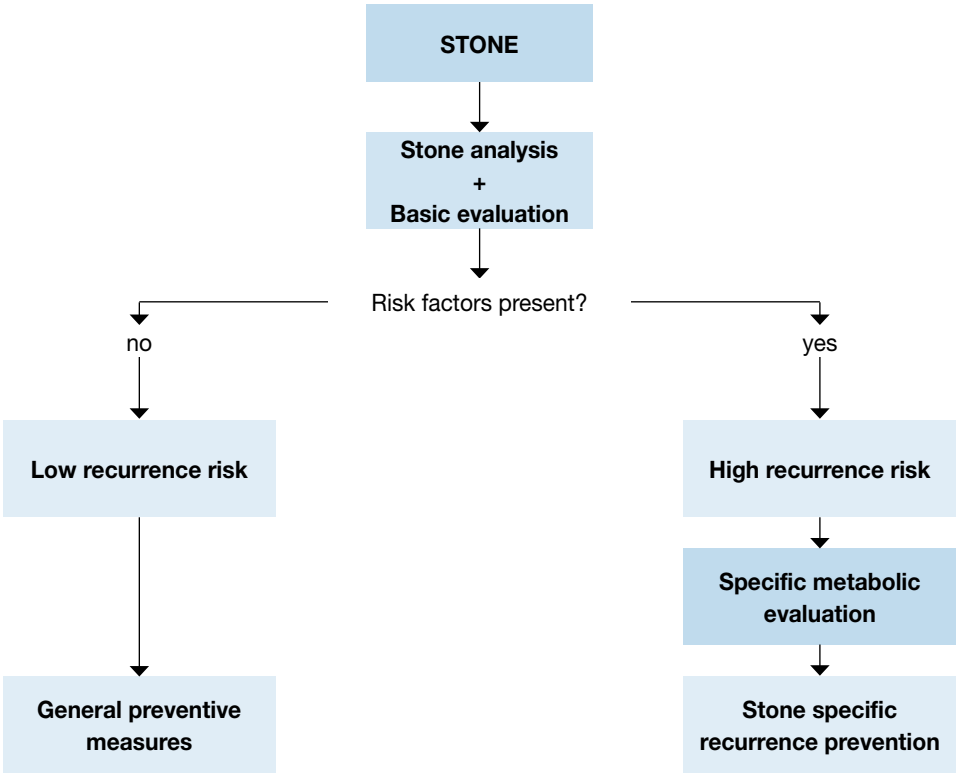
11.1 General metabolic considerations for patient work-up

*11.1.1 **Evaluation of patient risk***

After stone passage, every patient should be assigned to a low- or high-risk group of stone formers (Figure 3). For correct classification, two items are mandatory:

- reliable stone analysis by infrared spectroscopy or X-ray diffraction;
- basic analysis (*see* Section 3.2).

Figure 3: Assignment of patients to low- or high-risk groups of stone formers



Only high-risk stone formers require specific metabolic evaluation. Stone type is the deciding factor for further diagnostic tests. The different stone types include:

- calcium oxalate;
- calcium phosphate;
- uric acid;
- ammonium urate;
- struvite (and infection stones);
- cystine;
- xanthine;
- 2,8-dihydroxyadenine;
- drug stones;
- unknown composition.

*11.1.2 **Urine sampling***

Specific metabolic evaluation requires collection of two consecutive 24-h urine samples (1-3). The collecting bottles should be prepared with 5% thymol in isopropanol or stored at ≤ 8°C during collection (4). Preanalytical errors can be minimised by carrying out urinalysis immediately after collection. Urine pH should be assessed during collection of freshly voided urine four times daily (5).

HCl can be used as a preservative in special situations to prevent precipitation of calcium oxalate and calcium phosphate. However, in samples preserved with HCl, pH measurement is impossible and uric acid precipitates immediately. Alkalinisation is needed to dissolve urate crystals if urate excretion is of interest (6).

Spot urine samples are an alternative method of sampling, particularly when 24-h urine collection is difficult, e.g. in younger children (7,8). Spot urine studies normally link the excretion rates to creatinine (8,9). Spot urine studies are limited because the results may vary with collection time and patients' sex, body weight and age.

*11.1.3 **Timing of specific metabolic work-up***

For the initial specific metabolic work-up, the patient should be stone free. A minimum of 20 days is recommended between stone expulsion or removal and 24-h urine collection (4).

Follow-up studies are necessary in patients receiving recurrent stone prophylaxis (1). The first follow-up 24-h urine measurement should be at 8-12 weeks after starting pharmacological prevention of stone recurrence. This enables drug dosage to be adjusted if urinary risk factors have not normalised, with further 24-h urine measurements if necessary. Once urinary parameters have been normalised, it is sufficient to perform 24-h urine evaluation every 12 months.

The panel realise that on this issue there is only very limited published evidence.

*11.1.4 **Reference ranges of laboratory values***

Tables 24-26 provide the internationally accepted reference ranges for the different laboratory values in serum and urine.

Table 24: Normal laboratory values for blood parameters in adults

Blood parameter	Reference range	
Creatinine	20-100 µmol/L	
Sodium	135-145 mmol/L	
Potassium	3.5-5.5 mmol/L	
Calcium	2.0-2.5 mmol/L (total calcium)	
	1.12-1.32 mmol/L (ionised calcium)	
Uric acid	119-380 µmol/L	
Chloride	98-112 mmol/L	
Phosphate	0.81-1.29 mmol/L	
Blood gas analysis	pH	7.35-7.45
	pO_2	80-90 mmHg
	pCO_2	35-45 mmHg
	HCO_3	22-26 mmol/L
	BE	± 2

BE = base excess (loss of buffer base to neutralise acid).

*11.1.5 **Risk indices and additional diagnostic tools***

Several risk indices have been developed to describe the crystallisation risk for calcium oxalate or calcium phosphate in urine:

- AP_{CaOx} index (10,11);
- EQUIL (12-14);
- Bonn Risk Index (15-17).

Another approach to risk assessment is the Joint Expert Speciation System (JESS), which is based on an extensive database of physiochemical constants and is most like the EQUIL (18).

However, clinical validation of these risk indices for recurrence prediction or therapy improvement is ongoing and the benefit remains controversial.

Table 25: Normal laboratory values for urinary parameters in adults

Urinary Parameters	Reference ranges and limits for medical attention
pH	Constantly > 5.8 Constantly > 7.0 Constantly ≤ 5.8
Specific weight	> 1010
Creatinine	7-13 mmol/day females 13-18 mmol/day males
Calcium	> 5.0 mmol/day ≥ 8.0 mmol/day
Oxalate	> 0.5 mmol/day 0.45-0.85 mmol/day ≥ 1.0 mmol/day
Uric acid	> 4.0 mmol/day
Citrate	< 2.5 mmol/day
Magnesium	< 3.0 mmol/day
Inorganic phosphate	> 35 mmol/day
Ammonium	> 50 mmol/day
Cystine	> 0.8 mmol/day

Table 26: Reference urinary values in paediatric patients (19)

Soluble:creatinine ratio (spot urine samples)

11.2 General considerations for recurrence prevention

All stone formers, independent of their individual risk, should follow the preventive measures in Table 27. The main focus of these is normalisation of dietary habits and lifestyle risks. Stone formers at high risk need specific prophylaxis for recurrence, which is usually pharmacological treatment and based on stone analysis.

Table 27: General preventive measures

Fluid intake (drinking advice)	Fluid amount: 2.5-3.0 L/day Circadian drinking Neutral pH beverages Diuresis: 2.0-2.5 L/day Specific weight of urine: < 1010
Nutritional advice for a balanced diet	Balanced diet* Rich in vegetable and fibre Normal calcium content: 1-1.2 g/day** Limited NaCl content: 4-5 g/day Limited animal protein content: 0.8-1.0 g/kg/day
Lifestyle advice to normalise general risk factors	BMI: 18-25 kg/m^2 (target adult value, not applicable to children) Stress limitation measures Adequate physical activity Balancing of excessive fluid loss

Caution: The protein need is age-group dependent, therefore protein restriction in childhood should be handled carefully.

** Avoid excessive consumption of vitamin supplements.*

*** Exception: Patients with absorptive hypercalciuria, calcium excretion ≥ 8 mmol/day.*

11.2.1 ***Fluid intake***

An inverse relationship between high fluid intake and stone formation has been repeatedly demonstrated (1,2). The effect of fruit juices is mainly determined by the presence of citrate or bicarbonate (3). If hydrogen ions are present, the net result is neutralisation. However, if potassium is present, both pH and citrate are increased (4,5).

Recommendation	LE	GR
The aim should be to obtain a 24-h urine volume ≥ 2 L.	1b	A

11.2.2 ***Diet***

A common sense approach to diet should be taken, i.e. a mixed balanced diet with contributions from all food groups, but without any excesses (6).

Fruits, vegetables and fibres: fruit and vegetable intake should be encouraged because of the beneficial effects of fibre (7). The alkaline content of a vegetarian diet also increases urinary pH.

Oxalate: excessive intake of oxalate-rich products should be limited or avoided to prevent oxalate load (3), particularly in patients who have high oxalate excretion.

Vitamin C: although vitamin C is a precursor of oxalate, its role as a risk factor in calcium oxalate stone formation remains controversial (8-11). However, it seems wise to advise calcium oxalate stone formers to avoid excessive intake.

Animal protein should not be taken in excess (12-14) and limited to 0.8-1.0 g/kg body weight. Excessive consumption of animal protein has several effects that favour stone formation, including hypocitraturia, low urine pH, hyperoxaluria and hyperuricosuria.

Calcium intake should not be restricted unless there are strong reasons because of the inverse relationship between dietary calcium and stone formation (15). The minimum daily requirement for calcium is 800 mg and the general recommendation is 1000 mg/day (16). Calcium supplements are not recommended except in enteric hyperoxaluria, when additional calcium should be taken with meals to bind intestinal oxalate (14,17-19).

Sodium: the daily sodium intake should not exceed 3-5 g. High intake adversely affects urine composition:

- calcium excretion is increased by reduced tubular reabsorption;
- urinary citrate is reduced due to loss of bicarbonate;
- increased risk of sodium urate crystal formation.

Calcium stone formation can be reduced by restricting sodium and animal protein (13,14). A positive correlation between sodium consumption and risk of first-time stone formation has been confirmed only in women (15,20). There have been no prospective clinical trials on the role of sodium restriction as an independent variable in reducing the risk of stone formation.

Urate: Intake of urate-rich food should be restricted in patients with hyperuricosuric calcium oxalate stones (21-24) and uric acid stones (16). Intake should not exceed 500 mg/day.

11.2.3 ***Lifestyle***

Lifestyle factors may influence the risk of stone formation, e.g. overweight and obesity (25-27). Another risk factor is arterial hypertension (28,29).

11.3 Stone-specific metabolic work-up and pharmacological recurrence prevention

11.3.1 ***Introduction***

Pharmacological treatment is necessary in patients at high risk for recurrent stone formation, which is normally used with general preventive measures. The ideal drug should halt stone formation, have no side effects, and be easy to administer. Each of these aspects is important to achieve good compliance. The following descriptions highlight the most important characteristics of commonly used medication.

11.3.1.1 Thiazides and thiazide-like agents

Hydrochlorothiazide, bendroflumethiazide, trichlorothiazide and the non-thiazide indapamide have been used for recurrence prevention in patients with calcium stones. Thiazide treatment aims to reduce excretion

of calcium in hypercalciuria, but calcium reduction is also found in patients with normocalciuria (1,2). The hypocalciuric action of thiazides is thought to be mediated by increased reabsorption of calcium in the proximal and distal nephron (3).

Good evidence from RCTs has proven that thiazides are effective in preventing calcium stone recurrence (Table 28) (4).

Table 28: RCTs of thiazides for the prevention of recurrent stone formation (LE: 1b)

Author	Treatment	Selection	Duration of Study (yrs)	No. pts.	Stones/ pt/yr	Remission rate (%)	p-value
Borghi, et al. (5)	Indapamide No tx	Hypercalciuria	3	19 21	0.06 0.28	84.2 57.1	< 0.05
Brocks, et al. (6)	BFMZ Placebo	Non-selective	4	33 29	0.09 0.11	84.8 82.8	NS
Ettinger, et al. (7)	Chlorthalidone Placebo	Non-selective	4	23 31	0.05 0.22	87.0 54.8	< 0.05
Mortensen, et al. (8)	BFMZ Placebo	Non-selective	2	12 10	- -	100.0 60.0	< 0.1
Laerum and Larsen (9)	HCTZ Placebo	Non-selective	3	23 25	0.07 0.18	78.3 52.0	< 0.05
Ohkawa, et al. (10)	Triclorme-thiazide No Tx	Hypercalciuria	2	82 93	0.13 0.31	86.5 55.9	< 0.05
Robertson, et al. (11)	BFMZ No Tx	Non-selective	3	13 9	0.22 0.58	- -	"sig"
Scholz, et al. (12)	HCTZ Placebo	Non-selective	1	25 26	0.20 0.20	76.0 76.9	NS
Wilson, et al. (13)	HCTZ No Rx	Non-selective	3	23 21	0.15 0.31	- -	< 0.05

BFMZ = bendroflumethiazide; HCTZ = hydrochlorothiazide; Tx = treatment.

However, thiazide treatment has side effects. The unmasking of normocalcaemic hyperparathyroidism, development of diabetes and gout, as well as erectile dysfunction, contribute to limited tolerance and a high drop-out rate, resulting in 50-70% overall compliance.

The use of thiazide induces potassium loss. This can be compensated for by giving potassium citrate (3.5-7.0 mmol twice daily), which is preferable to KCl because it results in better potassium substitution (14).

11.3.1.2 Alkaline citrate

Commonly used alkalinising agents are: sodium potassium citrate, potassium citrate, sodium citrate, potassium magnesium citrate, potassium bicarbonate and sodium bicarbonate. Tubular cell alkalinisation is responsible for increased levels of urinary citrate, although only a small fraction of the administered citrate is directly excreted. Alkaline citrates are used for:

- correction of hypocitraturia;
- urine alkalinisation;
- inhibition of growth and aggregation of calcium oxalate;
- inhibition of agglomeration of calcium phosphate (15).

There is evidence from RCTs that alkaline citrates are effective in preventing calcium stone recurrence (4) (Table 29).

Table 29: RCTs evaluating alkali citrate therapy in preventing stone recurrence (LE: 1b)

Author	Treatment	Selection	Duration of Study (yrs)	N	Stones/ pt/yr	Remission (%)	p-value
Barcelo, et al. (16)	K-cit	Hypocitraturia	3	18	0.01	73.23	< 0.05
	Placebo			20	1.1	20	
Hofbauer, et al. (17)	Na-K-cit	Non-selective	3	16	0.9	31.3	NS
	No Rx			22	0.7	27.3	
Ettinger, et al. (18)	K-Mag-C	Non-selective	3	16	-	87.1	rr=0.06
	Placebo			25	-	36.4	

Potassium citrate (16,19), sodium citrate and potassium magnesium citrate (4) significantly reduce recurrence rate. A favourable effect has been reported with potassium magnesium citrate (18), but not sodium potassium citrate. Although potassium magnesium citrate appears to prevent stone recurrence, it is not yet generally available. Further studies are necessary to show whether it is superior to potassium citrate.

Alkaline citrate has a high occurrence of side effects, therefore, overall compliance rates do not exceed ~50%.

11.3.1.3 Magnesium
Magnesium oxide, magnesium hydroxide, potassium magnesium citrate and magnesium aspartate increase urinary magnesium excretion. Biochemically increased urinary magnesium levels reduce the ion-activity product of calcium oxalate and inhibit growth of calcium phosphate crystals. Magnesium is important for the transformation between various calcium phosphate crystal phases. A high urinary concentration of magnesium is thought to decrease the risk of brushite formation.

There is still not enough evidence to recommend magnesium as monotherapy in calcium stone prevention. In two RCTs, magnesium hydroxide was compared with placebo (7) and magnesium oxide with untreated controls (13). Neither showed a significant effect on stone formation, despite follow-up of 4 and 3 years, respectively. The previously reported positive effects of magnesium (20,21) have not been confirmed by recent studies (22).

11.3.1.4 Calcium supplements
See Section 11.2.2.

11.3.1.5 Allopurinol
Allopurinol is an inhibitor of xanthine oxidase. It has been used to prevent recurrence of calcium oxalate stones ever since a relationship was found between hyperuricosuria and calcium oxalate stone formation (23).

Although allopurinol tolerance is normally good, there are severe side effects with high doses.
The potential benefits of allopurinol on calcium oxalate stone formation are:

- reduced salting-out effect;
- decreased risk of uric acid or urate crystals as promoters of calcium oxalate precipitation;
- complex formation between colloidal urate and macromolecular inhibitors;
- reduced excretion of oxalate.

In a placebo-controlled, randomised study of hyperuricosuric calcium-oxalate stone formers, 75% of those treated with allopurinol were free of recurrent stone formation compared with 45% in the placebo group (significant difference) (24). The effectiveness of allopurinol (300 mg/day) has been tested in RCTs in calcium oxalate stone formers (13,24,25). Only one trial demonstrated a significant benefit of allopurinol in preventing stone recurrence (25). However, this trial solely enrolled patients with hyperuricosuria, while the other three enrolled patients regardless of metabolic background.

11.3.1.6 Pyridoxine
Theoretically, pyridoxine (vitamin B6) might favourably influence endogenous production of oxalate, probably due to increased transamination of glyoxylate resulting from action of the coenzyme pyridoxal phosphate.

Due to the rarity (and severity) of primary hyperoxaluria, there are no randomised studies on pyridoxine efficacy. However, it has been confirmed that a few patients with type 1 hyperoxaluria respond favourably to large doses of pyridoxine (26-28).

Due to the lack of other effective treatments, it is worth trying pyridoxine, with the aim of reducing oxalate excretion in patients with primary hyperoxaluria type I.

There are no controlled studies to support the use of pyridoxine in patients with idiopathic calcium oxalate stones.

11.3.1.7 L-Methionine

Acidification of urine can be achieved with 600-1500 mg/day L-methionine. Methionine acidifies urine pH by donating protons. Stable acidification is difficult to achieve. Long-term acidification in children is not justified (4).

11.3.1.8 Tiopronin-α-mercaptopropionylglycine

Tiopronin - which has a thiol-containing biomolecule - is able to form drug-cysteine complexes by splitting the disulphide binding of cystine. Consequently, cystine saturation of urine decreases, while solubility increases significantly (29-31). Although no RCTs have been reported, tiopronin lowers cystine stone formation, when rates before and after treatment are compared (32-35). Due to the significant level of side effects, tiopronin (and other cysteine-binding drugs) should be reserved for patients who are unable to control stone formation with high fluid intake, dietary modification and urine alkalinisation. The side effects appear to be dose related, including: nausea, rash, fatigue, fever, and proteinuria.

11.3.2 ***Recommendations for pharmacological treatment of patients with specific abnormalities in urine composition***

Urinary risk factor	**Suggested treatment**	**LE**	**GR**
Hypercalciuria	Thiazide + potassium citrate	1a	A
Hyperoxaluria	Oxalate restriction	2b	A
Hypocitraturia	Potassium citrate	1b	A
Enteric hyperoxaluria	Potassium citrate Calcium supplement Oxalate absorption	3-4 2 3	C B B
High sodium excretion	Restricted intake of salt	1b	A
Small urine volume	Increased fluid intake	1b	A
Urea level indicating a high intake of animal protein	Avoid excessive intake of animal protein	1b	A
Distal renal tubular acidosis	Potassium citrate	2b	B
Primary hyperoxaluria	Pyridoxine	3	B
No abnormality identified	High fluid intake	2b	B

11.4 Calcium oxalate stones

The criteria for identification of calcium oxalate stone formers with high recurrence risk are listed in Section 2.6.

11.4.1 ***Diagnosis***

Blood analysis requires measurement of creatinine, sodium, potassium, chloride, ionized calcium (or total calcium + albumin), uric acid, and parathyroid hormone (PTH) in case of increased calcium levels. Urinalysis requires measurement of urine volume, urine pH profile, specific weight, calcium, oxalate, uric acid, citrate, and magnesium.

11.4.2 ***Interpretation of results and aetiology***

- Elevated levels of ionised calcium in serum (or total calcium and albumin) require assessment of intact PTH to confirm or exclude suspected hyperparathyroidism (HPT).
- "Acidic arrest" (urine pH constantly < 6) may promote co-crystallisation of uric acid and calcium oxalate. Similarly, increased uric acid excretion (> 4 mmol/day in adults or > 12 mg/kg/day in children) can act as a promoter.
- Urine pH levels constantly > 5.8 in the day profile indicate renal tubular acidosis (RTA), provided UTI has been excluded. An ammonium chloride loading test confirms RTA and identifies RTA subtype (see Section 11.6.4).
- Oxalate excretion > 0.5 mmol/day in adults (> 0.37 mmol/1.73 m^2/day in children) confirms hyperoxaluria:
  - primary hyperoxaluria (oxalate excretion mostly ≥ 1 mmol/day), appears in three genetically determined forms;
  - secondary hyperoxaluria (oxalate excretion ≥ 0.5 mmol/day, usually < 1 mmol/day), occurs due to intestinal hyperabsorption of oxalate or extreme dietary oxalate intake;
  - mild hyperoxaluria (oxalate excretion 0.45-0.85 mmol/day), commonly found in idiopathic calcium oxalate stone formers.

11.4.3 ***Specific treatment***

General preventive measures are recommended for fluid intake and diet. Hyperoxaluric stone formers should consume foods with low oxalate content, while hyperuricosuric stone formers benefit from daily dietary reduction of purine. Table 30 summarises pharmacological treatment of calcium oxalate stones.

Table 30: Pharmacological treatment of calcium oxalate stones

Biochemical risk factor	Rationale for pharmacological therapy	Medication
Hypercalciuria	Calcium excretion 5-8 mmol/day	Alkaline citrate, 9-12 g/day, **OR** Sodium bicarbonate, 1.5 g 3 times daily
	Calcium excretion > 8 mmol/day	Hydrochlorothiazide, 25 mg/day initially, up to 50 mg/day
hypocitraturia	Citrate excretion < 2.5 mmol/day	Alkaline citrate, 9-12 g/day
Hyperoxaluria (enteric)	Oxalate excretion > 0.5 mmol/day	Calcium, ≥ 500 mg/day with meals **NB: BE AWARE OF EXCESS CALCIUM EXCRETION** Magnesium, 200-400 mg/day **NB: NO MAGNESIUM THERAPY IN PATIENTS WITH RENAL INSUFFICIENCY**
Hyperuricosuria	Uric acid excretion > 4.0 mmol/day	Alkaline citrate, 9-12 g/day **OR** Sodium bicarbonate, 1.5 g, 3 times daily **PLUS** Allopurinol,100 mg/day
	Hyperuricosuria and hyperuricemia > 380 µmol	Alkaline citrate, 9-12 g/day **PLUS** Allopurionol, 100-300 mg/day, depending on kidney function
Hypomagnesiuria	Magnesium excretion < 3.0 mmol/day	Magnesium, 200-400 mg/day **NB: NO MAGNESIUM THERAPY IN CASE OF RENAL INSUFFICIENCY**

11.5 Calcium phosphate stones

Some calcium phosphate stone formers are at high risk of recurrence. Further information on identifying high-risk patients is given in Section 2.6.

Calcium phosphate mainly appears in two completely different minerals: carbonate apatite and brushite:

- Carbonate apatite crystallisation occurs at pH ≥ 6.8 and may be associated with infection.
- Brushite crystallises at an optimum pH of 6.5-6.8, at high urinary concentrations of calcium (> 8 mmol/day) and phosphate (> 35 mmol/day). Its occurrence is not related to UTI.

Possible causes of calcium phosphate stones include HPT, RTA and UTI; each of which requires different therapy.

*11.5.1 **Diagnosis***

Diagnosis requires blood analysis for: creatinine, sodium, potassium, chloride, ionised calcium (or total calcium + albumin), and PTH (in case of increased calcium levels). Urinalysis includes measurement of: volume, urine pH profile, specific weight, calcium, phosphate, and citrate.

*11.5.2 **Specific treatment***

General preventive measures are recommended for fluid intake and diet.

*11.5.3 **Pharmacological therapy (Table 31)***

HPT and RTA are common causes of calcium phosphate stone formation. Although most patients with primary HPT require surgery, RTA can be corrected pharmacologically. If primary HPT and RTA have been excluded, pharmacotherapy for calcium phosphate calculi depends on effective reduction of urinary calcium levels using thiazides. If urine pH remains constantly > 6.2, urinary acidification with L-methionine may be helpful. For

infection-associated calcium phosphate stones, it is important to consider the guidance given for infection stones.

Table 31: Pharmacological treatment of calcium phosphate stones

Biochemical risk factor	Rationale for pharmacological therapy	Medication
Hypercalciuria	Calcium excretion > 8 mmol/day	Hydrochlorothiazide, initially 25 mg/day, increasing up to 50 mg/day
Inadequate urine pH	pH constantly > 6.2	L-Methionine, 200-500 mg 3 times daily, with the aim of reducing urine pH to 5.8-6.2
Urinary tract infection	Eradication of urea-splitting bacteria	Antibiotics

11.6 Disorders and diseases related to calcium stones

11.6.1 ***Hyperparathyroidism (1-6)***

The clinical appearance of HPT typically comprises bone loss, gastric ulcers and urolithiasis. Elevated levels of PTH significantly increase calcium turnover, leading to hypercalcaemia and hypercalciuria. If HPT is suspected, neck exploration should be performed to confirm the diagnosis (7). Primary HPT can only be cured by surgery.

11.6.2 ***Primary hyperoxaluria (PH) (8-14)***

Patients with primary hyperoxaluria (PH) should be referred to specialised centres, because successful management requires an experienced interdisciplinary team. The main therapeutic aim is to reduce endogenous oxalate production, which is increased in patients with PH. In approximately one-third of patients with PH type I, pyridoxine therapy normalises or significantly reduces urinary oxalate excretion. The goal of adequate urine dilution is achieved by adjusting fluid intake to 3.5-4.0 L/day in adults (children 1.5 L/m^2 body surface area) and following a circadian drinking regimen.

Therapeutic options for preventing calcium oxalate crystallisation include hyperdiuresis, alkaline citrates and magnesium. However, in end-stage renal failure, primary PH requires simultaneous liver-kidney transplantation. Treatment regimens are:

- Pyridoxine in PH type I: 5-20 mg/kg/day according to urinary oxalate excretion and patient tolerance;
- Alkaline citrate: 9-12 g/day in adults, 0.1-0.15 meq/kg/day in children;
- Magnesium: 200-400 mg/day (no magnesium in case of renal insufficiency).

11.6.3 ***Enteric hyperoxaluria (15-20)***

Enteric hyperoxaluria is a particularly problematic condition in patients with intestinal malabsorption of fat. This abnormality is associated with a high risk of stone formation, and is seen after intestinal resection, jejunoileal bypass for treatment of obesity, and in Crohn's disease and pancreas insufficiency. Intestinal loss of fatty acids is combined with loss of calcium. The normal complex formation between oxalate and calcium is therefore disturbed and oxalate absorption is increased. In addition to hyperoxaluria, these patients usually present with hypocitraturia because of loss of alkali. Urine pH is usually low, as are urinary calcium and urine volume. All these abnormalities contribute to high levels of supersaturation with calcium oxalate, crystalluria and stone formation.

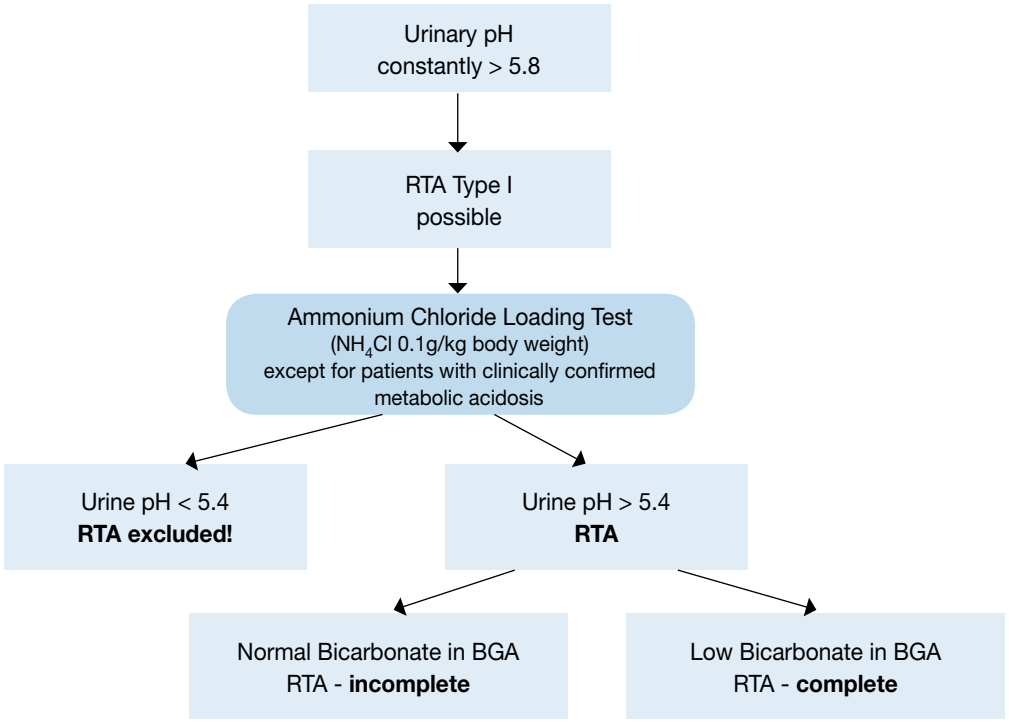
Specific preventive measures are:

- restricted intake of oxalate-rich foods;
- restricted fat intake;
- calcium supplementation at meal times to enable calcium oxalate complex formation in the intestine (20,21);
- sufficient fluid intake to balance intestinal loss of water caused by diarrhoea;
- alkaline citrates to raise urinary pH and citrate (22).

11.6.4 ***Renal tubular acidosis (RTA) (24,25)***

Renal tubular acidosis is caused by severe impairment of proton or bicarbonate handling along the nephron. Kidney stone formation most probably occurs in patients with distal RTA type I. Figure 4 outlines the diagnosis of RTA.

Figure 4: Diagnosis of renal tubular acidosis (RTA)



The main therapeutic aim is restoring a normal acid-base equilibrium. Despite the alkaline pH of urine in RTA, alkalinisation using alkaline citrates or sodium bicarbonate is key to normalising the metabolic changes (intracellular acidosis) responsible for stone formation (Table 32). The alkali load reduces tubular reabsorption of citrate, which in turn normalises citrate excretion and simultaneously reduces calcium turnover. Therapeutic success can be monitored by venous blood gas analysis (base excess: ± 2.0) in complete RTA. If excessive calcium excretion (> 8 mmol/day) persists after re-establishing acid-base equilibrium, thiazides may lower urinary calcium excretion.

Table 32: Pharmacological treatment of renal tubular acidosis

Biochemical risk factor	**Rationale for pharmacological therapy**	**Medication**
Hypercalciuria	Calcium excretion > 8 mmol/day	Hydrochlorothiazide, - in adults, 25 mg/day initially, up to 50 mg/day - in children, 0.5-1 mg/kg/day
Inadequate urine pH	Intracellular acidosis in nephron	Alkaline citrate, 9-12 g/day **OR** Sodium bicarbonate, 1.5 g 3 times daily

11.6.5 ***Nephrocalcinosis (26,27)***

Nephrocalcinosis (NC) refers to increased crystal deposition within the renal cortex or medulla, and occurs alone or in combination with kidney stones. There are various metabolic causes. The main risk factors are: HPT, PH, RTA, vitamin D metabolic disorders, idiopathic hypercalciuria and hypocitraturia, and genetic disorders, including Dent's disease and Bartter's syndrome. The many causes of NC means there is no single standard therapy. Therapeutic attention must focus on the underlying metabolic or genetic disease, while minimising the biochemical risk factors.

11.6.5.1 Diagnosis

Diagnosis requires the following blood analysis: PTH (in case of increased calcium levels), vitamin D and metabolites, vitamin A, sodium, potassium, magnesium, chloride and blood gas analysis. Urinalysis should

investigate: urine pH profile (minimum 4 times a day), daily urine volume, specific weight of urine, and levels of calcium, oxalate, phosphate, uric acid, magnesium and citrate.

11.7 Uric acid and ammonium urate stones

All uric acid and ammonium urate stone formers are considered to be at high risk of recurrence (1). Hyperuricosuria may be a result of dietary excess, endogenous overproduction (enzyme defects), myeloproliferative disorders, tumour lysis syndrome, drugs, gout or catabolism (2). Ammonium urate crystals are associated with UTI, malabsorption and malnutrition.

11.7.1 ***Diagnosis***

Blood analysis requires measurement of creatinine and uric acid levels. Urinalysis requires measurement of urine volume, urine pH profile, specific weight of urine, and uric acid level.

Interpretation of results

Uric acid and ammonium urate stones form under completely different biochemical conditions. Acidic arrest (urine pH constantly < 6) promotes uric acid crystallisation.

Hyperuricosuria is defined as uric acid excretion ≥ 4 mmol/day in adults or > 0.12 mmol/kg/day in children.

Hyperuricaemia may be present, but there is only weak evidence for its association with stone formation. Ammonium urate crystals form in urine at pH > 6.5, at high uric acid concentration, and in the presence of cations.

11.7.2 ***Specific treatment***

General preventive measures are recommended for fluid intake and diet. Hyperuricosuric stone formers benefit from purine reduction of their daily diet. Table 33 describes pharmacological treatment.

Table 33: Pharmacological treatment of uric acid and ammonium urate stones

Biochemical risk factor	Rationale for pharmacological therapy	Medication
Inadequate urine pH	Urine pH constantly ≤ 6.0; 'acidic arrest' in **uric acid stones**	Alkaline citrate, 9-12 g/day **OR** Sodium bicarbonate, 1.5 g 3 times daily **NB: DOSE DEPENDS ON TARGETED URINE PH** Prevention: targeted urine pH **6.2-6.8** Chemolitholysis: targeted urine pH **7.0-7.2**
	Urine pH constantly > 6.5 in **ammonium urate stones**	Adequate antibiotics in case of urinary tract infection with urea-degrading bacteria L-Methionine, 200-500 mg 3 times daily; targeted urine pH **5.8-6.2**
Hyperuricosuria	Uric acid excretion > 4.0 mmol/day	Allopurinol, 100 mg/day
	Hyperuricosuria and hyperuricemia > 380 µmol	Allopurinol, 100-300 mg/day, depending on kidney function

11.8 Struvite and infection stones

All infection-stone formers are deemed at high risk of recurrence.

11.8.1 ***Diagnosis***

Blood analysis requires measurement of creatinine, and urinalysis requires urine pH profile and urine culture.

Interpretation

- Infection stones contain struvite and/or carbonate apatite and/or ammonium urate.
- Urine culture typically provides evidence for urease-producing bacteria (Table 34).

Table 34: Most important species of urease-producing bacteria

Obligate urease-producing bacteria (> 98 %)
• *Proteus* spp. • *Providencia rettgeri* • *Morganella morganii* • *Corynebacterium urealyticum* • *Ureaplasma urealyticum*
Facultative urease-producing bacteria
• *Enterobacter gergoviae* • *Klebsiella* spp. • *Providencia stuartii* • *Serratia marcescens* • *Staphylococcus* spp.
CAUTION: About 0-5% of strains of *Escherichia coli*, *Entercoccus* and *Pseudomonas aeruginosa* may produce urease.

11.8.2 ***Specific treatment***

General preventive measures are recommended for fluid intake and diet. Specific measures include complete surgical stone removal (1), short- or long-term antibiotic treatment (2), urinary acidification using methionine (3) or ammonium chloride (4), and urease inhibition (5,6). For severe infections, acetohydroxamic acid (Lithostat) may be an option.

Recommendations for therapeutic measures	**Refs.**	**LE**	**GR**
Surgical removal of the stone material as completely as possible	1		
Short-term antibiotic course	2	3	B
Long-term antibiotic course	2	3	B
Urinary acidification: ammonium chloride, 1 g x 2-3 daily	4	3	B
Urinary acidification: methionine, 200-500 mg, 1-3 times daily	3	3	B
Urease inhibition	5,6	1b	A

11.9 Cystine stones

All cystine stone formers are deemed at high risk of stone recurrence.

11.9.1 ***Diagnosis***

Blood analysis includes measurement of creatinine, and urinalysis includes measurement of urine volume, pH profile, specific weight, and cystine.

Interpretation

- Cystine is poorly soluble in urine and crystallizes spontaneously within the physiological range of urine pH.
- Cystine solubility depends strongly on urine pH: at pH 6.0, the limit of solubility is 1.33 mmol/L.
- Routine analysis of cystine is not suitable for therapeutic monitoring.
- Reductive therapy targets disulphide bond splitting in cystine; it is essential to differentiate between cystine, cysteine and drug-cysteine complexes. Only HPLC-based analysis differentiates between the different complexes formed by therapy.

11.9.2 ***Specific treatment***

General preventative measures for fluid intake and diet are recommended. Although theoretically a diet low in methionine may reduce urinary excretion of cystine, patients are unlikely to comply sufficiently with such a diet. However, a restricted intake of sodium is more easily achieved and is more effective in reducing urinary cystine. Patients are usually advised to avoid sodium consumption > 2 g/day (1).

A high diuresis is of fundamental importance, aiming for 24-h urine volume of ≥ 3 L (2,3). A considerable fluid intake evenly distributed during the day is necessary.

11.9.2.1 Pharmacological treatment of cystine stones

The main therapeutic option for avoiding cystine crystallisation is to maintain urine pH above 7.5 to improve cystine solubility (Table 35) and to ensure appropriate hydration with a minimum of 3.5 L/day in adults, or 1.5 L/m^2 body surface area in children.

Free cystine concentration can be decreased by reductive substances, which act by splitting the disulphide binding of cystine

Tiopronin: Tiopronin is currently the best choice for cystine reduction. However, side effects often lead to treatment termination, e.g. when nephritic syndrome develops, or poor compliance, especially with long-term use.

After carefully considering the risk of early tachyphylaxis, putting into place a dose-escape phenomenon for long-term use, and recurrence risk, tiopronin is recommended at cystine levels > 3.0 mmol/day or in the case of troublesome disease.

Ascorbic acid is used when cystine excretion is < 3.0 mmol/day. However, it has limited reductive power and is estimated to lower urinary cystine levels by ~20% (4). The effectiveness and use of ascorbic acid as a standard therapeutic regimen are controversial (5).

Results for the angiotensin-converting enzyme inhibitor, captopril, are controversial (6-10). Captopril remains a second-line option, for use when tiopronin is not feasible or unsuccessful.

Table 35: Pharmacological treatment of cystine stones

Biochemical risk factor	Rationale for pharmacological therapy	Medication
Cystinuria	Cystine excretion > 3.0-3.5 mmol/day	Tiopronin, 250 mg/day initially, up to a maximum dose of 2 g/day **NB: TACHYPHYLAXIS IS POSSIBLE**
Inadequate urine pH	Improvement of cystine solubility. Urine pH optimum 7.5-8.5	*Alkaline Citrate* dose according to urine pH alternative *Sodium Bicarbonate* dose according to urine pH

Recommendations for the treatment of cystine stones

Therapeutic measures	Refs.	LE	GR
Urine dilution High fluid intake recommended so that 24-h urine volume exceeds 3 L. Intake should be ≥ 150 mL/h.	1-3,5	3	B
Alkalinisation For cystine excretion < 3 mmol/day: potassium citrate 3-10 mmol 2 or 3 times daily, to achieve pH > 7.5.	1-3,5	3	B
Complex formation with cystine For patients with cystine excretion > 3 mmol/day, or when other measures are insufficient: tiopronin, 250-2000 mg/day; captopril, 75-150 mg remains a second-line option in case tiopronin is unfeasible or unsuccessful.	1-10	3	B

11.10 2,8-dihydroyadenine stones and xanthine stones (1)

All 2,8-dihydroxyadenine and xanthine stone formers are considered to be at high risk of recurrence. Both stone types are rare. Diagnosis and specific prevention are similar to those for uric acid stones.

11.10.1 ***2,8-dihydroxyadenine stones***

A genetically determined defect of adenine phosphoribosyl transferase causeshigh urinary excretion of poorly soluble 2,8-dihydroxyadenine. High-dose allopurinol is an option, but should only be tried with regular monitoring.

11.10.2 ***Xanthine stones***

Patients who form xanthine stones usually show decreased levels of serum uric acid. There is no available pharmacological intervention.

11.10.3 ***Fluid intake and diet***

Recommendations for general preventive measures apply. Pharmacological intervention is difficult, therefore, high fluid intake ensures optimal specific weight levels of urine < 1.01. A purine-reduced diet decreases risk of spontaneous crystallisation in urine.

11.11 Drug stones (2)

Drug stones are induced by pharmacological treatment (3,4) (Table 36). Two types exist:

- stones formed by crystallised compounds of the drug;
- stones formed due to unfavourable changes in urine composition under drug therapy.

Table 36: Compounds that cause drug stones

Active compounds crystallizing in urine
• Allopurinol/oxypurinol
• Amoxicillin/ampicillin
• Ceftriaxone
• Ciprofloxacin
• Ephedrine
• Indinavir
• Magnesium trisilicate
• Sulfonamide
• Triamterene
Substances impairing urine composition
• Acetazolamide
• Allopurinol
• Aluminium magnesium hydroxide
• Ascorbic acid
• Calcium
• Furosemide
• Laxatives
• Methoxyflurane
• Vitamin D

11.12 Unknown stone composition (5)

An accurate medical history is the first step towards identifying risk factors (Table 37).

Diagnostic imaging begins with ultrasound examination of both kidneys to establish whether the patient is stone-free. Stone detection by ultrasound should be followed by KUB and unenhanced multislice CT in adults to differentiate between calcium-containing and non-calcium stones.

Blood analysis demonstrates severe metabolic and organic disorders, such as renal insufficiency, HPT or other hypercalcaemic states and hyperuricaemia. In children, hyperoxalaemia is additionally screened.

Urinalysis is performed routinely with a dipstick test as described above. Urine culture is required if there are signs of infection.

Constant urine pH > 6 in the daily profile indicates acidic arrest, which may promote uric acid crystallisation. Persistent urine pH > 5.8 in the daily profile indicates RTA, if UTI is excluded.

Microscopy of urinary sediment can help to discover rare stone types, as crystals of 2,8-dihydroxyadenine, cystine and xanthine are pathognomonic for the corresponding disease.

Following this programme, the most probable stone type can be assumed and specific patient evaluation can follow.

However, if any expulsed stone material is available, it should be analysed by diagnostic confirmation or correction.

Table 37: Investigating patients with stones of unknown composition

Investigation	Rationale for investigation
Medical history	Stone history (former stone events, family history) Dietary habits Medication chart
Diagnostic imaging	Ultrasound in case of a suspected stone Unenhanced helical-CT (Determination of Hounsfield units provides information about the possible stone composition)
Blood analysis	Creatinine Calcium (ionised calcium or total calcium + albumin) Uric acid
Urinalysis	Urine pH profile (measurement after each voiding, minimum 4 times daily) Dipstick test: leukocytes, erythrocytes, nitrite, protein, urine pH, specific weight Urine culture Microscopy of urinary sediment (morning urine)

12. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

BFMZ	bendroflumethiazide
BMI	body mass index
CI	credible intervals
CT	computed tomography
DPTA	diethylene triamine pertaacetic acid (radiotracer)
EAU	European Association of Urology
SWL	(extracorporeal) shock wave lithotripsy
GR	grade of recommendation
HCTZ	hydrochlorothiazide
HIRU	Health Information Research Unit
Ho:YAG	holmium:yttrium-aluminium-garnet [laser]
HPT	hyperparathyroidism
INR	international normalised ratio
IRS	infrared spectroscopy
IVU	intravenous urography
JESS	joint expert speciation system
KUB	Kidney ureter bladder
LE	level of evidence
MAG 3	mercapto acetyltriglycine (radiotracer)
MET	medical expulsive therapy
MMC	myelomeningocele
MRU	magnetic resonance urography
NC	nephrocalcinosis
NCCT	non-contrast enhanced computed tomography
NSAIDs	non-steroidal anti-inflammatory drugs
PCN	percutaneous nephrostomy
PH	primary Hyperoxaluria
PNL	percutaneous nephrolithotomy
PTH	parathyroid hormone
PTT	partial thrombolastin time
RCT	randomised controlled trial
RIRS	retrograde renal surgery
RTA	renal tubular acidosis
SFR	stone free rate
SIGN	Scottish Intercollegiate Guidelines Network
THAM	tris-hydroxymethyl-aminomethane
UPJ	ureteropelvic junction
URS	ureterorenoscopy
US	ultrasonography
UTI	urinary tract infection
XRD	X-ray diffraction

Conflict of interest

All members of the Urolithiasis Guidelines working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on Paediatric Urology

TABLE OF CONTENTS PAGE

1. METHODOLOGY

1.1 Introduction

A collaborative working group consisting of members representing the European Society for Paediatric Urology (ESPU) and the European Association of Urology (EAU) has prepared these guidelines to make a document available that may help to increase the quality of care for children with urological problems.

This compilation document addresses a number of common clinical pathologies in paediatric urological practice, but covering the entire field of paediatric urology in a single guideline document is unattainable, nor practical.

The majority of urological clinical problems in children are distinct and in many ways different to those in adults. This publication intends to outline a practical and preliminary approach to paediatric urological problems. Complex and rare conditions that require special care with experienced doctors should be referred to designated centres where paediatric urology practice has been fully established and a multidisciplinary approach is available.

For quite some time, paediatric urology has informally developed, expanded, matured and established its diverse body of knowledge and expertise and may now be ready to distinguish itself from its parent specialties. Thus, paediatric urology has recently emerged in many European countries as a distinct subspecialty of both urology and paediatric surgery, and presents a unique challenge in the sense that it covers a large area with many different schools of thought and a huge diversity in management.

Knowledge gained by increasing experience, new technological advances and non-invasive diagnostic screening modalities has had a profound influence on treatment modalities in paediatric urology, a trend that is likely to continue in the years to come. We now have new techniques for the treatment of reflux, our techniques for the treatment of complex congenital anomalies have substantially improved, and totally new technologies for bladder replacement and laparoscopic procedures have been developed.

1.2 Data identification and evidence sources

The guidelines were compiled based on current literature following a systematic review using MEDLINE. Application of a structured analysis of the literature was not possible in many conditions due to a lack of well-designed studies.

Due to the limited availability of large randomised controlled trials (RCTs) - influenced also by the fact that a considerable number of treatment options relate to surgical interventions on a large spectrum of different congenital problems - this document will largely be a consensus document. Also, there is clearly a need for continuous re-evaluation of the information presented in the current document.

It must be emphasised that clinical guidelines present the best evidence available but following the recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, also taking individual circumstances and patient and parent preferences into account.

1.3 Level of evidence and grade of recommendation

The level of evidence (LE) and grade of recommendation (GR) provided in this guideline follow the listings in Tables 1 and 2. The aim of grading the recommendations is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports

4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

**Modified from Sackett et al. (1).*

It should be noted that when recommendations are graded, there is not an automatic relationship between the level of evidence and the grade of recommendation. The availability of RCTs may not necessarily translate into a grade A recommendation if there are methodological limitations or disparities in the published results. Conversely, an absence of high-level evidence does not necessarily preclude a grade A recommendation if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations in which corroborating studies cannot be performed, perhaps for ethical or other reasons. In this case, unequivocal recommendations are considered helpful for the reader. Whenever this occurs, it has been clearly indicated in the text with an asterisk as 'upgraded based on panel consensus'. The quality of the underlying scientific evidence is a very important factor, but it has to be balanced against benefits and burdens, values and preferences and costs when a grade is assigned (2-4).

The EAU Guidelines Office does not perform cost assessments, nor can they address local/national preferences in a systematic fashion. However, whenever such data are available, the expert panels will include the information.

Table 2: Grade of recommendation*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett et al. (1).*

1.4 Publication history

The Paediatric Urology Guidelines were first published in 2001 with subsequent partial updates achieved in 2005, 2006, 2008, 2009, 2010, 2011, and this 2012 publication includes a considerable number of updated chapters and sections detailed below.

This 2012 guidelines publication underwent a blinded peer-review process before publication.

Standard procedure for EAU publications includes an annual assessment of newly published literature in this field, guiding future updates. An ultra-short reference document is being published alongside this publication. All documents are available with free access through the EAU website Uroweb (http://www.uroweb.org/guidelines/online-guidelines/).

1.4.1 Summary of updated and new information

Amended: new literature included and the text has been revised for:
Chapter 6 - Hypospadias
Chapter 12 - Monosymptomatic enuresis. A new algorithm has been included and the text was revisited.
Chapter 13 - sections

- Botulinum toxin injections
- Follow-up of neurogenic bladder patients

Chapter 15 - Vesicoureteric reflux. The literature has been updated and the text has been revised.
Section 16.5.3 - Ureterorenoscopy. A small section has been added with new literature.
Chapter 17 - Obstructive pathology of renal duplication: ureterocele and ectopic ureter. This section has been completely revised and a new algorithm included.

New topics included in this 2012 print
Urinary tract infections in children (Chapter 10)
Post-operative fluid management in children (Chapter 20)
Post-operative pain management in children (Chapter 21)

1.5 Potential conflict of interest statement

The expert panel have submitted potential conflict of interest statements which can be viewed on the EAU

website: http://www.uroweb.org/guidelines/online-guidelines/.

2. PHIMOSIS

2.1 Background

At the end of the first year of life, retraction of the foreskin behind the glandular sulcus is possible in only about 50% of boys; this rises to approximately 89% by the age of 3 years. The incidence of phimosis is 8% in 6 to 7-year-olds and just 1% in males aged 16-18 years (1). The phimosis is either primary (physiological) with no sign of scarring, or secondary (pathological) to a scarring such as balanitis xerotica obliterans. Phimosis has to be distinguished from normal agglutination of the foreskin to the glans, which is a physiological phenomenon (2).

The paraphimosis must be regarded as an emergency situation: retraction of a too narrow prepuce behind the glans penis into the glanular sulcus may constrict the shaft and lead to oedema. It interferes with perfusion distally from the constrictive ring and brings a risk of consecutive necrosis.

2.2 Diagnosis

The diagnosis of phimosis and paraphimosis is made by physical examination.

If the prepuce is not retractable or only partly retractable and shows a constrictive ring on drawing back over the glans penis, a disproportion between the width of the foreskin and the diameter of the glans penis has to be assumed. In addition to the constricted foreskin, there may be adhesions between the inner surface of the prepuce and the glanular epithelium and/or a fraenulum breve. A fraenulum breve leads to a ventral deviation of the glans once the foreskin is retracted. If the tip remains narrow and glanular adhesions were separated, than the space is filled with urine during voiding causing the foreskin to balloon outward.

The paraphimosis is characterised by retracted foreskin with the constrictive ring localised at the level of the sulcus, which prevents replacement of the foreskin over the glans.

2.3 Treatment

Treatment of phimosis in children is dependent on the parents' preferences and can be plastic or radical circumcision after completion of the second year of life. Plastic circumcision has the objective of achieving a wide foreskin circumference with full retractability, while the foreskin is preserved (dorsal incision, partial circumcision). However, this procedure carries the potential for recurrence of the phimosis. In the same session, adhesions are released and an associated fraenulum breve is corrected by fraenulotomy. Meatoplasty is added if necessary.

An absolute indication for circumcision is secondary phimosis. The indications in primary phimosis are recurrent balanoposthitis and recurrent urinary tract infections in patients with urinary tract abnormalities (3-6) (LE: 2; GR: B). Simple ballooning of the foreskin during micturition is not a strict indication for circumcision.

Routine neonatal circumcision to prevent penile carcinoma is not indicated. Contraindications for circumcision are coagulopathy, an acute local infection and congenital anomalies of the penis, particularly hypospadias or buried penis, because the foreskin may be required for a reconstructive procedure (7,8). Childhood circumcision has an appreciable morbidity and should not be recommended without a medical reason (9-12) (LE: 2; GR B). As a conservative treatment option of the primary phimosis, a corticoid ointment or cream (0.05-0.1%) can be administered twice a day over a period of 20-30 days (13-16) (LE: 1; GR: A). This

treatment has no side effects and the mean bloodspot cortisol levels are not significantly different from an untreated group of patients (17) (LE: 1). Agglutination of the foreskin does not respond to steroid treatment (14) (LE: 2).

Treatment of paraphimosis consists of manual compression of the oedematous tissue with a subsequent attempt to retract the tightened foreskin over the glans penis. Injection of hyaluronidase beneath the narrow band may be helpful to release it (18) (LE: 4; GR: C). If this manoeuvre fails, a dorsal incision of the constrictive ring is required. Depending on the local findings, a circumcision is carried out immediately or can be performed in a second session.

3. CRYPTORCHIDISM

3.1 Background

At 1 year of age, nearly 1% of all full-term male infants have cryptorchidism, which is the commonest congenital anomaly affecting the genitalia of newborn males (1). The most useful classification of cryptorchidism is into palpable and non-palpable testes, as clinical management is decided by the location and existence of the testis.

- Retractile testes require only observation as they may become ascendant. Although they have completed their descent, a strong cremasteric reflex may cause their retention in the groin (2).
- Bilateral, non-palpable testes and any suggestion of sexual differentiation problems (e.g. hypospadias) require urgent, mandatory endocrinological and genetic evaluation (3) (LE: 3; GR: B).

3.2 Diagnosis

A physical examination is the only way of differentiating between palpable or non-palpable testes. There is no benefit in performing ultrasound, computed tomography (CT), magnetic resonance imaging (MRI) or angiography.

Clinical examination includes a visual description of the scrotum and an examination of the child in both a supine and crossed-leg position. The examiner should inhibit the cremasteric reflex with his non-dominant hand, immediately above the symphysis in the groin region, before touching, or reaching for, the scrotum. The groin region may be 'milked' towards the scrotum in an attempt to move the testis into the scrotum. This manoeuvre also allows an inguinal testis to be differentiated from enlarged lymph nodes that could give the impression of an undescended testis. A retractile testis can generally be brought into the scrotum, where it will remain until a cremasteric reflex (touching the inner thigh skin) will retract it again into the groin (4).

A unilateral, non-palpable testis and an enlarged contralateral testis may suggest testicular absence or atrophy, but this is not a specific finding and does not preclude surgical exploration. An inguinal, non-palpable testis requires specific visual inspection of the femoral, penile and perineal region to exclude an ectopic testis. Diagnostic laparoscopy is the only examination that can reliably confirm or exclude an intra-abdominal, inguinal and absent/vanishing testis (non-palpable testis) (5) (LE: 1b; GR: A). Before carrying out laparoscopic assessment, an examination under general anaesthesia is recommended because some, originally nonpalpable, testes become palpable under anaesthetic conditions.

3.3 Treatment

If a testis has not descended by the age of 1 year, there is no benefit in waiting for a spontaneous descent. To prevent histological deterioration, treatment should be carried out and finished before 12-18 months of age (6-9).

3.3.1 ***Medical therapy***

Medical therapy using human chorionic gonadotrophin (hCG) or gonadotrophin-releasing hormone (GnRH) is based on the hormonal dependence of testicular descent with maximum success rates of 20% (10,11). Hormonal therapy for testicular descent has lower success rates, the higher the undescended testis is located. A total dose of 6000 to 9000 units of hCG is given in four doses over a period of 2 to 3 weeks depending on weight and age, along with GnRH, given for 4 weeks as a nasal spray in a dose of 1.2 mg/day, divided into three doses per day.

Medical treatment may be beneficial before surgical orchidolysis and orchidopexy (dosage as described earlier) or afterwards (low intermittent dosages) (12), in terms of increasing the fertility index, which is a predictor for fertility in later life (12). However, long-term follow-up data are awaited. But there is data reporting that hCDG treatment may be harmful to future spermatogenesis through increased apoptosis of germ cells (13).

3.3.2 ***Surgery***

Palpable testis: surgery for the palpable testis includes orchidofuniculolysis and orchidopexy, via an inguinal approach, with success rates of up to 92% (14). It is important to remove and dissect all cremasteric fibres

to prevent secondary retraction. Associated problems, e.g. an open processus vaginalis, must be carefully dissected and closed. It is recommended that the testis is placed in a subdartos pouch. With regard to sutures, there should either be no fixation sutures or they should be made between the tunica vaginalis and the dartos musculature.

The lymph drainage of a testis that has undergone surgery for orchidopexy has been changed from iliac drainage to iliac and inguinal drainage (important in the event of later malignancy). Scrotal orchidopexy can also be an option in less severe cases.

Non-palpable testis: inguinal surgical exploration with possible laparoscopy should be attempted. There is a significant chance of finding the testis via an inguinal incision. In rare cases, it is necessary to search into the abdomen if there are no vessels or vas deferens in the groin. Laparoscopy is the best way of examining the abdomen for a testis. In addition, either removal or orchidolysis and orchiopexy can be performed via laparoscopic access (15). Before starting diagnostic laparoscopy, examine the child under general anaesthesia since a previously non-palpable testes might now be palpable under anaesthesia.

An intra-abdominal testis in a 10-year-old boy or older, with a normal contralateral testis, should be removed. In bilateral intra-abdominal testes, or in a boy younger than 10 years, a one-stage or two-stage Fowler-Stephens procedure can be performed. In the event of a two-stage procedure, the spermatic vessels are either laparoscopically clipped or coagulated proximal to the testis to allow development of collateral vasculature (16). The second-stage procedure, in which the testis is brought directly over the symphysis and next to the bladder into the scrotum, can also be performed by laparoscopy 6 months later. The testicular survival rate in a one-stage procedure varies between 50% and 60%, with success rates rising up to 90% in a two-stage procedure (17). Microvascular autotransplantation can also be performed with a 90% testicular survival rate. However, the procedure requires very skilful and experienced surgical techniques (18).

3.4 Prognosis

Although boys with one undescended testis have a lower fertility rate, they have the same paternity rate as boys with bilateral descended testes. Boys with bilateral undescended testes have a lower fertility and paternity rate.

Boys with an undescended testis have a 20-fold higher risk of developing testicular malignancy, a risk uninfluenced by any kind of treatment. Screening both during and after puberty is therefore recommended for these boys. Recently, a Swedish study, with a cohort of almost 17,000 men who were treated surgically for undescended testis and followed for a total of almost 210,000 person years, showed that treatment for undescended testis before puberty decreased the risk of testicular cancer. The relative risk of testicular cancer among those who underwent orchiopexy before 13 years of age was 2.23 when compared with the Swedish general population; this increased to 5.40 for those treated at 13 years of age or older 5.40 (19). A systematic review and meta-analysis of the literature by an American group has also concluded that prepubertal orchiopexy may decrease the risk of testicular cancer and that early surgical intervention is indicated in children with cryptorchidism (20).

Boys with retractile testes do not need medical or surgical treatment, but require close follow-up until puberty.

3.5 Recommendations for crytorchidism

Due to the lack of spontaneous testicular descent after the age of 1 year, and because of the potential loss of testicular quality, it is recommended that surgical orchidolysis and orchidopexy should be performed at the latest by 12-18 months of age.

To date, it seems that pre- or post-operative hormonal treatment may have a beneficial effect on fertility later in life.

4. HYDROCELE

4.1 Background

Hydrocele is defined as a collection of fluid between the parietal and visceral layer of tunica vaginalis (1). Pathogenesis of hydrocele is based on an imbalance between the secretion and reabsorption of this fluid. This is in contrast with inguinal hernia, which is defined as the protrusion of a portion of organs or tissues through the abdominal wall (2). Incomplete obliteration of the processus vaginalis peritonei results in formation of various types of communicating hydrocele alone or connected with other intrascrotal pathology (hernia). The exact time of obliteration of processus vaginalis is not known. It persists in approximately 80-94% of newborns and in 20% of adults (3). If complete obliteration of processus vaginalis occurs with patency of midportion, a hydrocele of the cord occurs. Scrotal hydroceles without associated patency of the processus vaginalis are encountered in newborns as well (4). Non-communicating hydroceles are found secondary to minor trauma, testicular torsion, epididymitis, varicocele operation or may appear as a recurrence after primary repair of a communicating hydrocele.

4.2 Diagnosis

The classic description of a communicating hydrocele is that of a hydrocele that vacillates in size, and is usually related to activity. It may be diagnosed by history; physical investigation and transillumination of the scrotum make the diagnosis in the majority of cases (5). If the diagnosis is that of a hydrocele, there will be no history of reducibility and no associated symptoms; the swelling is translucent, smooth and usually non-tender. If there are any doubts about the character of an intrascrotal mass, scrotal ultrasound should be performed and has nearly 100% sensitivity in detecting intrascrotal lesions. Doppler ultrasound studies help to distinguish hydroceles from varicocele and testicular torsion, although these conditions may also be accompanied by a hydrocele.

4.3 Treatment

In the majority of infants, the surgical treatment of hydrocele is not indicated within the first 12-24 months because of the tendency for spontaneous resolution (LE: 4; GR: C). Early surgery is indicated if there is suspicion of a concomitant inguinal hernia or underlying testicular pathology (6). The question of contralateral disease should be addressed by both history and examination at the time of initial consultation (5). Persistence of a simple scrotal hydrocele beyond 24 months of age may be an indication for surgical correction. However, there is no evidence that this type of hydrocele risks testicular damage. In the paediatric age group, the operation consists of ligation of patent processus vaginalis via inguinal incision and the distal stump is left open, whereas in hydrocele of the cord the cystic mass is excised or unroofed (1,5,6) (LE: 4; GR: C). In expert hands, the incidence of testicular damage during hydrocele or inguinal hernia repair is very low (0.3%) (LE: 3; GR: B). Sclerosing agents should not be used because of the risk of chemical peritonitis in communicating processus vaginalis peritonei (5,6) (LE: 4; GR: C). The scrotal approach (Lord or Jaboulay technique) is used in the treatment of a secondary non-communicating hydrocele.

5. ACUTE SCROTUM IN CHILDREN

5.1 Background

Acute scrotum is a paediatric urology emergency case, most commonly caused by torsion of the testis, torsion of the appendix testis and epididymitis/epididymo-orchitis (1-6). Other causes of acute scrotal pain are idiopathic scrotal oedema, mumps orchitis, varicocele, scrotal haematoma, incarcerated hernia, appendicitis or systemic disease (Henoch-Schönlein purpura) (7-19).

Torsion of the testis occurs most often in the neonatal period and around puberty, while torsion of the appendix testes occurs over a wider age range. Acute epididymitis affects two age groups: below the age of 1 year and between 12 and 15 years (5,20,21). Acute epididymitis was found most often (37-64.6%) in boys with acute scrotum (1-4). One study predicted the incidence of epididymitis as about 1.2 per 1,000 male children per year (22).

5.2 Diagnosis

Patients usually present with scrotal pain. The duration of symptoms is shorter in testicular torsion (69% present within 12 hours) compared to torsion of the appendix testes (62%) and acute epididymitis (31%) (5,6,20).

In the early phase, location of the pain can lead to the diagnosis. Patients with acute epididymitis experience a tender epididymitis, while patients with testicular torsion are more likely to have a tender testicle, and patients with torsion of the appendix testis feel isolated tenderness of the superior pole of the testis (20).

An abnormal position of the testis was more frequent in testicular torsion than in patients with epididymitis (20). Looking for the absence of the cremasteric reflex is a simple method with a sensitivity of 100% and specificity of 66% for the presence of testicular torsion (21,23) (LE:3; GR: C).

Fever occurs often in epididymitis (11-19%). The classical sign of a 'blue dot' was found only in 10-23% patients with torsion of the appendix testis (4,6,21,24).

In many cases, it is not easy to determine the cause of acute scrotum based on history and physical examination alone (1-6,21,24).

A positive urine culture is only found in a few patients with epididymitis (3,21,24,25). It should be remembered that a normal urinalysis does not exclude epididymitis. Similarly, an abnormal urinalysis does not exclude testicular torsion.

Doppler ultrasound is useful to evaluate an acute scrotum, with a sensitivity of 63.6-100% and a specificity of 97-100%, and a positive predictive value of 100% and negative predictive value 97.5% (26-31) (LE: 3; GR: C). The use of Doppler ultrasound may reduce the number of patients with acute scrotum undergoing scrotal exploration, but it is operator-dependent and can be difficult to perform in prepubertal patients (29,32). It may also show a misleading arterial flow in the early phases of torsion and in partial or intermittent torsion: persistent arterial flow does not exclude testicular torsion. In a multicentre study of 208 boys with torsion of the testis, 24% patients had normal or increased testicular vascularisation (29). Better results were reported using high-resolution ultrasonography (HRUS) for direct visualisation of the spermatic cord twist with a sensitivity of 97.3% and a specificity of 99% (29,33) (LE: 2; GR: C).

Scintigraphy and, more recently, dynamic contrast-enhanced subtraction MRI of the scrotum also provide a comparable sensitivity and specificity to ultrasound (34-37). These investigations may be used when diagnosis is less likely and if torsion of the testis still cannot be excluded from history and physical examination. This should be done without inordinate delays for emergent intervention (24).

The diagnosis of acute epididymitis in boys is mainly based on clinical judgement and adjunctive investigation. However, it should be remembered that findings of secondary inflammatory changes in the absence of evidence of an extra-testicular nodule by Doppler ultrasound might suggest an erroneous diagnosis of epididymitis in children with torsion of appendix testes (38).

Prepubertal boys with acute epididymitis have an incidence of underlying urogenital anomalies of 25-27.6%. Complete urological evaluation in all children with acute epididymitis is still debatable (3,21,22).

5.3 Treatment

*5.3.1 **Epididymitis***

In prepubertal boys, the aetiology is usually unclear, with an underlying pathology of about 25%. A urine culture is usually negative, and unlike in older boys, a sexually transmitted disease is very rare.

Antibiotic treatment, although often started, is not indicated in most cases unless urinalysis and urine culture show a bacterial infection (22,39). Epididymitis is usually self-limiting and with supportive therapy (i.e. minimal physical activity and analgesics) heals without any sequelae (LE: 3; GR: C). However, bacterial epididymitis can be complicated by abscess or necrotic testis and surgical exploration is required (40).

Torsion of the appendix testis can be managed conservatively (LE: 4; GR: C). During the six-week-follow-up, clinically and with ultrasound, no testicular atrophy was revealed. Surgical exploration is done in

equivocal cases and in patients with persistent pain (27).

5.3.2 ***Testicular torsion***

Manual detorsion of the testis is done without anaesthesia. It should initially be done by outwards rotation of the testis unless the pain increases or if there is obvious resistance. Success is defined as the immediate relief of all symptoms and normal findings at physical examination (41) (LE: 3; GR: C). Doppler ultrasound may be used for guidance (42).

Bilateral orchiopexy is still required after successful detorsion. This should not be done as an elective procedure, but rather immediately following detorsion. One study reported residual torsion during exploration in 17 out of 53 patients, including 11 patients who had reported pain relief after manual detorsion (41,43).

5.3.3 ***Surgical treatment***

Testicular torsion is an urgent condition, which requires prompt surgical treatment. The two most important determinants of early salvage rate of the testis are the time between onset of symptoms and the detorsion and degree of twisting of the cord (44). Severe testicular atrophy occurred after torsion for as little as 4 hours when the turn was more than 360°. In cases of incomplete torsion (180° to 360°), with symptom duration up to 12 hours, no atrophy was observed. However, an absent or severely atrophied testis was found in all cases of torsion of more than 360° and symptom duration of more than 24 hours (45).

Early surgical intervention with detorsion (mean torsion time < 13 hours) was found to preserve fertility (46). Urgent surgical exploration is mandatory in all cases of testicular torsion within 24 hours of the onset of symptoms.

In those patients with testicular torsion of more than 24 hours, semi-elective exploration is necessary (44,45) (LE: 3; GR: C). There is still controversy on whether to carry out detorsion and to preserve the ipsilateral testis, or to perform an orchiectomy, in order to preserve contralateral function and fertility after testicular torsion of long duration (> 24 hours).

A recent study in humans found that sperm quality was preserved in both orchiectomy and orchiopexy groups in comparison to control normal men, although orchiectomy resulted in better sperm morphology (47).

During exploration, fixation of the contralateral testis is also performed. Recurrence after orchiopexy is rare (4.5%) and may occur several years after operation. There is no common recommendation about the preferred type of fixation and suture material; however, many urologists currently use a Dartos pouch orchiopexy (48).

External cooling before exploration and several medical treatments seem effective in reducing ischaemia-reperfusion injury and preserving the viability of the torsed testis and the contralateral testis (49-53).

5.4 Prognosis

5.4.1 ***Fertility***

The results vary and are conflicting. In one study, unilateral torsion of the testis seriously intervened with subsequent spermatogenesis in about 50% of the patients and produced borderline impairment in another 20%.

5.4.2 ***Subfertility***

Subfertility is found in 36-39% of the patients after torsion. Semen analysis may be normal in only 5-50% in long-term follow-up (44). Early surgical intervention (mean torsion time < 13 hours) with detorsion was found to preserve fertility, but a prolonged torsion period (mean torsion time of 70 hours) followed by orchiectomy jeopardises fertility (46).

One study identified antisperm antibodies in the semen of patients with testicular torsion and correlated antibody levels with infertility, while other studies have failed to confirm these results (44,47). Anderson et al. found pre-existing contralateral testis abnormalities in biopsies performed at the time of surgery and did not detect any case of antisperm antibodies after testicular torsion (46).

5.4.3 ***Androgen levels***

A study in rats showed a long-term reduction in testicular androgen production after testicular torsion. This effect was considered to be caused by reperfusion/oxidative stress in the testis (45). Even though the levels of FSH, LH and testosterone are higher in patients after testicular torsion compared to normal controls, endocrine testicular function remains in the normal range in patients after testicular torsion (47).

5.4.4 ***Testicular cancer***

There may be a 3.2-fold increased risk of developing a testis tumour 6-13 years after torsion. However, two of nine reported cases had torsion of a tumour-bearing testis and four had a tumour in the contralateral testis to the torsed testicle (44).

*5.4.5 **Nitric oxide***

A study in rats found that spermatic cord torsion did not lead to impairment in nitric oxide-mediated relaxant responses of the isolated penile bulb (54).

5.5 Perinatal torsion

Perinatal torsion of the testis most often occurs prenatally. After birth, perinatal torsion occurs in 25%, with bilateral perinatal torsion comprises 11-21% of all perinatal torsions (55). Most cases are extravaginal torsion in contrast to the usual intravaginal torsion, which occurs during puberty.

Intrauterine torsion may present as:

- patients with a testicular nubbin;
- patients with a small and hard testis;
- patients with a normal-sized and hard testis;
- patients with an acute scrotum.

Torsion occurring in the postnatal period within the first month of life presents with signs of an acute scrotum. The clinical signs correlate well with surgical and histological findings and thus define the need and the urgency to explore the history (56). Doppler ultrasound can be an additional diagnosis tool. The sensitivity for diagnosis of torsion of the testis is high, though the specificity is unknown for neonates. Doppler ultrasound may also be used to exclude congenital testicular neoplasm (57). Neonates with acute scrotal signs as well as bilateral cases should be treated as surgical emergencies (56,58).

In cases of postnatal torsion, one study reported 40% of testes were salvaged with emergency exploration (59). The contralateral scrotum should also be explored because of the risk of asynchronous contralateral testicular torsion in as many as 33% of cases (58).

6. HYPOSPADIAS

6.1 Background

Hypospadias can be defined as hypoplasia of the tissues forming the ventral aspect of the penis beyond the division of the corpus spongiosum. Hypospadias are usually classified based on the anatomical location of the proximally displaced urethral orifice:

- distal-anterior hypospadias (located on the glans or distal shaft of the penis and the most common type of hypospadias);
- intermediate-middle (penile);
- proximal-posterior (penoscrotal, scrotal, perineal).

The pathology may be much more severe after skin release.

*6.1.1 **Risk factors***

Risk factors associated with hypospadias are likely to be genetic, placental and/or environmental (1) (LE: 2b): There is a 7% familial recurrence risk for hypospadias (2)

- Endocrine disorders can be detected in a very few cases.
- Babies of young or old mothers and babies with a low birth weight have a higher risk of hypospadias. (2)
- A significant increase in the incidence of hypospadias over the last 20 years suggests a role for environmental factors (hormonal disruptors and pesticides) (3-6). This information has been questioned recently (7).

The use of oral contraceptives prior to pregnancy has not been associated with an increased risk of hypospadias in the offspring (8) (LE: 2a; GR: B).

6.2 Diagnosis

Patients with hypospadias should be diagnosed at birth (except for the megameatus intact prepuce variant).

Diagnosis includes a description of the local findings:

- position, shape and width of the orifice;
- presence of atretic urethra and division of corpus spongiosum;
- appearance of the preputial hood and scrotum;
- size of the penis;
- curvature of the penis on erection.

The diagnostic evaluation also includes an assessment of associated anomalies, which are:

- cryptorchidism (in up to 10% of cases of hypospadias);
- open processus vaginalis or inguinal hernia (in 9-15%).

Severe hypospadias with unilaterally or bilaterally impalpable testis, or with ambiguous genitalia, require a complete genetic and endocrine work-up immediately after birth to exclude intersexuality, especially congenital adrenal hyperplasia.

Urine trickling and ballooning of the urethra requires exclusion of meatal stenosis.

The incidence of anomalies of the upper urinary tract does not differ from the general population, except in very severe forms of hypospadias (3,4).

6.3 Treatment

Differentiation between functionally necessary and aesthetically feasible operative procedures is important for therapeutic decision-making.

The functional indications for surgery are:

- proximally located meatus;
- ventrally deflected urinary stream;
- meatal stenosis;
- curved penis.

The cosmetic indications, which are strongly linked to the psychology of the parent or future patient's psychology, are:

- abnormally located meatus;
- cleft glans;
- rotated penis with abnormal cutaneous raphe;
- preputial hood;
- penoscrotal transposition;
- split scrotum.

As all surgical procedures carry the risk of complications, thorough pre-operative counselling of the parents is crucial.

The therapeutic objectives are to correct the penile curvature, to form a neo-urethra of an adequate size, to bring the neomeatus to the tip of the glans, if possible, and to achieve an overall acceptable cosmetic appearance of the boy's genitalia (3,4) (LE: 4; GR: C) (Figure 1).

The use of magnifying spectacles and special fine synthetic absorbable suture materials (6/0-7/0) is required. As in any penile surgery, an exceptional prudence should be adopted with the use of cautery. Knowledge of a variety of surgical reconstructive techniques, wound care and post-operative treatment are essential for a satisfactory outcome. Pre-operative hormonal treatment with local or parenteral application of testosterone, dihydrotestosterone or beta-chorionic gonadotropin can be helpful in patients with a small penis or for repeat surgery. In order to prevent healing complications, it has been recommended to postpone the surgery 3 months after completion of hormonal therapy (9) (LE: 2b; GR: B).

*6.3.1 **Age at surgery***

The age at surgery for primary hypospadias repair is usually 6-18 [24] months (3) (LE: 4; GR: C). However, earlier repair between 4 and 6 months of age has been reported recently (10) (LE: 3; GR; B).

*6.3.2 **Penile curvature***

If present, penile curvature is often released by degloving the penis (skin chordee) and by excision of the connective tissue of the genuine chordee on the ventral aspect of the penis in up to 70% (11). The urethral

plate has well vascularised connective tissue and does not cause curvature in most cases. The residual curvature is caused by corporeal disproportion and requires straightening of the penis, mostly using dorsal midline plication or orthoplasty or ventral corporotomies with or without grafting (12,13) (LE: 2b; GR: B).

6.3.3 ***Preservation of the well-vascularised urethral plate***

The mainstay of hypospadias repair is preservation of the well-vascularised urethral plate and its use for urethral reconstruction has become the mainstay of hypospadias repair (14). Mobilisation of the corpus spongiosum/urethral plate and the bulbar urethra decreases the need for urethral plate transection (11,13,15) (LE: 2b; GR: B).

If the urethral plate is wide, it can be tubularised following the Thiersch-Duplay technique. If the plate is too narrow to be simply tubularised, it is recommended that a midline-relaxing incision of the plate, followed by reconstruction according to the Snodgrass-Orkiszewski technique, is performed in distal hypospadias, as well as in proximal hypospadias (though the complication rate is higher) (16-21).

The onlay technique is preferred in proximal hypospadias and in cases of a plate that is unhealthy or too narrow (11). For distal forms of hypospadias, a range of other techniques is available (e.g. Mathieu, urethral advancement, etc.) (22) (LE: 2b; GR: B).

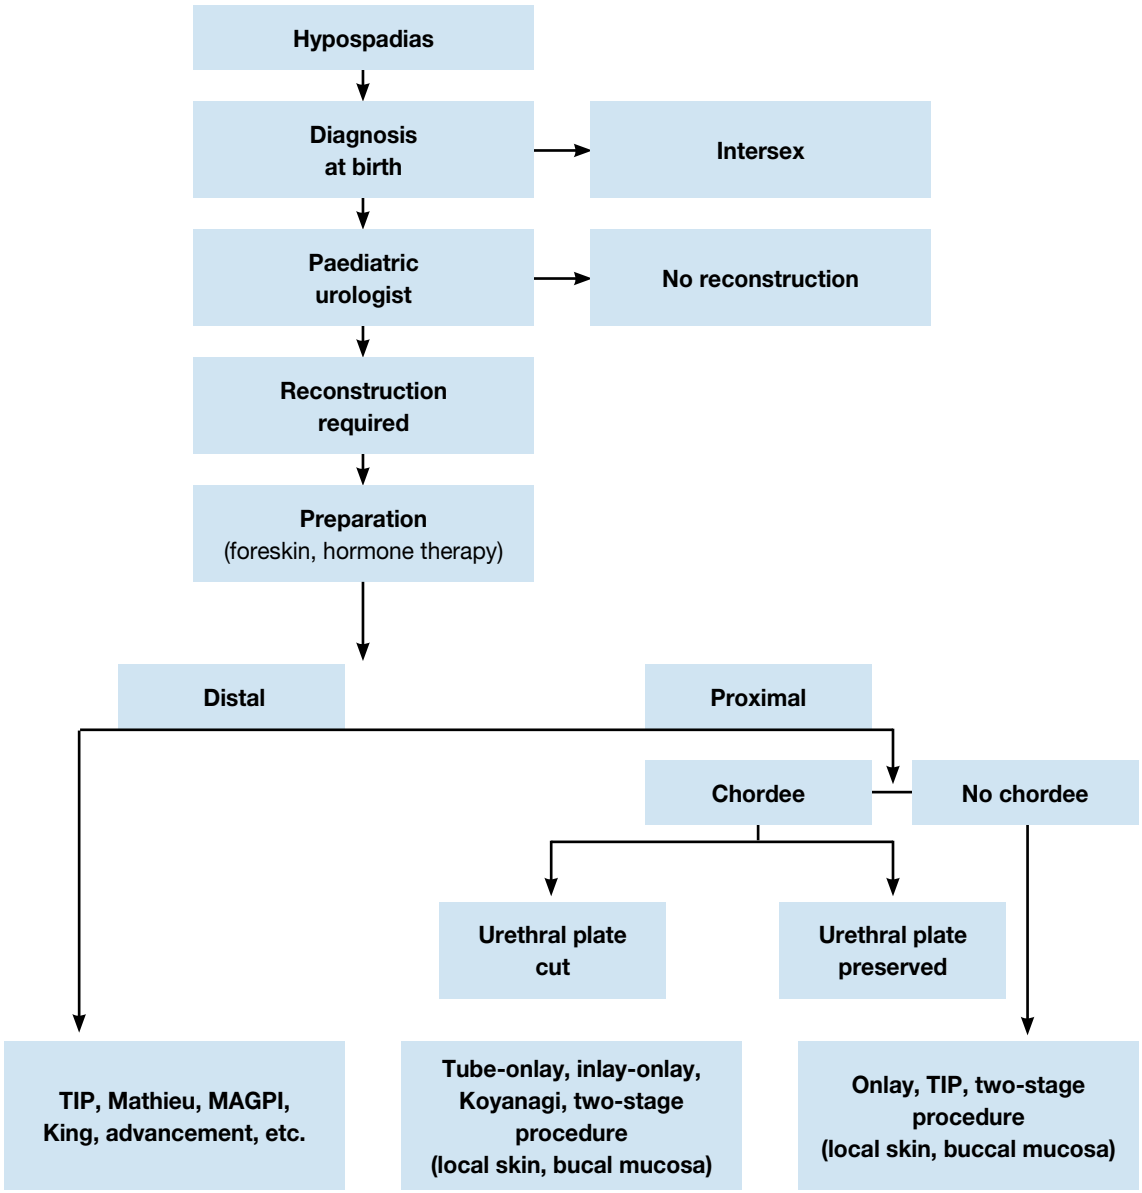
If the continuity of the urethral plate cannot be preserved, a modification of the tubularised flap, such as a tube-onlay or an inlay-onlay flap, is used to prevent urethral stricture (23,24) (LE: 3; GR: C). In this situation, as well as in severe scrotal or penoscrotal hypospadias, the Koyanagi technique or two-stage procedure may be an option (25-27).

If preputial or penile skin is not available, or has signs of balanitis xerotica obliterans, a buccal mucosa graft is used in an onlay or two-stage repair (28-30) (LE: 3; GR; C). The use of inlay skin grafts may allow an increased number of single-stage repairs to be performed (31).

6.3.4 ***Re-do hypospadias repairs***

For re-do hypospadias repairs, no definitive guidelines can be given. All the above-mentioned procedures are used in different ways and are often modified according to the individual needs of the patient.

Figure 1: Algorithm for the management of hypospadias



TIP = tubularised incised plate urethroplasty; MAGPI = meatal advancement and granulaplasty.

6.3.5 Urethral reconstruction

Following formation of the neo-urethra, the procedure is completed by glansplasty and by reconstruction of the penile skin. If there is a shortage of skin covering, the preputial double-face technique or placement of the suture line into the scrotum may be used. In countries where circumcision is not routinely performed, preputial reconstruction can be considered. However, in the TIP repair, the parents should be advised that use of a preputial dartos flap reduces the fistula rate (17, 21) (LE: 2; GR: B).

6.3.6 Urine drainage and wound dressing

Urine is drained with a transurethral dripping stent, or with a suprapubic tube. Some surgeons use no drainage after distal hypospadias repair. Circular dressing with slight compression, as well as prophylactic antibiotics during surgery, are established procedures (LE: 4; GR: C) (32). Postoperative prophylaxis is associated with a lower complication rate (LE: 1b; GR: A) (33).

A large variety of duration of stenting and dressing is described. No recommendation can be given due to the low level of evidence.

6.3.7 Outcome

Long-term follow-up, into adolescence, is necessary to detect urethral strictures, voiding dysfunction and recurrent penile curvature.

The complication rate of TIP and onlay repairs is similar, 24% and 27%, respectively. It is higher in free graft and in preputial island tube urethroplasty (11).

Overall, between 7% and 67% of patients operated on for hypospadias end up with an obstructive flow, (24.6% in TIP). These children should be followed until adulthood to clarify the clinical significance. Spontaneous improvement has been described (34,35) (LE: 2a).

Adolescents and adults, who have undergone hypospadias repair in childhood, have a slightly higher rate of dissatisfaction with penile size, especially proximal hypospadias patients, but their sexual behaviour is not different from that in control subjects (36,37) (LE: 2a-2b). The later corrective surgery is completed, the more likely the patients may become insecure with regard to gender-role behaviour. (38-39) (LE: 2b).

7. CONGENITAL PENILE CURVATURE

7.1 Background

Penile curvature may be ventral, dorsal or lateral. Most of ventral curvatures are associated with hypospadias due to chordee or ventral dysplasia of cavernous bodies (1). Similarly, the dorsal curvature is mostly associated with epispadias (2). Isolated penile curvature is not frequent with an incidence of 0.6 % (3) (LE: 2). The curvature is caused by asymmetry of the cavernous bodies (1,4).

Curvature over 30 degrees is considered clinically significant; curvature over 60 degrees may interfere with satisfactory sexual intercourse in adulthood (5) (LE: 4).

7.2 Diagnosis

Diagnosis is made during hypospadias or epispadias repair using an artificial erection (6). The isolated anomaly is usually not recognised until later in childhood because the appearance of the penis is normal. The curvature is only observed during erections.

7.3 Treatment

The treatment is surgical. An artificial erection is used to determine the degree of curvature and to check the symmetry after the repair (6).

In hypospadias, chordee related to the tethering of the ventral skin and to the spongiosal pillars is first released. Only in a few cases the penile curvature is caused by a short urethral plate, which should be cut. To repair the corporeal angulation in the isolated curvature or curvature associated with hypospadias, different techniques of plication of corpora cavernosa (orthoplasty) are used (5).

In epispadias, a combination of complete release of the urethral body from the corpora and a different kind of corporoplasty with or without corporotomy is usually necessary to achieve a straight penis (7,8).

8. VARICOCELE IN CHILDREN AND ADOLESCENTS

8.1 Background

Varicocele is defined as an abnormal dilatation of testicular veins in the pampiniformis plexus caused by venous reflux. It is unusual in boys under 10 years of age and becomes more frequent at the beginning of puberty. It is found in 15-20% of adolescents, with a similar incidence during adulthood. It appears mostly on the left side (78-93% of cases). Right-sided varicoceles are least common; they are usually noted only when bilateral varicoceles are present and seldom occur as an isolated finding (1,2).

Varicocele develops during accelerated body growth by a mechanism that is not clearly understood. Varicocele can induce apoptotic pathways because of heat stress, androgen deprivation and accumulation of toxic materials. Severe damage is found in 20% of adolescents affected, with abnormal findings in 46% of affected adolescents. Histological findings are similar in children or adolescents and in infertile men. In 70% of patients with grade II and III varicocele, left testicular volume loss was found. However, studies correlating a hypoplastic testicle with poor sperm quality have reported controversial results (3,4).

Several authors reported on reversal of testicular growth after varicocelectomy in adolescents (LE: 2) (5,6). However, this may partly be attributable to testicular oedema associated with the division of lymphatic vessels (LE: 2) (7).

In about 20% of adolescents with varicocele, fertility problems will arise (8). The adverse influence of varicocele increases with time. Improvement in sperm parameters has been demonstrated after adolescent varicocelectomy (3,9) (LE: 1).

8.2 Diagnosis

Varicocele is mostly asymptomatic, rarely causing pain at this age. It may be noticed by the patient or parents, or discovered by the paediatrician at a routine visit. The diagnosis depends upon the clinical finding of a collection of dilated and tortuous veins in the upright posture; the veins are more pronounced when the patient performs the Valsalva manoeuvre.

Varicocele is classified into 3 grades: Grade I - Valsalva positive (palpable at Valsalva manoeuvre only); Grade II - palpable (palpable without the Valsalva manoeuvre); Grade III - visible (visible at distance) (10). The size of both testicles should be evaluated during palpation to detect a smaller testis.

Venous reflux into the plexus pampiniformis is diagnosed using Doppler colour flow mapping in the supine and upright position (11). Venous reflux detected on ultrasound only is classified as subclinical varicocele. The ultrasound examination includes assessment of the testicular volume to discriminate testicular hypoplasia. In adolescents, a testis that is smaller by more than 2 mL compared to the other testis is considered to be hypoplastic (1) (LE: 4).

In order to assess testicular injury in adolescents with varicocele, supranormal follicle-stimulating hormone (FSH) and luteinizing hormone (LH) responses to the luteinizing hormone-releasing hormone (LHRH) stimulation test are considered reliable, as histopathological testicular changes have been found in these patients (9,12).

8.3 Therapy

Surgical intervention is based on ligation or occlusion of the internal spermatic veins. Ligation is performed at different levels:

- inguinal (or subinguinal) microsurgical ligation;
- suprainguinal ligation, using open or laparoscopic techniques (13-16).

The advantage of the former is the lower invasiveness of the procedure, while the advantage of the latter is a considerably lower number of veins to be ligated and safety of the incidental division of the internal spermatic artery at the suprainguinal level.

For surgical ligation, some form of optical magnification (microscopic or laparoscopic magnification) should be used because the internal spermatic artery is 0.5 mm in diameter at the level of the internal ring (13-15,17). The recurrence rate is usually less than 10%. Angiographic occlusion is based on retrograde or antegrade sclerotisation of the internal spermatic veins (18,19).

Lymphatic-sparing varicocelectomy is preferred to prevent hydrocele formation and testicular hypertrophy development and to achieve a better testicular function according to the LHRH stimulation test (LE: 2; GR: A) (7,13,16,17,20). The methods of choice are subinguinal or inguinal microsurgical (microscopic) repairs, or suprainguinal open or laparoscopic lymphatic-sparing repairs.

Angiographic occlusion of the internal spermatic veins also meets these requirements. However, although this method is less invasive, it appears to have a higher failure rate (1,19) (LE: 2; GR: B).

There is no evidence that treatment of varicocele at paediatric age will offer a better andrological outcome than an operation performed later. The recommended indication criteria for varicocelectomy in children and adolescents are (1,21):

- varicocele associated with a small testis;
- additional testicular condition affecting fertility;
- bilateral palpable varicocele;
- pathological sperm quality (in older adolescents);
- varicocele associated with a supranormal response to LHRH stimulation test;
- symptomatic varicocele.

Repair of a large varicocele physically or psychologically causing discomfort may be also considered. Other varicoceles should be followed-up until a reliable sperm analysis can be performed (LE: 4; GR: C).

9. MICROPENIS

9.1 Background

Micropenis is a small but otherwise normally formed penis with a stretched length of less than 2.5 SD below the mean (1-3).
Besides an idiopathic micropenis, two major causes of abnormal hormonal stimulation have been identified:

- Hypogonadotropic hypogonadism (due to an inadequate secretion of GnRH)
- Hypergonadotropic hypogonadism (due to failure of the testes to produce testosterone).

9.2 Diagnosis

The penis is measured on the dorsal aspect, while stretching the penis, from the pubic symphysis to the tip of the glans (1). The corpora cavernosa are palpated, the scrotum is often small, and the testes may be small and descended. Micropenis should be distinguished from buried and webbed penis, which is usually of normal size.

The initial evaluation has to define whether the aetiology of the micropenis is central (hypothalamic/ pituitary) or testicular. A paediatric endocrinology work-up has to be carried out immediately. Karyotyping is mandatory in all patients with a micropenis.

Endocrine testicular function is assessed (baseline and stimulated testosterone, LH and FSH serum levels). Stimulated hormone levels may also give an idea of the growth potential of the penis. In patients with non-palpable testes and hypogonadotropic hypogonadism, laparoscopy should be carried out to confirm vanishing testes syndrome or intra-abdominal undescended hypoplastic testes. This investigation can be delayed until the age of 1 year (2).

9.3 Treatment

Pituitary or testicular insufficiency are treated by the paediatric endocrinologist. In patients with testicular failure and proven androgen sensitivity, androgen therapy is recommended during childhood and at puberty to stimulate the growth of the penis (4-7) (LE: 2; GR: B). In the presence of androgen insensitivity, good outcome of sexual function is questioned and gender conversion can be considered (8-10).

10. URINARY TRACT INFECTIONS IN CHILDREN

10.1 Introduction

Urinary tract infection (UTI) represents the most common bacterial infection in children < 2 years of age. In neonates, the symptoms differ in many aspects from those in UTIs in infants and children. The prevalence is higher; there is a male predominance; infections not caused by *Escherichia coli* are more frequent; and there is a higher risk of urosepsis (1-4).

The incidence of UTIs varies depending on age and sex. One meta-analysis showed that, in the first 3 months of life, UTIs were present in 7.5% of girls, 2.4% (CI: 1.4-3.5) of circumcised boys, and 20.1% (CI: 16.8-23.4) of uncircumcised boys, who presented with fever (2). In the first year of life, UTIs are more common in boys (3.7%) than in girls (2%). Later, the incidence changes and ~3% of pre-pubertal girls and 1% of pre-pubertal boys are diagnosed with UTIs (2-7).

E. coli is found in ~75% of UTIs and is more frequent in community-acquired than nosocomial. In the latter, *Klebsiella pneumoniae, Enterobacter* spp., *Enterococcus* spp., *Pseudomonas* spp. and *Candida* spp. are more frequent than in community-acquired UTIs. Neonatal UTI is frequently complicated by bacteremia. In a retrospective study, 12.4% of blood cultures from neonates admitted for UTI were positive for bacteremia in around 12% (8), however, it is less frequent in community-acquired than in nosocomial UTI (8,9).

10.2 Classification

There are five widely used classification systems according to the site, episode, severity, symptoms and complicating factors. For acute treatment, site and severity are most important.

*10.2.1 **Classification according to site***

Lower urinary tract (cystitis) is an inflammatory condition of the urinary bladder with general signs and symptoms including dysuria, frequency, urgency, malodorous urine, enuresis, haematuria, and suprapubic pain.

Upper urinary tract (pyelonephritis) is a diffuse pyogenic infection of the renal pelvis and parenchyma. The onset of pyelonephritis is generally abrupt. Clinical signs and symptoms include fever (≥ 38 °C), chills, costovertebral angle or flank pain, and tenderness. Older children may report cystitis symptoms along with fever/flank pain. Infants and children may have non-specific signs such as poor appetite, failure to thrive, lethargy, irritability, vomiting or diarrhoea.

10.2.2 ***Classification according to episode (10)***

First infection: the first UTI may be a sign of anatomical anomalies that may predispose to complications of UTI and potential renal damage (11). Anatomical evaluation is recommended (see below).
Recurrent infection can be divided into unresolved and persistent infection.

In unresolved infection, initial therapy is inadequate for elimination of bacterial growth in the urinary tract [inadequate therapy, inadequate antimicrobial urinary concentration (poor renal concentration/gastrointestinal malabsorption), and infection involving multiple organisms with differing antimicrobial susceptibilities].

Persistent infection is caused by re-emergence of bacteria from a site within the urinary tract coming from a nidus for persistent infection that cannot be eradicated (e.g. infected stones, non-functioning or poorly functioning kidneys/renal segments, ureteral stumps after nephrectomy, necrotic papillae in papillary necrosis, urachal cyst, urethral diverticulum, periurethral gland, vesicointestinal, rectourethral or vesicovaginal fistulas). The same pathogen is identified in recurrent infections, but episodes of sterile urine may occur during and shortly following antimicrobial treatment.

Reinfection: each episode can be caused by a variety of new infecting organisms, in contrast to bacterial persistence in which the same infecting organism is always isolated. However, the most common general pathogenic species is *E. coli*, which occurs in many different serotypes. Therefore, recurrent *E. coli* UTI does not equate to infection with the same organism.

10.2.3 ***Classification according to severity***

In simple UTI, children may have only mild pyrexia; are able to take fluids and oral medication; are only slightly or not dehydrated; and have a good expected level of compliance. When a low level of compliance is expected, such children should be managed as those with severe UTI.

In severe UTI, infection is related to the presence of fever of > 39°C, the feeling of being ill, persistent vomiting, and moderate or severe dehydration.

10.2.4 ***Classification according to symptoms***

Asymptomatic bacteriuria indicates attenuation of uropathogenic bacteria by the host, or colonisation of the bladder by non-virulent bacteria that are incapable of activating a symptomatic response.

In symptomatic bacteriuria, symptoms associated with UTI include irritative voiding symptoms, suprapubic pain (cystitis), fever and malaise (pyelonephritis). Cystitis may represent early recognition of an infection destined to become pyelonephritis, or bacterial growth controlled by a balance of virulence and host response.

10.2.5 ***Classification according to complicating factors (12)***

In uncomplicated UTI, infection occurs in a patient with a morphologically and functionally normal urinary tract. This category includes mostly isolated or recurrent bacterial cystitis and is usually associated with a narrow spectrum of infecting pathogens that are easily eradicated by a short course of oral antimicrobial agents. Patients can be managed on an outpatient basis, with an emphasis on documenting resolution of their bacteriuria, followed by elective evaluation for potential anatomical or functional abnormalities of the urinary tract.

In complicated UTI, all neonates, most patients with clinical evidence of pyelonephritis, and all children with known mechanical or functional obstructions of the urinary tract are considered to have complicated UTI. Mechanical obstruction is commonly due to the presence of posterior urethral valves, strictures or stones, independent from their location. Functional obstruction often results from lower urinary tract dysfunction of either neurogenic or non-neurogenic origin and dilating vesicoureteral reflux. Patients with complicated UTI require hospitalisation and parenteral antibiotics. Prompt anatomical evaluation of the urinary tract is critical to exclude the presence of significant abnormalities (13). If mechanical or functional abnormalities are present, adequate drainage of the infected urinary tract is necessary.

10.3 Diagnosis

10.3.1 ***Medical history***

Medical history includes the question of a primary (first) or secondary (recurring) infection; possible malformations of the urinary tract (e.g. pre- or postnatal ultrasound screening); family history; and whether there is constipation or presence of lower urinary tract symptoms.

10.3.2 ***Clinical signs and symptoms***

Neonates with pyelonephritis or urosepsis can present with non-specific symptoms (failure to thrive, jaundice, hyperexcitability and without any fever). UTI is the cause of fever in 4.1-7.5% of children who present to a paediatric clinic (14,15). Septic shock is unusual, even with very high fever. Signs of a UTI may be vague and unspecific in small children, but later on, when they are > 2 years old, frequent voiding, dysuria and suprapubic, abdominal or lumbar pain can be detected.

10.3.3 ***Physical examination***

Physical examination includes a general examination of the throat, lymph nodes, abdomen (constipation, palpable and painful kidney, or palpable bladder), flank, the back (stigmata of spina bifida or sacral agenesis), genitalia (phimosis, labial adhesion, vulvitis, epididymo-orchitis), and temperature.

10.4 Urine sampling, analysis and culture

Urine sampling should be performed before any antimicrobial agent is administered. The technique for obtaining urine for urinalysis as well as culture affects the rate of contamination, which influences interpretation of the results. Especially in early infancy it can be challenging and depends on the mode of urine sampling (16,17).

10.4.1 ***Urine sampling***

Urine must be collected under defined conditions and investigated as soon as possible to confirm or exclude UTI, especially in children with fever.

In neonates, infants and non-toilet-trained children, there are four main methods with varying contamination rates and invasiveness to obtain urine in this age group:

(1) Plastic bag attached to the cleaned genitalia.
This technique is most often used in daily practice. It is helpful when the culture result is negative. Also, if the dipstick is negative for both leukocyte esterase and nitrite, or microscopic analysis is negative for both pyuria and bacteriuria, UTI can be excluded without the need for confirmatory culture (18). However, if the genitalia are not cleaned and culture is delayed, a high incidence of false-positive results (85-99%) can be found (19,20).

(2) Clean-catch urine collection.
The infant is placed in the lap of a parent or member of the nursing staff, who holds a sterile foil bowl underneath the infant's genitalia. The infant is offered oral fluids and urine collection is awaited (21). This is time consuming and requires proper instruction of the parents. However, there seems to be a good correlation between the results of urine culture obtained by this method and suprapubic aspiration (SPA), with a false-positive rate of 5% and false-negative rate of 12% (21,22).

(3) Bladder catheterisation.
Especially in boys, transurethral catheterisation is traumatic and bears the risk of nosocomial infection, but in experienced hands, this technique may be an alternative to SPA (23). In a prospective study using bladder catheterisation in febrile children aged ≤ 36 months, contamination was defined by multiple pathogens, non-pathogens, or colony counts < 10,000 cfu/mL. Ten percent of the children had true UTI and 14% of the cultures were contaminated. Univariate analysis of potential predictors identified age < 6 months, difficult catheterisation, and uncircumcised boys (24).

(4) Suprapubic bladder aspiration.
This is the most sensitive method to obtain an uncontaminated urine sample in this age group (24-26). Using ultrasound to assess bladder filling simplifies SPA and improves the diagnostic yield of obtaining a urine specimen from 60% to ~97% (25,26). Complications are rare and have been reported in only 0.22% of cases, ranging from transient haematuria to bowel perforation (27). However, bladder puncture causes more pain than catheterisation in infants < 2 months old (28).

In older, toilet-trained children, who can void on command, after carefully retracting the foreskin and cleaning the glans penis in boys and spreading the labia and cleaning the periurethral area in girls, the use of clean catch, especially midstream urine, could be an acceptable technique for obtaining urine. After cleaning the urethral meatus and perineum with gauze and liquid soap twice, the risk of contamination was reduced from 23.9% (41/171) to 7.8% (14/171) in a randomised trail (29).

If the clinical situation necessitates, and for differential diagnosis of sepsis, it is most appropriate to obtain

an adequate urine sample by catheterisation or SPA (22). In infants, a bag can only be used if the dipstick is negative, otherwise the urine should be obtained through catheterisation or SPA. This is also recommended in children, who are severely ill and a UTI needs to be excluded or confirmed. Blood sampling is dependent on the clinical situation.

*10.4.2 **Urinalysis***

There are three methods that are commonly used for urinalysis:

(1) Dipsticks:
These are appealing because they provide rapid results, do not require microscopy, and are ready to use. Leukocyte esterase (as a surrogate marker for pyuria) and nitrite (which is converted from dietary nitrates by most Gram-negative enteric bacteria in the urine) are the most frequent markers, and are usually combined in a dipstick test. The conversion of dietary nitrates to nitrites by bacteria requires approximately 4 h in the bladder (22,30). However, nitrite is not a very sensitive marker for infants, who empty their bladder frequently, and not all urinary pathogens reduce nitrate to nitrite. The test is helpful when the result is positive, because it is highly specific (i.e. there are few false-positive results) (1,22).

Table 3: Sensitivity and specificity of component of urinalysis, alone and in combination (22)*

Test	Sensitivity (Range), %	Specificity (Range), %
Leukocyte esterase test	83 (67-94)	78 (64-92)
Nitrite test	53 (15-82)	98 (90-100)
Leukocyte esterase or nitrite test positive	93 (90-100)	72 (58-91)
Microscopy, WBCs	73 (32-100)	81 (45-98)
Microscopy, bacteria	81 (16-99)	83 (11-100)
Leucocyte esterase test, nitrite test or microscopy positive	99.8 (99-100)	70 (60-92)

**Reproduced with permission from Pediatrics 2011 Sep;128(3):595-610, Copyright © 2011 by the AAP (22).*

(2) Microscopy.
This is the standard method of assessing pyuria after centrifugation of the urine with a threshold of 5 white blood cells (WBCs) per high-power field (25 WBC/μL) (27). In uncentrifuged urine, ≥ 10 WBC/μL has been demonstrated to be sensitive for UTI (31) and this could perform well in clinical situations (32). However, this is rarely done in an outpatient setting.

(3) Flow imaging analysis technology.
This is being used increasingly to classify particles in uncentrifuged urine specimens (33). The numbers of WBCs, squamous epithelial cells and red cells correlate well with those found by manual methods (22).

*10.4.3 **Urine culture***

After negative results for dipstick, microscopic or automated urinalysis, urine culture is generally not necessary, especially if there is an alternative source of fever. If the dipstick result is positive, confirmation by urine culture is recommended.

It is unclear what represents a significant UTI. In severe UTI, > 10^5 cfu/mL can be expected. However, the count can vary and be related to the method of specimen collection, diuresis, and time and temperature of storage until cultivation occurs (34). The classical definition of > 10^5 cfu/mL of voided urine is still used to define a significant UTI (35,36). The recent American Academy of Pediatric Guidelines on Urinary tract İnfection suggest that the diagnosis should be on the basis of the presence of both pyuria and at least 50 000 cfu. However, some studies have shown that, in voided specimens, ≤ 10^4 organisms may indicate a significant UTI (37,38). If urine is obtained by catheterisation, 1,000-50,000 cfu/mL is considered to be positive, and any counts obtained after SPA should be considered as significant. Mixed cultures are indicative of contamination.

Table 4: Criteria for UTI in children (adapted from the EAU Guideline on Urological Infections [39])

Urine specimen from suprapubic bladder puncture	Urine specimen from bladder catheterisation	Urine specimen from midstream void
Any number of cfu/mL (at least 10 identical colonies)	≥ 1,000-50,000 cfu/mL	≥ 10^4 cfu/mL with symptoms ≥ 10^5 cfu/mL without symptoms

Pyuria without bacteriuria (sterile pyuria) may be due to incomplete antibiotic treatment, urolithiasis, or foreign bodies in the urinary tract, and infections caused by Mycobacterium tuberculosis or Chlamydia trachomatis.

10.5 Therapy

10.5.1 ***Administration route***

The choice between oral and parenteral therapy should be based on patient age; clinical suspicion of urosepsis; illness severity; refusal of fluids, food and/or oral medication; vomiting; diarrhoea; non-compliance; and complicated pyelonephritis (e.g. urinary obstruction). As a result of the increased incidence of urosepsis and severe pyelonephritis in newborns and infants aged < 2 months, parenteral antibiotic therapy is recommended. Electrolyte disorders with hyponatremia and hyperkalemia can occur in these cases (13). Combination treatment with ampicillin and an aminoglycoside (e.g. tobramycin or gentamicin) or respectively a third-generation cephalosporin achieves excellent therapeutic results (high efficacy of aminoglycosides, respectively cephalosporines against common uropathogens; enterococcus gap is closed with Ampillicin). Compared to the division in two doses, a daily single dose of aminoglycosides is safe and effective (13,40,41).

The choice of agent is also based on local antimicrobial sensitivity patterns, and should later be adjusted according to sensitivity testing of the isolated uropathogen (22). Especially in infancy, not all available antibiotics are approved by the national health authorities. In uncomplicated nephritis, both oral and parenteral treatment can be considered, because both are equally effective in children without urinary tract abnormalities. Some studies have demonstrated that once daily parenteral administration of gentamicin or ceftriaxone in a day treatment centre is safe, effective and cost-effective in children with UTI (41-43).

10.5.2 ***Duration of therapy***

Adequate treatment of UTI can prevent the spread of infection and renal scarring. Outcomes of short courses (1-3 days) are inferior to those of 7-4-day courses (22). In newborns and young infants with a febrile UTI, up to 20% may have a positive blood culture (8,13). In late infancy, there are no differences between strategies regarding the incidence of parenchymal scars, as diagnosed with DMSA (dimercaptosuccinic acid) scan (44). Some recent studies using exclusively oral therapy with a third-generation cephalosporin (e.g. cefixime or ceftibuten) have demonstrated that this is equivalent to the usual 2-4 days intravenous therapy followed by oral treatment (40,45-47). Similar data have been shown for amoxicillin-clavulanate (48), however, these antibiotics are associated with increasing rates of resistance. If ambulatory therapy is chosen, adequate surveillance, medical supervision and, if necessary, adjustment of therapy must be guaranteed. In the initial phase of therapy, a close ambulant contact to the family is advised (49).

In complicated UTI, uropathogens other than *E. coli*, such as Proteus mirabilis, Klebsiella spp., Pseudomonas aeruginosa, enterococci and staphylococci, are more often to be anticipated (13). Parenteral treatment with broad-spectrum antibiotics is preferred. A temporary urinary diversion (suprapubic cystostomy or percutaneous nephrostomy) might be required in case of failure of conservative treatment in obstructive uropathy.

Acute focal bacterial nephritis (lobar nephronia) is a localised bacterial infection of the kidney that presents as an inflammatory mass without abscess formation. This may represent a relatively early stage of renal abscess. For the majority of children, the pathogenesis is related to ascending infection due to pre-existing uropathy, especially vesicorenal reflux or urinary obstruction (megaureter). Prolonged intravenous antibiotic treatment is sufficient in most cases (50), and intravenous and oral therapy tailored to the pathogen identified in culture is recommended (51).

*10.5.3 **Antimicrobial agents***

Table 5: Frequently used antibacterial substances for the therapy of urinary tract infections in infants and children*

Chemotherapeutics	Daily dosage	Application	Comments
Parenteral cephalosporins			
Group 3a, e.g. cefotaxime	100-200 mg/kg *(Adolesc.: 3-6 g)*	i.v. in 2-3 D	
Group 3b, e.g. ceftazidime	100-150 mg/kg *(Adolesc.: 2-6 g)*	i.v. in 2-3 D	
Ceftriaxone	75 mg/kg,	i.v. in 1 D	
Oral cephalosporins			
Group 3, e.g. ceftibuten	9 mg/kg *(Adolesc.: 0,4 g)*	p.o. in 1-2 D p.o. in 1-2 D	
Group 3, e.g. cefixime	8-12 mg/kg *(Adolesc.: 0,4 g)*	p.o. in 1-2 D	
Group 2, e.g. cefpodoxime proxetil	8-10 mg/kg *(Adolesc.: 0,4 g)*	p.o. in 2D	
Group 2, e.g. cefuroximaxetil	20-30 mg/kg (Adolesc.: 0,5-1 g)	p.o. in 3 D	
Group 1, e.g. cefaclor	50 -100 mg/kg *(Adolesc.: 1,5-4 g)*	p.o. in 2-3 D	
Trimethoprim or Trimethoprim/sulfamethoxazole	5-6 mg/kg 5-6 mg/kg (TMP-Anteil) *(Adolesc.: 320 mg)*	p.o. in 2 D p.o. in 2 D	
Ampicillin	100-200 mg/kgKG *(Adolesc.: 3-6 g)*	i.v. in 3 D i.v. in 3-4 D	Ampicillin and Amoxicillin are not eligible for calculated therapy
Amoxicillin	50-100 mg/kg *(Adolesc.: 1,5-6 g)*	p.o. in 2-3 D[1] p.o. in 2-3 D	
Amoxicillin/clavulanic acid (parenteral) Amoxicillin/clavulanic acid (oral)	60-100 mg/kg *(Adolesc.: 3,6-6,6 g)* 45-60 mg/kg (Amoxicillin-fraction) *(Adolesc.: 1500 + 375 mg)*	i.v. in 3 D i.v. in 3 D p.o. in 3 D p.o.in 3 D	
Piperacillin	300 mg/kg	i.v. in 3-4 D	
Tobramycin	5 mg/kg *(Adolesc.: 3-5 mg/kg, max. 0,4 g)*	i.v. in 1 D	Drug monitoring
Gentamicin	5 mg/kg *(Adolesc.: 3-5 mg/kg, max. 0,4g)*	i.v. in 1 D	
Ciprofloxacin	Children and adolesc. (1-17 years of age): 20-30 mg/kg (max. D: 400 mg) (parenterally) Children and adolesc. (1-17 years of age): 20-40 mg/kg (max. D 750 mg) (orally)	i.v. in 3 D p.o. in 2 D	Approved in most European countries as second- or third line medication for complicated UTIs, „reserve-antibiotic“ !
Nitrofurantoin	3-5 mg	p.o. in 2 D	Contraindicated in the case of renal insufficiency

Consultation on Urogenital Infections, 2009. Copyright © by the European Association of Urology (52).
Dosage for adolescents in paracentesis, if differing.
[1] Infants 2 D, children 1-12 ys. 3 D.

Table 6: Recommendations for calculated antibacterial therapy of pyelonephritis dependent on age and severity of the infection*

Diagnosis	Proposal	Application	Duration of therapy	LE
Pyelonephritis during the first 0-6 months of life	Ceftazidime + Ampicillin[1] or Aminoglycoside + Ampicillin[1]	3-7 days parenterally, for at least 2 days after defervescence, then oral therapy[2] In newborns: parenteral therapy for 7-14 days, then oral therapy[2]	10 (-14) days Newborns 14-21 days	4
Uncomplicated pyelonephritis after 6 months of age	Cephalosporin group 3[2]	Orally (initially parenterally, if necessary)	(7-)10 days	1
Complicated pyelonephritis/ urosepsis (all ages)	Ceftazidime + Ampicillin[1] or Aminoglycoside + Ampicillin[1]	7 days parenterally, then oral therapy[2]	10-14 days	4

** Reproduced with permission from the International Consultation on Urological Diseases (ICUD), International Consultation on Urogenital Infections, 2009. Copyright © by the European Association of Urology (52).*
[1] after receipt of microbiological findings (pathogen, resistance) adaptation of therapy.
[2] i.v.: e.g. cefotaxime; orally: e.g. cefpodoxime proxetil, ceftibuten, cefixime.

Table 7: Recommendations for antibacterial treatment in cystitis und cystourethritis
(Dosages for children up to 12 years of age)*

Chemotherapeutics	Daily dosage	Application
Oral cephalosporins		
Group 1, e.g. cefaclor	50 (-100) mg/kgbw	p.o. in 2-3 D
Group 1, e.g. cefalexin	50 mg/kgbw	p.o. in 3-4 D
Group 2, e.g. cefuroximaxetil	20-30 mg/kgbw	p.o. in 2 D
Group 2, e.g. cefpodoxime proxetil	8-10 mg/kgbw	p.o. in 2 D
Group 3, e.g. ceftibuten	9 mg/kgbw	p.o. in 1 D
Trimethoprim	5-6 mg/kgbw	p.o. in 2 D
Trimethoprim/sulfamethoxazole	5-6 mg/kgbw /TMP-fraction)	p.p. in 3 D
Amoxicillin/clavulanic acid	37.5-75 mg/kgbw (Amoxicillin-fraction)	p.o. in 3 D
Nitrofurantoin	3-5 mg/kgbw	p.o. in 2 D

** Reproduced with permission from the International Consultation on Urological Diseases (ICUD), International Consultation on Urogenital Infections, 2009. Copyright © by the European Association of Urology (52).*

*10.5.4 **Chemoprophylaxis***

Long-term antibacterial prophylaxis should be considered in cases of high susceptibility to UTI and risk of acquired renal damage. Some recently published prospective, randomised studies do not support the efficacy of antibacterial prophylaxis (53-56). The Australian PRIVENT study demonstrated risk reduction using

trimethoprim-sulfamethoxazole in children from birth to 18 years of age who had at least one symptomatic UTI (19% of the placebo group and 13% of the antibiotic group) (46) (see also Chapter 15).

Table 8: Drugs for antibacterial prophylaxis*

Substance**	Prophylactic dosage (mg/kgbw/d)	Limitations in young infants
Trimethoprim	1	until 6 weeks of age
Nitrofurantoin	1	Until 3 months of age
Cefaclor	10	No age limitations
Cefixim	2	Preterms and newborns
Ceftibuten	2	***
Cefuroximaxetil	5	***

** Reproduced with permission from the International Consultation on Urological Diseases (ICUD), International Consultation on Urogenital Infections, 2009. Copyright © by the European Association of Urology.*
*** Substances of first choice are nitrofurantoin and trimethoprim. In exceptional cases, oral cephalosporin can be used.*
**** In Germany, ceftibuten is not approved for infants < 3 months old.*

10.6 Monitoring of UTI

With successful treatment, urine usually becomes sterile after 24 h, and leukocyturia normally disappears within 3-4 days. Normalisation of body temperature can be expected within 24-48 h after the start of therapy in 90% of cases. In patients with prolonged fever and failing recovery, treatment-resistant uropathogens or the presence of congenitaluropathy or acute urinary obstruction should be considered. Immediate ultrasound examination is recommended in these cases.

Procalcitonin (among other laboratory inflammatory parameters such as C-reactive protein and leukocyte count) can be used as reliable serum marker for early prediction of renal parenchymal inflammation with first febrile UTI (57). In patients with febrile UTI, serum electrolytes and blood cell counts should be obtained.

10.7 Imaging

*10.7.1 **Ultrasound***

Renal and bladder ultrasonography is strongly recommended in infants with febrile UTI to exclude obstruction of the upper and lower urinary tract. Abnormal results are found in ~15% of cases, and 1-2% have abnormalities that require prompt action (e.g., additional evaluation, referral, or surgery) (22). In other studies, renal ultrasound revealed abnormalities in up to 37% of cases, whereas voiding cystourethrography (VCUG) showed vesicoureteral reflux (VUR) in 27% of cases (9). Dilating VUR is missed by ultrasound in around one third of cases (58). Post-void residual urine should be measured in toilet-trained children to exclude voiding abnormalities as a cause of UTI.

*10.7.2 **Radionuclide scanning***

Changes in DMSA clearance during acute UTI indicate pyelonephritis or parenchymal damage, correlated well with the presence of dilating reflux and the risk of further pyelonephritis episodes, break-through-infections (59) and future renal scarring. DMSA scanning may be used as a first-line diagnostic procedure based on observations that dilating VUR occurs in almost all children with abnormal DMSA scan (58,60). These findings are different in neonates. After the first symptomatic, community-acquired UTI, the majority of renal units with VUR grade III or higher had normal early DMSA scanning (61).

*10.7.3 **Voiding cystourethrography***

VCUG is still the gold standard to exclude or confirm VUR. Due to the risk of renal scarring, VCUG is recommended after the first episode of febrile UTI in boys and girls. The timing of VCUG does not influence the presence or severity of VUR (62,63). Performance of early VCUG in patients with proven sterile urine does not cause any significant morbidity (64). Another option is doing DMSA first, followed by VCUG if there is renal cortical uptake deficiency after urinary tract infection (see Chapter 15).

10.8 Bladder and bowel dysfunction

Bladder and bowel dysfunction are risk factors for which each child with UTI should be screened upon

presentation. Normalisation of micturition disorders or bladder overactivity is important to lower the rate of UTI recurrence. If there are signs of bladder and/or bowel dysfunction at infection-free intervals, further diagnosis and effective treatment are strongly recommended (65-68). Treatment of constipation leads to a decrease in UTI recurrence (69-71). Therefore, exclusion of bladder and bowel dysfunction is strongly recommended in any child with febrile and/or recurrent UTI, and it should be treated if there is evidence of a dysfunctional elimination syndrome.

11. DAYTIME LOWER URINARY TRACT CONDITIONS

11.1 Background

Following the new terminology document by the International Children's Continence Society (ICCS), 'daytime lower urinary tract (LUT) conditions' is the new term used to group together functional incontinence problems in children (1). After any possible underlying uropathy or neuropathy has been excluded, a problem of incontinence in children is grouped into the category of 'daytime LUT conditions'. Night-time wetting is known as 'enuresis'.

Although exact data are unavailable, it is clear that the incidence of daytime LUT conditions is increasing. The changes in toilet training and toilet habits associated with a modern lifestyle have been blamed for the increase in incidence, but with little evidence. Rather, it is that modern life and higher hygiene standards have probably resulted in incontinence problems receiving more attention, so that an increase in prevalence could probably be attributed to an increased awareness. There exists a wide variation in reported prevalence ranging from 2% to 20% (2-6). This wide variation might reflect the variation in definitions used.

11.2 Definition

Daytime LUT conditions are conditions that present with lower urinary tract symptoms (LUTS), including urge, incontinence, weak stream, hesitancy, frequency and urinary tract infections, but without overt uropathy or neuropathy.

Normal bladder storage and voiding involves low pressure and adequate bladder volume filling. This is followed by a continuous detrusor contraction, which results in complete bladder emptying, associated with an adequate relaxation of the sphincter complex. Normal urine storage by the bladder and evacuation are controlled by a complex interaction between the spinal cord, brain stem, midbrain and higher cortical structures, associated with a complex integration of sympathetic, parasympathetic and somatic innervations (7).

It is understandable that this complex control mechanism is likely to be susceptible to developing different types of dysfunction. Various functional disorders of the detrusor-sphincter complex may occur during the sophisticated early development of normal mechanisms of micturition control. Voiding dysfunction is therefore thought to be the expression of incomplete or delayed maturation of the bladder sphincter complex.

Normal daytime control of bladder function matures between 2 and 3 years of age, while nighttime control is normally achieved between 3 and 7 years of age (8). There are two main groups of voiding dysfunction, namely, filling-phase dysfunctions and voiding-phase dysfunctions.

*11.2.1 **Filling-phase dysfunctions***

In filling-phase dysfunctions, the detrusor can be overactive, as in **overactive bladder (OAB) and urge syndrome**, or underactive, as in **underactive or highly compliant bladder** (formerly known as 'lazy bladder'). Some children habitually postpone micturition leading to **voiding postponement**.

*11.2.2 **Voiding-phase (emptying) dysfunctions***

In voiding-phase (emptying) dysfunctions, interference with the sphincter and pelvic floor during detrusor contraction is the main dysfunction. The general term for this condition is dysfunctional voiding. Different degrees of dysfunction are described, depending on the strength of interference with the sphincter and pelvic floor. Weak interference results in staccato voiding, while stronger interference results in interrupted voiding and straining, due to an inability to relax during voiding.

Bladder sphincter dysfunction is often associated with bowel dysfunction such as obstipation and soiling. Sometimes, secondary anatomical changes are observed, such as trabeculation, diverticulae and vesicoureteral reflux.

11.3 Diagnosis

A non-invasive screening, consisting of history-taking, clinical examination, uroflow, ultrasound and voiding diary, is essential to reach a diagnosis.

In the paediatric age group, where the history is taken from both the parents and child together, a structured approach is recommended using a questionnaire. Many signs and symptoms related to voiding and wetting will be unknown to the parents and should be specifically requested, using the questionnaire as a checklist. A voiding diary is mandatory to determine the child's voiding frequency and voided volumes as well as the child's drinking habits. History-taking should also include assessment of bowel function. Some dysfunctional voiding scores have recently been developed and validated (9,10).

Upon clinical examination, genital inspection and observation of the lumbosacral spine and the lower extremities is necessary to exclude obvious uropathy and neuropathy. Uroflow with post-void residual evaluates the emptying ability, while an upper urinary tract ultrasound screens for secondary anatomical changes. A voiding diary provides information about storage function and incontinence frequency, while a pad test can help to quantify the urine loss.

In the case of resistance to initial treatment, or in the case of former failed treatment, re-evaluation is warranted and further video-urodynamic studies may be considered. Sometimes, there are minor, underlying, urological or neurological problems, which can only be suspected using video-urodynamics.

In the case of anatomical problems, such as urethral valve problems, syringocoeles, congenital obstructive posterior urethral membrane (COPUM) or Moormann's ring, it may be necessary to perform further cystoscopy with treatment. If neuropathic disease is suspected, MRI of the lumbosacral spine and medulla can help to exclude tethered cord, lipoma or other rare conditions.

Psychological screening may be useful for children or families with major psychological problems associated with the voiding dysfunction.

11.4 Treatment

Treatment of voiding dysfunction consists of lower urinary tract rehabilitation, mostly referred to as urotherapy. Urotherapy means non-surgical, non-pharmacological, treatment of LUT function. It is a very broad therapy field, incorporating many treatments used by urotherapists and other healthcare professionals (11). Urotherapy can be divided into standard therapy and specific interventions.

11.4.1 ***Standard therapy***

Standard urotherapy is defined as non-surgical, non-pharmacological, treatment for LUT malfunction. It includes the following components:

- Information and demystification, which includes explanation about normal LUT function and how a particular child deviates from normal function.
- Instruction about what to do about the problem, i.e. regular voiding habits, sound voiding posture, avoiding holding manoeuvres, etc.
- Lifestyle advice, regarding fluid intake, prevention of constipation, etc.
- Registration of symptoms and voiding habits using bladder diaries or frequency-volume charts
- Support and encouragement via regular follow-up by the caregiver.

A success rate of 80% has been described for urotherapy programmes, independent of the components of the programme. However, the evidence level is low as most studies of urotherapy programmes are retrospective and non-controlled.

11.4.2 ***Specific interventions***

As well as urotherapy, there are some specific interventions, including physiotherapy (e.g. pelvic floor exercises), biofeedback, alarm therapy and neurostimulation. Although good results with these treatment modalities have been reported, there have been no randomised controlled treatment trials (RCTs), so that the level of evidence is low (11-15).

In some cases, pharmacotherapy may be added. Antispasmodics and anticholinergics have been shown to be effective, though the level of evidence was low. More recently, a few RCTs have been published. One trial on tolterodine showed safety but not efficacy (16), while another RCT on propiverine showed both safety and efficacy (17) (LE: 1). The difference in results is probably due to study design.
Despite the low level of evidence for the use of anticholinergics and antimuscarinics, their use is recommended (GR: B) because of the large number of studies reporting a positive effect on OAB symptoms.

Although alpha-blocking agents are used occasionally, an RCT showed no benefit (18). Botulinum toxin injection seems promising, but can only be used off-label (19).

12. MONOSYMPTOMATIC ENURESIS

12.1 Background

Enuresis is synonymous to intermittent nocturnal incontinence. It is a frequent symptom in children. With a prevalence of 5-10% at 7 years of age, it is one of the most prevalent conditions in childhood. With a spontaneous yearly cure rate of 15%, it is considered relatively benign (1,2). Nocturnal enuresis is considered primary when a child has not yet had a prolonged period of being dry. The term "secondary nocturnal enuresis" is used when a child or adult begins wetting again after having stayed dry. In most cases of secondary nocturnal enuresis the causes are either organic or stem from a psychologic problem.

However, 7 out of 100 children wetting the bed at age 7 will take this condition into adulthood. As it is a stressful condition, which puts a high psychological burden on children resulting in low self-esteem, treatment is advised from the age of 6-7 years onwards. Treatment is unnecessary in younger children in whom spontaneous cure is likely. The child's mental status, family expectations, social issues and cultural background need to be considered before treatment can be started.

12.2 Definition

Enuresis is the condition describing the symptom of incontinence during night. Any wetting during sleep above the age of 5 years is enuresis. However, most importantly, there is a single symptom only. Children with other LUT symptoms and enuresis are said to have **non-monosymptomatic enuresis**. Thorough history-taking, excluding any other daytime symptoms, is mandatory before diagnosing **monosymptomatic enuresis**. Any associated urinary tract symptoms make the condition a '**daytime LUT condition**' (3).

The condition is described as 'primary' when the symptom has always existed and the patient has not been dry for a period longer than 6 months. The condition is described as 'secondary', when there has been a symptom-free interval of 6 months. Genetically, enuresis is a complex and heterogeneous disorder. Loci have been described on chromosomes 12, 13 and 22 (3).

Three factors play an important pathophysiological role:

- high night-time urine output;
- night-time low bladder capacity or increased detrusor activity;
- arousal disorder.

Due to an imbalance between night-time urine output and night-time bladder capacity, the bladder can become easily full at night and the child will either wake up to empty the bladder or will void during sleep if there is a lack of arousal from sleep (1-3).

12.3 Diagnosis

The diagnosis is obtained by history-taking. In a patient with monosymptomatic enuresis, no further investigations are needed. A voiding diary, which records daytime bladder function and night-time urine output, will help to guide the treatment. An estimate of night-time urine production can be obtained by weighing diapers (nappies) in the morning and adding the volume of the morning void. Measuring the daytime bladder capacity gives an estimate of bladder capacity compared to normal values for age (4).

In most children, bedwetting is a familial problem, with most affected children found to have a history of bedwetting within the family.

A urinary dipstick may help differentiate between true enuresis resulting from polyuria due to insispidis diabetis.

12.4 Treatment

Before using alarm treatment or medication, simple therapeutic interventions should be considered.

*12.4.1 **Supportive treatment measures***

Explaining the condition to the child and his parents helps to demystify the problem. Eating and drinking habits should be reviewed, stressing normal fluid intake during the day and reducing fluid intake in the hours before sleep. Keeping a chart depicting wet and dry nights has been shown to be successful.

Counselling, provision of information, positive reinforcement, and increasing (and supporting) motivation of the child should be introduced first. There is a high level of evidence to show that supportive treatment is more successful than doing nothing, although the cure rate is not significantly high. However, supportive therapy as an initial management carries a high grade of recommendation (4).

Supportive measures have limited success when used alone, they should be used in conjunction with other treatment modalities, of which pharmacological and alarm treatment are the two most important.

*12.4.2 **Alarm treatment***

Alarm treatment is the best form for arousal disorder (LE: 1; GR: A). Initial success rates of 80% are realistic,

with low relapse rates, especially when night-time diuresis is not too high and bladder capacity is not too low (5).

12.4.3 ***Medication***

In the case of high night-time diuresis, success rates of 70% can be obtained with desmopressin (DDAVP), either as tablets, 200-400 µg, or as sublingual desmopressin oral lyophilisate, 120-240 µg. A nasal spray is no longer recommended due to an increased risk of overdose (6,7) (LE: 1; GR: A). However, relapse rates are high after desmopressin discontinuation (4).
In the case of small bladder capacity, treatment with antispasmodics or anticholinergics is possible (4). However, when these medications are necessary, the condition is no longer considered to be mono-symptomatic.
Imipramine, which has been popular for treatment of enuresis, achieves only a moderate response rate of 50% and has a high relapse rate. Furthermore, cardiotoxicity and death with overdose are described. Its use should therefore be discouraged (8) (LE: 1;GR: C).

13. MANAGEMENT OF NEUROGENIC BLADDER IN CHILDREN

13.1 Background

Neurogenic detrusor-sphincter dysfunction (NDSD) can develop as a result of a lesion at any level in the nervous system. This condition contributes to various forms of lower urinary tract dysfunction, which may lead to incontinence, UTIs, VUR, and renal scarring. Surgery may be required to establish adequate bladder drainage. If not managed properly, NDSD can potentially cause renal failure, requiring dialysis or transplantation.

The management of neurogenic bladder sphincter dysfunction in children has undergone major changes over the years. Although nappies (diapers), permanent catheters, external appliances, Crede's manoeuvre and various forms of urinary diversion have been acceptable treatment methods, these are now reserved for only a small number of resistant patients. The introduction of clean intermittent catheterisation (IC) has revolutionised the management of children with neurogenic bladder. Not only has it made conservative management a very successful treatment option, but it has also made surgical creation of continent reservoirs a very effective treatment alternative, with a good outcome for quality of life and kidney protection (1-3).

Neurogenic bladder in children with myelodysplasia presents with various patterns of detrusor-sphincter dysfunction within a wide range of severity. About 15% of neonates with myelodysplasia have no signs of neurourological dysfunction at birth. However, there is a high chance of progressive changes in the dynamics of neurological lesions with time. Even babies with normal neurourological function at birth have a one in three risk of developing either detrusor sphincter dyssynergia or denervation by the time they reach puberty. At birth, the majority of patients have normal upper urinary tracts, but nearly 60% of them develop upper tract deterioration due to infections, bladder changes and reflux (4-7).

As our understanding of urodynamic studies has evolved, it has allowed us to understand the nature and severity of problems and manage these patients in a more rational and individualised manner. Despite the remarkable changes of the last quarter of the 20th century, the main goals of treatment have remained the same, i.e. prevention of urinary tract deterioration and achievement of continence at an appropriate age.

13.2 Definition

The most common presentation is at birth with myelodysplasia. The term myelodysplasia includes a group of developmental anomalies that result from defects in neural tube closure. Lesions may include spina bifida occulta, meningocele, lipomyelomeningocele, or myelomeningocele. Myelomeningocele is by far the most common defect seen and the most detrimental. Traumatic and neoplastic spinal lesions of the cord are less frequent in children. Additionally, different growth rates between the vertebral bodies and the elongating spinal

cord can introduce a dynamic factor to the lesion. Scar tissue surrounding the cord at the site of meningocele closure can tether the cord during growth.

In occult myelodysplasia, the lesions are not overt and often occur with no obvious signs of neurological lesion. In nearly 90% of patients, however, a cutaneous abnormality overlies the lower spine, and this condition can easily be detected by simple inspection of the lower back (8).

Total or partial sacral agenesis is a rare congenital anomaly that involves absence of part or all of one or more sacral vertebrae. This anomaly can be part of the caudal regression syndrome, and must be considered in any child presenting with anorectal malformation (ARM). Patients with cerebral palsy may also present with varying degrees of voiding dysfunction, usually in the form of uninhibited bladder contractions (often due to spasticity of the pelvic floor and sphincter complex) and wetting.

Bladder sphincter dysfunction is poorly correlated with the type and spinal level of the neurological lesion.

13.3 Classification

The purpose of any classification system is to facilitate the understanding and management of the underlying pathology. There are various systems of classification of neurogenic bladder.

Most systems of classification were formulated primarily to describe those types of dysfunction secondary to neurological disease or injury. Such systems are based on the localisation of the neurological lesion and the findings of the neurourological examination. These classifications have been of more value in adults, in whom neurogenic lesions are usually due to trauma and are more readily identifiable.

In children, the spinal level and extent of congenital lesion are poorly correlated with the clinical outcome. Urodynamic and functional classifications have therefore been more practical for defining the extent of the pathology and planning treatment in children.

The bladder and sphincter are two units working in harmony to make a single functional unit. The initial approach should be to evaluate the state of each unit and define the pattern of bladder dysfunction. According to the nature of the neurological deficit, the bladder and sphincter may be in either an overactive or inactive state:

- the bladder may be overactive with increased contractions, and low capacity and compliance, or inactive with no effective contractions;
- the outlet (urethra and sphincter) may be independently overactive causing functional obstruction, or paralysed with no resistance to urinary flow;
- these conditions may present in different combinations.

This is mainly a classification based on urodynamic findings. The understanding of the pathophysiology of disorders is essential to plan a rational treatment plan for each individual patient. In meningomyelocele, most patients will present with hyper-reflexive detrusor and dyssynergic sphincter, which is a dangerous combination as pressure is built up and the upper tract is threatened.

13.4 Urodynamic studies

Urodynamic studies enable the clinician to observe lower urinary tract function and its deviations from normal. Since the treatment plan mainly depends upon a good understanding of the underlying problem in the lower urinary tract, a well-performed urodynamic study is mandatory in the evaluation of each child with neurogenic bladder.

As the bony level often does not correspond with the neurological defect present, and as the effect of the lesion on bladder function cannot be entirely determined by radiographic studies or physical examination, the information gained from a urodynamic study is priceless. A urodynamic study also provides the clinician with information about the response of the vesicourethral unit to therapy, as demonstrated by improvement or deterioration in follow-up.

It is important to determine several urodynamic parameters, including:

- the bladder capacity;
- the intravesical filling pressure;
- the intravesical pressure at the moment of urethral leakage;
- the presence or absence of reflex detrusor activity;

- the competence of the internal and external sphincteric mechanisms;
- the degree of coordination of the detrusor and sphincteric mechanisms;
- the voiding pattern;
- the post-voiding residual urine volume.

13.4.1 ***Method of urodynamic study***

There is very little comparative data evaluating the complexity and invasiveness of urodynamic testing for neurogenic bladders in children.

13.4.2 ***Uroflowmetry***

As uroflowmetry is the least invasive of all urodynamic tests, it can be used as an initial screening tool. It provides an objective way of assessing the efficiency of voiding, and, together with an ultrasonographic examination, the residual urine volume can also be determined. Unlike in children with non-neurogenic voiding dysfunction, uroflowmetry will rarely be used as a single investigational tool in children with neurogenic bladders, as it does not provide information for bladder storage, yet it may be very practical to monitor emptying in the follow-up. The main limitation of a urodynamic study is the need for the child to be old enough to follow instructions and void on request.

The recording of pelvic floor or abdominal skeletal muscle activity by electromyography (EMG) during uroflowmetry can be used to evaluate coordination between detrusor and the sphincter. As it is a non-invasive test, combined uroflowmetry and EMG may be very useful in evaluating sphincter activity during voiding (9-12) (LE: 3; GR: C).

13.4.3 ***Cystometry***

Although moderately invasive and dependent on a cooperative child, cystometry in children provides valuable information regarding detrusor contractility and compliance. The amount of information obtained from each study is related to the degree of interest and care given to the test.

It is important to be aware of the alterations in filling and emptying detrusor pressures as the infusion rates change during cystometry. Slow fill cystometry (filling rate < 10 mL/min) is recommended by the ICCS for use in children (13). However, it has been suggested that the infusion rate should be set according to the child's predicted capacity, based on age and divided by 10 (14).

Several clinical studies using conventional artificial fill cystometry to evaluate neurogenic bladder in children have reported that conventional cystometry provides useful information for diagnosis and follow-up of children with neurogenic bladder (15-20). All the studies were retrospective clinical series and lacked comparison with natural fill cystometry, so that the grade of recommendation for an artificial cystometry in children with neurogenic bladder is not high (LE: 4). Additionally, there is evidence suggesting that natural bladder behaviour is altered during regular artificial filling cystometry (21,22).

However, conventional cystometry in infants is useful for predicting future deterioration. Urodynamic parameters, such as low capacity and compliance and high leak-point pressures, are poor prognostic factors for future deterioration. Resolution of reflux is less likely to happen in such bladders (15,20,22) (LE: 4).

During natural fill cystometry, the bladder is allowed to fill naturally and the bladder and abdominal pressures are recorded using microtransducer catheters. Theoretically, this allows investigation of bladder function in near-physiological conditions. Studies on natural fill cystometry in children report similar results to those of studies done in adults. Natural fill cystometry gives a lower detrusor pressure rise during filling, and lower voided volumes with higher voiding pressures. The incidence of bladder overactivity is higher with natural filling cystometry when compared with conventional artificial filling cystometry (21,23,24).

Although there are only a few studies on natural fill cystometry in children with neurogenic bladder, the results suggest that natural fill cystometry detects new findings compared with diagnoses delivered by conventional cystometry (21) (LE: 3). However, the comparison between natural fill and artificial fill cystometry has not been performed against a gold standard, making it difficult to conclude which study is a true reflection of natural bladder behaviour. Findings in the non-neurogenic adult population have questioned the reliability of natural fill cystometry, as natural fill cystometry has shown a high incidence of bladder overactivity in totally normal asymptomatic volunteers (25).

The main disadvantage of natural fill cystometry is that it is labour-intensive and time-consuming. Moreover,

because of the transurethral catheter used during this study, false-positive findings caused by the catheter are possible. Especially in children, the recording of events is difficult and there is an increased risk of artefacts, which makes interpretation of the huge amount of data even more difficult.

Natural fill cystometry remains a new technique in the paediatric population. More data need to be gathered in a standard way before it can be widely accepted (11).

13.5 Management

The medical care of children with myelodysplasia with a neurogenic bladder requires constant observation and adaptation to new problems. In the first years of life, the kidneys are highly susceptible to back-pressure and infection. During this period, the emphasis is on documenting the pattern of NDSD, and assessing the potential for functional obstruction and VUR.

13.5.1 ***Investigations***

An abdominal ultrasound obtained as soon as possible after birth will detect hydronephrosis or other upper genitourinary tract pathology. Following ultrasound, a voiding cystourethrogram should be obtained to evaluate the lower urinary tract. Measurement of residual urine during both ultrasound and cystography should also be done. These studies provide a baseline for the appearance of the upper and lower urinary tracts, can facilitate the diagnosis of hydronephrosis or VUR, and can help identify children at risk for upper genitourinary tract deterioration and impairment of renal function.

A urodynamic evaluation can be done after some weeks, and needs to be repeated at regular intervals, in combination with evaluation of the upper tracts (26-28) (LE: 3; GR: B).

13.5.2 ***Early management with intermittent catheterisation***

Overwhelming experience gained over the years with early management of neurogenic bladder in infants has led to a consensus that children do not have upper tract deterioration when managed early with IC and anticholinergic medication. IC should be started soon after birth in all babies, especially in those with signs of possible outlet obstruction (26,29-37) (LE: 2; GR: B).

The early initiation of IC in the newborn period makes it easier for parents to master the procedure and for children to accept it as they grow older (38,39).

Early management results in fewer upper tract changes, but also better bladder protection and lower incontinence rates. It has been suggested that increased bladder pressures due to detrusor sphincter dyssynergia cause secondary changes of the bladder wall. These fibroproliferative changes in the bladder wall may cause further loss of elasticity and compliance, resulting in a small non-compliant bladder with progressively elevated pressures.

Early institution of IC and anticholinergic drugs may prevent this in some patients (2,37,40) (LE: 3). The retrospective evaluation of patients has also shown that significantly fewer augmentations were required in patients with an early start of IC (33,34) (LE: 4).

13.5.3 ***Medical therapy***

At present, oxybutynin, tolterodine, trospium and propiverine are the most frequently used drugs, with oxybutynin being the most studied.

Two different forms of tolterodine have been investigated in children with neurogenic bladder. The extended release formulation of tolterodine has been found to be as efficient as the instant release form, with the advantages of being single dosage and less expensive. Although the clinical outcome is encouraging, the level of evidence is low for anticholinergic medication because there are no controlled studies (40,41-47) (LE: 3; GR: B).

The use of medication to facilitate emptying in children with neurogenic bladder has not been well studied in the literature. A few studies investigating the use of α-adrenergic blockade in children with neurogenic bladder have reported a good response rate, but the studies lacked controls, and long-term follow-up is warranted (48) (LE: 4; GR: C).

13.5.3.1 Botulinum toxin injections

In neurogenic bladders that are refractory to anticholinergics, injection of botulinum toxin into the detrusor

muscle is a novel treatment alternative. Initial promising results in adults have initiated its use in children. It has been shown that this treatment has beneficial effects on clinical and urodynamic variables. Complete continence was achieved in 65-87% of patients; in most studies mean maximum detrusor pressure was reduced to at least 40 cmH_2O and bladder compliance was increased to at least 20 cmH_2O/mL. However these findings are limited by the lack of controlled trials and the fact that most studies involved small numbers of patients (49-54).

Botulinum toxin seems to be more effective in bladders with obvious detrusor muscle overactivity, whereas non-compliant bladders without obvious contractions are unlikely to respond (55-60).

The most commonly used dose of botulinum toxin is 10 U/kg with a maximum dose of 300 U/kg. No dose study has been performed in children and there is no evidence regarding the optimal dose. Currently, it is unclear how many times this treatment can be repeated, although repetitive treatment has been found to be safe in adults (61-64).

Injection of botulinum toxin in therapy-resistant bladders appears to be an effective and safe treatment alternative (LE: 3; GR: C). Urethral sphincter botulinum-A toxin injection has been shown to be effective in decreasing urethral resistance and improve voiding. The evidence is still too low to recommend its routine use in decreasing outlet resistance, but it could be considered as an alternative in refractory cases (65-67).

13.5.4 ***Management of bowel incontinence***

Children with neurogenic bladder have disturbances of bowel function as well as urinary function. Bowel incontinence in these children is frequently unpredictable. It is related to the turnover rate of faecal material in the anal area after evacuation, the degree of intactness of sacral cord sensation and motor function, and reflex reactivity of the external anal sphincter (68).

Bowel incontinence is managed most commonly with mild laxatives, such as mineral oil, combined with enemas to facilitate removal of bowel contents. A regular and efficient bowel emptying regimen is often necessary to maintain faecal continence, and may have to be started at a very young age. With antegrade or retrograde enemas, most of these children will have decreased constipation problems and may attain some degree of faecal continence (69-73) (LE: 3).

Biofeedback training programmes to strengthen the external anal sphincter have not been shown to be more effective than a conventional bowel management programme in achieving faecal continence (74). Electrostimulation of the bowel may also offer a variable improvement in some patients (75) (LE: 3; GR: C).

13.5.5 ***Urinary tract infection***

Urinary tract infections are common in children with neurogenic bladders. In the absence of reflux, UTIs should be treated symptomatically. There is strong evidence for not prescribing antibiotics to patients who have bacteriuria but no clinical symptoms. Although bacteriuria is seen in more than half of children on clean IC, patients who are asymptomatic do not need treatment (76-78) (LE: 3). Patients with VUR should usually be placed on prophylactic antibiotics to reduce the incidence of pyelonephritis, which can potentially lead to renal damage (79,80).

13.5.6 ***Sexuality***

Sexuality, while not an issue in childhood, becomes progressively more important as the patient gets older. This issue has historically been overlooked in individuals with myelodysplasia. However, patients with myelodysplasia do have sexual encounters. Studies indicate that at least 15-20% of males are capable of fathering children and 70% of females can conceive and carry a pregnancy to term. It is therefore important to counsel patients about sexual development in early adolescence.

13.5.7 ***Bladder augmentation***

Children with a good response to anticholinergic treatment and an overactive sphincter may be continent between catheterisations. Bladder pressure and development of the upper urinary tract will determine whether additional treatment is necessary.

Therapy-resistant overactivity of the detrusor, or small capacity and poor compliance, will usually need to be treated by bladder augmentation. A simple bladder augmentation using intestine may be carried out if there is any bladder tissue, a competent sphincter and/or bladder neck, and a urethra that can be catheterised. Stomach is rarely used as an augmenting patch because of the associated complications (81). Ileal or colonic

patches are frequently used for augmenting the bladder, with either intestinal segment appearing to be equally useful. Despite some advantages (e.g. avoiding mucus, decreased malignancy rate and fewer complications), alternative urothelium-preserving techniques, such as autoaugmentation and seromuscular cystoplasty, have not proven to be as successful as standard augmentation with intestine (82,83).

A range of applications of engineered bladder tissues are at different stages of development. There have been a few in pre-clinical trials; recent progress suggests that engineered bladder tissues may have an expanded clinical application in the future (84).

13.5.8 ***Bladder outlet procedures***

Children with detrusor overactivity, but with underactive sphincters, will be better for protecting their upper tracts, although they will be severely incontinent. Initial treatment is IC (as it might reduce the degree of incontinence and offers much better control over UTIs) with anticholinergic drugs. At a later age, the outlet resistance will be increased in order to render them continent. No medical treatment available has been validated to increase bladder outlet resistance. Alpha-adrenergic receptor stimulation of the bladder neck has not been very effective (85-90).

When conservative measures fail, surgical procedures need to be considered for maintaining continence. Although a simple augmentation is sufficient for most low-capacity, high-pressure bladders, augmentation with additional bladder outlet procedures is required when both the bladder and outlet are deficient. Bladder outlet procedures include bladder neck reconstruction or other forms of urethral reconstruction.

Various procedures can be used on the bladder neck to increase resistance, but all of them may complicate transurethral catheterisation. Augmentation with surgical closure of the bladder neck may be required primarily, or as a secondary procedure in certain rare clinical situations. In this situation, a continent stoma will be required. However, most surgeons prefer to leave the bladder neck and urethra patent as a safety precaution.

13.5.9 ***Continent stoma***

Augmentation with an additional continent stoma is utilised primarily after failure of previous bladder outlet surgery. It is also advisable when an inability to catheterise transurethrally is likely. An abdominal wall continent stoma may be particularly beneficial to wheelchair-bound spina bifida patients, who often have difficulty with urethral catheterisation or are dependent on others to catheterise the bladder. For continence with augmentation and an abdominal wall stoma, an adequate bladder outlet mechanism is essential to maintain continence.

13.5.10 ***Total bladder replacement***

Total bladder replacement in anticipation of normal voiding in children is very rare, as there are infrequent indications for a total cystectomy, with preservation of the bladder outlet and a competent urethral sphincter. This type of bladder replacement is much more common in adult urological reconstruction. Any type of major bladder and bladder outlet construction should be performed in centres with sufficient experience of the surgical technique, and with experienced healthcare personnel to carry out post-operative follow-up (91-93).

13.5.11 ***Lifelong follow-up of neurogenic bladder patients***

Neurogenic bladder patients require lifelong supervision, and the monitoring of renal function is extremely important. Periodic investigation of upper tract changes, renal function and bladder status is mandatory. Repeat urodynamic tests are therefore needed more frequently (every year) in younger children and less frequently in older children. From the urological viewpoint, a repeat urodynamic study is warranted when the patient has a change in symptoms or undergoes any neurosurgical procedure. In the case of any apparent changes in the upper and lower urinary tract, or changes in neurological symptoms, a more detailed examination including urodynamics and spinal magnetic resonance imaging is indicated.
Renal failure can progress slowly or occur with startling speed in these children. Patients who have undergone reconstructive procedures using intestine should be regularly followed up for complications such as infection, stone formation, reservoir rupture, metabolic changes, and malignancy (93).

The risk of malignancy in enteric augmentations has been reported to be higher than expected, and the risk increases with length of follow-up. Malignancy has been found to occur in 0.6-2.8% of patients during median follow-up of 13-21 years (94-99). In a study including 153 patients with a median follow-up time of 28 years (95), malignancy was found in 4.5%. The malignancy seemed to be associated with coexisting carcinogenic stimuli or with the inherent risk present with bladder exstrophy. Although there is poor data on follow-up schemes; after a reasonable time of follow up (f.i: 10 years), an annual diagnostic work-up including cystoscopy should be considered.

14. DILATATION OF THE UPPER URINARY TRACT (URETEROPELVIC JUNCTION AND URETEROVESICAL JUNCTION OBSTRUCTION)

14.1 Background

Dilatation of the upper urinary tract still presents a significant clinical challenge in determining which patient may gain benefit by therapy.

Ureteropelvic junction (UPJ) obstruction is defined as impaired urine flow from the pelvis into the proximal ureter with subsequent dilatation of the collecting system and the potential to damage the kidney. It is the most common cause of neonatal hydronephrosis (1). It has an overall incidence of 1:1500 and a ratio of males to females of 2:1 in newborns.

Ureterovesical junction (UVJ) obstruction is an obstructive condition of the distal ureter as it enters the bladder, commonly called a primary obstructive megaureter. Megaureters are ranked as second in the differential diagnosis of neonatal hydronephrosis. They occur more often in males and are more likely to occur on the left side (2).

Much more difficult is the definition of obstruction. Creating a divide between ‘obstructed’ and ‘nonobstructed’ urinary tracts, as if entities could be as clearly differentiated as ‘black’ and ‘white’, is impossible.

Currently, the most popular definition is that obstruction represents any restriction to urinary outflow that, if left untreated, will cause progressive renal deterioration (3).

14.2 Diagnosis

Due to the widespread use of ultrasonography during pregnancy, antenatal hydronephrosis is being detected with increasing frequency (4). The challenge in the management of dilated upper urinary tracts is to decide which child can be observed, which one should be managed medically, and which one requires surgical intervention. There is no single definitive test able to distinguish obstructive from non-obstructive cases (Figure 3).

14.2.1 ***Antenatal ultrasound***

Usually between the 16th and 18th week of pregnancy, the kidneys are visualised routinely, when almost all amniotic fluid consists of urine. The most sensitive time for foetal urinary tract evaluation is the 28th week. If dilatation is detected, ultrasound should focus on the laterality, severity of dilatation, and echogenicity of the kidneys, hydronephrosis or hydro-ureteronephrosis, bladder volume and bladder emptying, sex of the child, and amniotic fluid volume, respectively (5).

14.2.2 ***Postnatal ultrasound***

Since transitory neonatal dehydration lasts about 48 hours, imaging should be performed after this period of postnatal oliguria. In severe cases (bilateral dilatation, solitary kidney, oligohydramnios), immediate postnatal sonography is recommended (6). During ultrasound examination, the anteroposterior diameter of the renal

pelvis, calyceal dilatation, kidney size, thickness of the parenchyma, cortical echogenicity, ureters, bladder wall and residual urine are assessed.

*14.2.3 **Voiding cystourethrogram (VCUG)***

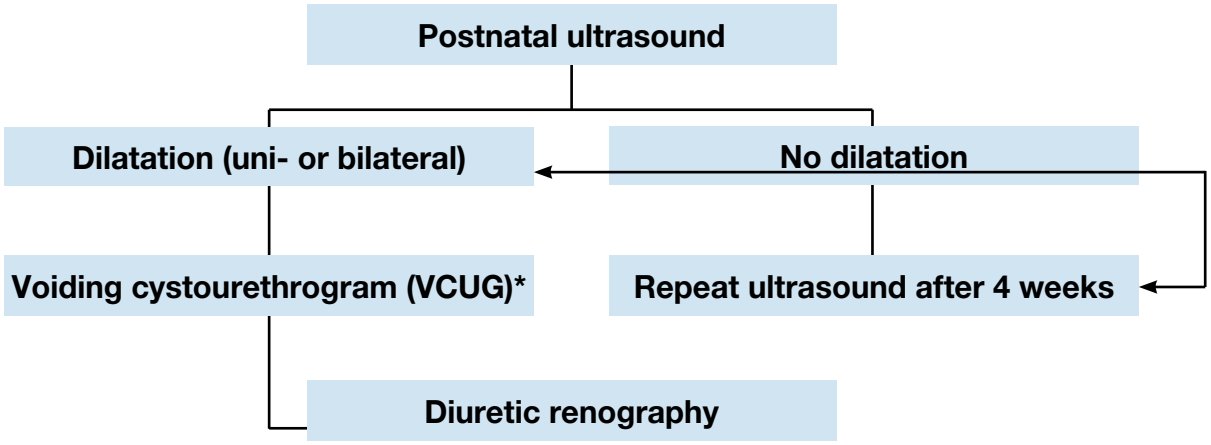
In newborns with identified upper urinary tract dilatation, the presence of primary or important associated factors that must be detected include vesicoureteral reflux in up to 25% of affected children (15), urethral valves, ureteroceles, diverticula and neurogenic bladder. Conventional VCUG is the method of choice for primary diagnostic procedures (7).

*14.2.4 **Diuretic renography***

Diuretic renography is the most commonly used diagnostic tool to detect the severity and functional significance of urine transport problems. ^{99}mTc-MAG3 is the radionuclide of choice. It is important to perform the study under standardised circumstances (hydration, transurethral catheter) between the fourth and sixth weeks of life (8).

Oral fluid intake is encouraged prior to examination. Fifteen minutes before injection of the radionuclide, it is mandatory to give normal saline intravenous infusion at a rate of 15 ml/kg over 30 minutes and then at a maintenance rate of 4 ml/kg/hour throughout the whole time of the investigation (9). The recommended dose of furosemide is 1 mg/kg for infants during the first year of life, while 0.5 mg/kg should be given to children aged 1 to 16 years up to a maximum dose of 40 mg.

Figure 3: Diagnostic algorithm for dilatation of the upper urinary tract



** A diagnostic work-up including VCUG has to be discussed with the parents since a possibly detected reflux might have absolutely no clinical impact. On the other hand, a reflux rate of up to 25% in cases of prenatally detected and postnatally confirmed hydronephrosis is reported in the literature (15) and might therefore have some forensic impact as well.*

14.3 Treatment

*14.3.1 **Prenatal management***

Counselling the parents is one of the most important aspects of care. The prognosis for an hydronephrotic kidney, even if severely affected, is hopeful. An hydronephrotic kidney may still be capable of providing meaningful renal function, whereas a severely hypoplastic and dysplastic kidney has a hopeless outlook. It is important to explain to the parents the timing and accuracy of establishing the definitive diagnosis for their child. In some cases, there is an obvious indication of severity, including massive bilateral dilatation, bilateral evidence of hypoplastic dysplasia, progressive bilateral dilatation with oligohydramnios, and pulmonary hypoplasia.

Intrauterine intervention is rarely indicated and should only be performed in well-experienced centres (10).

*14.3.2 **Ureteropelvic junction obstruction***

It is most important to make the decision on the basis of serial investigations, applying the same technique and performed by the same institution under standardised circumstances. Symptomatic obstruction (recurrent flank pain, urinary tract infection) requires surgical correction using a pyeloplasty, according to the standardised open technique of Hynes and Anderson (11). Recently, increasingly more data have become available supporting the use of a laparoscopic or retroperitoneoscopic approach to achieve a dismembered pyeloplasty.

In addition, laparoscopic suturing has been improved by the use of robotics (16). However, these methods lack very long-term data and will require time to be fully proven. In asymptomatic cases, conservative follow-up can be the treatment of choice.

Indications for surgical intervention are an impaired split renal function (< 40%), a decrease of split renal function of more than 10% in subsequent studies, increased anteroposterior diameter on the ultrasound, and grade III and IV dilatation as defined by the Society for Fetal Urology.

14.4 Megaureter

Concerning the treatment options of secondary megaureters (*see Chapter 15, Vesicoureteric reflux in children*). If a functional study reveals and confirms adequate ureteral drainage, conservative management is the best option. Initially, low-dose prophylactic antibiotics within the first year of life are recommended for prevention of urinary tract infections, although there are no prospective randomised trials to evaluate this regimen (12).

With spontaneous remission rates of up to 85% in primary megaureter cases, surgical management is no longer recommended, except for megaureters with recurrent UTI, deterioration of split renal function and significant obstruction (13).

The initial approach to the ureter can be either intravesical, extravesical, or combined. Straightening the ureter is necessary without devascularisation. Ureteral tapering should enhance urinary flow into the bladder. The ureter must be tapered to achieve a diameter for an antireflux repair. There are several tailoring techniques, e.g. ureteral imbrication or excisional tapering (14).

14.5 Conclusion

With the use of routine perinatal sonography, hydronephrosis caused by UPJ or UVJ obstruction is now increasingly recognised. Meticulous and repeat postnatal evaluation is mandatory to try to identify any obstructive cases at risk of renal deterioration and requiring surgical reconstruction. Surgical methods are fairly standardised and have a good clinical outcome.

15. VESICOURETERIC REFLUX IN CHILDREN

15.1 Methodology

The scientific literature for reflux disease is still limited and the level of evidence is generally low. Most of the studies are retrospective, include different patient groups, and have poor stratification of quality. Also, there is a high risk of presenting misleading results by combining different types of studies when systematically extracting data. Therefore, for reflux disease, it is unfortunately not possible to produce recommendations based on high-quality studies. The authors have assessed the current literature, but in the absence of conclusive findings, have provided recommendations based on panel consensus. These guidelines aim to provide a practical approach to the treatment of VUR based on risk analysis.

15.2 Background

Vesicoureteric reflux, or the retrograde flow of urine from the bladder into the ureter, is an anatomical and/or functional disorder with potentially serious consequences, such as renal scarring, hypertension, and renal failure. Fortunately, patients with VUR present within a wide range of severity, and a good proportion of reflux patients do not develop renal scars and probably do not need any intervention (1). VUR is a very common urological anomaly in children, with an incidence of nearly 1%. Its management is one of the most controversial issues in paediatric urology.

The main goal in management is the preservation of kidney function, by minimising the risk of pyelonephritis. By defining and analysing the risk factors for each patient [i.e. age, sex, reflux grade, lower urinary tract dysfunction (LUTD), anatomical abnormalities, and kidney status], it is possible to identify those patients with a potential risk of UTIs and renal scarring. Controversy persists over the optimal management of VUR, particularly the choice of diagnostic procedures, treatment (medical, endoscopic or open surgical), and the timing of treatment.

Many children present without symptoms of UTI and because invasive diagnostic procedures are performed only when clinically indicated, the exact prevalence of VUR is unknown. However, the prevalence of VUR in non-symptomatic children has been estimated at 0.4-1.8% (2). Among infants prenatally identified with hydronephrosis on ultrasonography (US), who were screened for VUR, the prevalence was 16.2% (7-35%) (3). Siblings of children with VUR had a 27.4% (3-51%) risk of also having VUR, whereas the offspring of parents with VUR had a higher incidence of 35.7% (21.2-61.4%) (3).

However, reflux detected by sibling screening is associated with lower grades (3) and significantly earlier resolution (4). When VUR is discovered in siblings after UTI, it is usually high grade and associated with a high incidence of reflux nephropathy, particularly if the sibling is male and the grade of reflux was high in the index patient. Even when asymptomatic, siblings and offspring of those with VUR may be diagnosed with high-grade reflux and scarring (5,6).

The incidence of VUR is much higher among children with UTIs (30-50%, depending on age). UTIs are more common in girls than boys due to anatomical differences. However, among all children with UTIs, boys are more likely to have VUR than girls (29% vs. 14%). Boys also tend to have higher grades of VUR diagnosed at

younger ages, although their VUR is more likely to resolve (7-10).

There is a clear co-prevalence between LUTD and VUR (11). LUTD refers to the presence of lower urinary tract symptoms (LUTSs), including urge, urge incontinence, weak stream, hesitancy, frequency and UTIs, which reflect the filling and/or emptying dysfunction that may be accompanied with bowel problems (11). Some studies have described a prevalence of 40-60% for VUR in children with LUTD (12). It is possible that VUR is secondary to LUTD, and that treatment of LUTD therefore results in correction of VUR. In contrast, high-grade VUR may affect bladder dynamics, which subsequently leads to LUTD. A recently published Swedish reflux trial has demonstrated LUTD in 34% of patients, and subdivision into groups characteristic of children revealed that 9% had isolated overactive bladder and 24% had voiding phase dysfunction. There was a significant negative correlation between dysfunction at 2 years and improved dilating reflux. Renal damage at study entry and follow-up was associated with LUTD at 2 years. Recurrent UTIs were seen in 33% of children with LUTD, and in 20% of those without (13).

The spontaneous resolution of VUR is dependent on age at presentation, sex, grade, laterality, mode of clinical presentation, and anatomy (4). Faster resolution of VUR is more likely with age < 1 year at presentation, lower grade of reflux (grade 1-3), and asymptomatic presentation with prenatal hydronephrosis or sibling reflux. The overall resolution rate is high in congenital high-grade VUR during the first years of life. In several Scandinavian studies, the complete resolution rate for high-grade VUR has been reported at > 25%, which is higher than the resolution rate for VUR detected after infancy (14,15).

The presence of renal cortical abnormality, bladder dysfunction, and breakthrough febrile UTIs are negative predictive factors for reflux resolution (16-18).

Dilating VUR increases the risk of developing acute pyelonephritis and renal scarring. Untreated recurrent UTIs may have a negative impact on somatic growth and medical status of the child. Ten to forty percent of children with symptomatic VUR have evidence of renal scarring, resulting from either congenital dysplasia and/or acquired post-infectious damage, which may have a negative impact on somatic growth and general wellbeing (19-21).

Higher grades of VUR present with higher rates of renal scars. Scar rates vary in different patient groups. In those with prenatal hydronephrosis, renal scarring occurs in ~10% of patients (22-27), whereas in patients with LUTD, this may increase up to 30% (28-30). Renal scarring may adversely affect renal growth and function, with bilateral scarring increasing the risk of insufficiency. Reflux nephropathy (RN) may be the most common cause of childhood hypertension. Follow-up studies have shown that 10-20% of children with RN develop hypertension or end-stage renal disease (31).

15.3 Diagnostic work-up

The diagnostic work-up should aim to evaluate the overall health and development of the child, the presence of UTIs, renal status, the presence of VUR, and lower urinary tract function. A basic diagnostic work-up comprises a detailed medical history (including family history, and screening for LUTD), physical examination including blood pressure measurement, urinalysis (assessing proteinuria), urine culture, and serum creatinine in patients with bilateral renal parenchymal abnormalities.

Imaging is the basis of diagnosis and management of VUR. The standard imaging tests include renal and bladder ultrasonography (US), voiding cystourethrography (VCUG) and nuclear renal scans. The criterion standard in diagnosis of VUR is VCUG, especially at the initial work-up. This test provides precise anatomical detail and allows grading of VUR (32). In 1985, the International Reflux Study Committee introduced a uniform system for the classification of VUR (33,34) (Table 9). The grading system combines two earlier classifications and is based upon the extent of retrograde filling and dilatation of the ureter, renal pelvis and calyces on VCUG (35).

Radionuclide studies for detection of reflux have lower radiation exposure than VCUG, but the anatomical details depicted are inferior (36). Recent studies on alternative imaging modalities for detection on VUR have yielded good results with voiding urosonography and magnetic resonance VCUG (37-39). However, despite the concerns about ionising radiation and its invasive nature, conventional VCUG still remains the gold standard because it allows better determination of the grade of VUR (in a single or duplicated kidney) and assessment of the bladder and urethral configuration.

Table 9: Grading system for VUR on VCUG, according to the International Reflux Study Committee (33)

Grade I	Reflux does not reach the renal pelvis; varying degrees of ureteral dilatation
Grade II	Reflux reaches the renal pelvis; no dilatation of the collecting system; normal fornices
Grade III	Mild or moderate dilatation of the ureter, with or without kinking; moderate dilatation of the collecting system; normal or minimally deformed fornices
Grade IV	Moderate dilatation of the ureter with or without kinking; moderate dilatation of the collecting system; blunt fornices, but impressions of the papillae still visible
Grade V	Gross dilatation and kinking of the ureter, marked dilatation of the collecting system; papillary impressions no longer visible; intraparenchymal reflux

Dimercaptosuccinic acid (DMSA) is the best nuclear agent for visualising the cortical tissue and differential function between both kidneys. DMSA is taken up by proximal renal tubular cells and is a good indicator of renal parenchyma function. In areas of acute inflammation or scarring, DMSA uptake is poor and appears as cold spots. DMSA scans are therefore used to detect and monitor renal scarring. A baseline DMSA scan at the time of diagnosis can be used for comparison with successive scans later during follow-up (35,40). DMSA can also be used as a diagnostic tool during suspected episodes of acute pyelonephritis (41). Children with a normal DMSA scan during acute UTI have a low risk of renal damage (42).
Video-urodynamic studies are only important in patients in whom secondary reflux is suspected, such as those with spina bifida or boys in whom VCUG is suggestive of posterior urethral valves. In the case of LUTSs, diagnosis and follow-up can be limited to non-invasive tests (e.g. voiding charts, US, or uroflowmetry) (11). Cystoscopy has a limited role in evaluating reflux, except for infravesical obstruction or ureteral anomalies that might influence therapy.

The choice of imaging modalities varies depending on the mode of presentation.

*15.3.1 **Infants presenting because of prenatally diagnosed hydronephrosis***

Ultrasound of the kidney and bladder is the first standard evaluation tool for children with prenatally diagnosed hydronephrosis. It is non-invasive and provides reliable information regarding kidney structure, size, parenchymal thickness and collecting system dilatation (43,44).

Ultrasound should be delayed until after the first week after birth because of early oliguria in the neonate. It is essential to evaluate the bladder, as well as the kidneys. The degree of dilatation in the collecting system under US, when the bladder is both full and empty, may provide significant information about the presence of VUR. Bladder wall thickness and configuration may be an indirect sign of LUTD and reflux. The absence of hydronephrosis on postnatal ultrasound excludes the presence of significant obstruction; however, it does not exclude VUR.
Monitoring with careful US avoids unnecessary invasive and irradiating examinations. The first two US scans within the first 1-2 months of life are highly accurate for defining the presence or absence of renal pathology. In infants with two normal, successive scans, VUR is a rare entity, and if present it is likely to be low grade (23,45). The degree of hydronephrosis is not a reliable indicator for the presence of VUR, even though cortical abnormalities are more common in high-grade hydronephrosis (3). The presence of cortical abnormalities on US (defined as cortical thinning and irregularity, as well as increased echogenicity) warrants the use of VCUG for detecting VUR (3). DMSA provides more reliable and quantitative measurement of the degree of cortical abnormalities when first detected with US.

The use of VCUG is recommended in patients with US findings of bilateral high-grade hydronephrosis, duplex kidneys with hydronephrosis, ureterocele, ureteric dilatation, and abnormal bladders, because the likelihood of VUR is much higher. In all other conditions, the use of VCUG to detect reflux is optional (3,46-48). When infants who are diagnosed with prenatal hydronephrosis become symptomatic with UTIs, further evaluation with VCUG should be considered (48). Patients with severe hydronephrosis and those whose hydronephrosis is sustained or progressive need further evaluation to exclude obstruction (see Chapter 14).

*15.3.2 **Siblings and offspring of reflux patients***

The screening of asymptomatic siblings and offspring is controversial. Some authors think that early identification of children with VUR may prevent episodes of UTI and therefore renal scarring, whereas others think that screening asymptomatic individuals is likely to result in significant over-treatment of clinically insignificant VUR.

The overall estimate for renal cortical abnormalities is 19.3% (11-54%), with 27.8% having renal damage in cohorts of symptomatic and asymptomatic children combined. In asymptomatic siblings only, the rate of renal damage is 14.4% (0-100%). Early screening and therefore early diagnosis and treatment appears to be more effective than late screening in preventing further renal damage. (3,5,49,50).

The lack of randomised clinical trials for screened patients to assess clinical health outcomes makes evidence-based guideline recommendations difficult.

Recommendations for paediatric screening for VUR
The parents of children with VUR should be informed that siblings and offspring have a high prevalence of VUR.
If screening is performed, siblings should be screened by renal US. VCUG is recommended if there is evidence of renal scarring on US or a history of UTI.
In older children who are toilet-trained, there is no added value in screening for VUR.

*15.3.3 **Children with febrile urinary tract infections***

VCUG is recommended at 0-2 years of age after the first proven febrile UTI. If reflux is diagnosed, further evaluation has traditionally consisted of a DMSA scan. However, it can be reserved for high-grade VUR or VUR associated with a suggestion of abnormal renal parenchyma on ultrasound, or it can be used as a baseline test to compare the consequences of potential pyelonephritic complications in the future.

An alternative “top-down” approach is also an option, as suggested by several studies in the literature. This approach carries out an initial DMSA scan close to the time of a febrile UTI, to determine the presence of pyelonephritis, which is then followed by VCUG if the DMSA scan reveals kidney involvement. A normal DMSA scan with no subsequent VCUG will fail to spot VUR in 5-27% of cases, with the missed VUR presumably being less significant. In contrast, a normal DMSA scan with no VCUG avoids unnecessary VCUG in > 50% of those screened (51-54).

*15.3.4 **Children with lower urinary tract symptoms and vesicoureteric reflux***

Detection of LUTD is essential in treating children with VUR. There are several hypotheses. For example, it is suggested that reflux with LUTD resolves faster after LUTD correction, and that patients with LUTD are at higher risk for developing UTI and renal scarring (55). Alternatively, it is possible that LUTD is secondary to VUR and that treatment of VUR therefore results in correction of LUTD. Or, it may be that there is a high co-prevalence of LUTD and VUR, but the treatment of one condition does not correct the other. In recent literature, there are no data to support any of the above hypotheses. Most studies are descriptive, uncontrolled and retrospective, and the evidence quality is low.

A recent Swedish reflux study, however, has indicated that patients who have both VUR and LUTD may have a worse final outcome after treatment, including an elevated risk for kidney damage (13). The results from the Swedish study indicate that the coexistence of both conditions should be explored in any patient who has VUR. If there are symptoms suggestive of LUTD (e.g. urgency, wetting, constipation or holding manoeuvres), an extensive history and examination, including voiding charts, uroflowmetry and residual urine determination, will reliably diagnose underlying LUTD.

In LUTD, VUR is often low grade and US findings are normal, and there is no indication for performing VCUG in all children with LUTD. Instead, it would be more rational to ask any patient with LUTD if he or she has a history of febrile UTI, because there is a greater possibility of finding VUR in such patients. However, because of the coexistence of LUTD and VUR, it would be better to do a test covering both conditions, such as a video-urodynamic study (VUDS). Any patient with LUTD and a history of febrile UTI should be investigated with a VUDS, if available. Furthermore, any child who fails standard therapy for LUTD should undergo urodynamic investigation. At this stage, combining a urodynamic study with VCUG is highly recommended.

15.4 Treatment

There are two main treatment approaches: conservative (non-surgical) and surgical.

*15.4.1 **Conservative therapy***

The objective of conservative therapy is prevention of febrile UTI. It is based on the understanding that:

- VUR resolves spontaneously, mostly in young patients with low-grade reflux. Resolution is nearly 80%

in VUR grades I and II and 30-50% in VUR grades III-V within 4-5 years of follow-up. Spontaneous resolution is low for bilateral high-grade reflux (56).

- VUR does not damage the kidney when patients are free of infection and have normal lower urinary tract function.
- There is no evidence that small scars can cause hypertension, renal insufficiency or problems during pregnancy. Indeed, these are possible only in cases of severe bilateral renal damage.
- The conservative approach includes watchful waiting, intermittent or continuous antibiotic prophylaxis, and bladder rehabilitation in those with LUTD (55,57-60).
- Circumcision during early infancy may be considered as part of the conservative approach, because it is effective in reducing the risk of infection in normal children (61).

15.4.1.1 Follow-up

Regular follow-up with imaging studies (e.g. VCUG, nuclear cystography, or DMSA scan) is part of the conservative management to monitor spontaneous resolution and kidney status. Conservative management should be dismissed in all cases of febrile breakthrough infections, despite prophylaxis, and intervention should be considered.

15.4.1.2 Continuous antibiotic prophylaxis (CAP)

The use of CAP and duration of follow-up during prophylaxis in reflux patients is another area of major controversy. Although it is difficult to make definitive recommendations based on recent literature, it is clear that antibiotic prophylaxis may not be needed in every reflux patient (58,62-64). Although there are trials showing no benefit of CAP, especially in low-grade reflux, there are also trials showing that CAP prevents further renal damage, particularly in patients with grade III and V reflux (65-69).

It is difficult and risky to select patients who do not need CAP. A safe approach would be to use CAP in most cases. Decision making may be influenced by the presence of risk factors for UTI, such as young age, high-grade VUR, status of toilet-training/LUTSs, female sex, and circumcision status. However, recent literature does not provide any reliable information about the duration of CAP in reflux patients.

A practical approach would be to use CAP until after children have been toilet-trained and ensuring that there is no LUTD. Active surveillance of UTI is needed after CAP is discontinued. The follow-up scheme and the decision to perform an antireflux procedure or discontinuation of CAP may also depend on personal preferences and the attitude of patients and parents. It is strongly advised that the advantages and disadvantages should be discussed in detail with the family.

15.4.2 ***Surgical treatment***

Surgical treatment can be carried out by endoscopic injection of bulking agents or ureteral reimplantation.

15.4.2.1 Subureteric injection of bulking materials

With the availability of biocompatible substances, subureteric injection of bulking materials has become increasingly popular because it is minimally invasive and performed on an outpatient basis. Using cystoscopy, bulking materials are injected beneath the intramural part of the ureter in a submucosal location. The injected bulking agent elevates the ureteral orifice and the distal ureter, so that coaptation is increased. This results in narrowing of the lumen, which prevents reflux of urine into the ureter, while still allowing its antegrade flow. With the availability of biodegradable substances, endoscopic subureteric injection of bulking agents has become an alternative to long-term antibiotic prophylaxis and surgical intervention in the treatment of VUR in children.

Several bulking agents have been used over the past two decades, including polytetrafluoroethylene (PTFE or Teflon), collagen, autologous fat, polydimethylsiloxane, silicone, chondrocytes, and more recently, a solution of dextranomer/hyaluronic acid (Deflux).

Although the best results have been obtained with PTFE (70), due to concerns about particle migration, PTFE has not been approved for use in children (71). Although they are all biocompatible, other compounds such as collagen and chondrocytes have failed to provide a good outcome. Deflux was approved by the US FDA in 2001 for the treatment of VUR in children. Initial clinical trials have demonstrated that this method is effective in treating reflux (72). Studies with long term follow-up have shown that there is a high recurrence rate which may go up to 20% in 2 years (62).

In a meta-analysis (73) including 5527 patients and 8101 renal units, the reflux resolution rate (by ureter)

following one treatment for grades I and II reflux was 78.5%, 72% for grade III, 63% for grade IV, and 51% for grade V. If the first injection was unsuccessful, the second treatment had a success rate of 68% and the third treatment 34%. The aggregate success rate with one or more injections was 85%. The success rate was significantly lower for duplicated (50%) versus single (73%) systems, and neuropathic (62%) versus normal (74%) bladders.

Clinical validation of the effectiveness of antireflux endoscopy is currently hampered by the lack of methodologically appropriate studies. In the most recent prospective, randomised trials comparing three treatment arms (I, endoscopic injection; II, antibiotic prophylaxis; III, surveillance without antibiotic prophylaxis) in 203 children aged 1-2 years with grade III/IV reflux, endoscopic treatment gave the highest resolution rate of 71% compared to 39% and 47% for treatment arms II and III, respectively, after 2 years' follow-up. The recurrence rate at 2 years after endoscopic treatment was 20%. The occurrence of febrile UTIs and scar formation was highest in the surveillance group at 57% and 11%, respectively. New scar formation rate was higher with endoscopic injection (7%) compared with antibiotic prophylaxis (0%) (74). Longer follow-up studies are needed to validate these findings.

15.4.2.2 Open surgical techniques

Various intra- and extravesical techniques have been described for the surgical correction of reflux. Although different methods have specific advantages and complications, they all share the basic principle of lengthening the intramural part of the ureter by submucosal embedding of the ureter. All techniques have been shown to be safe with a low rate of complications and excellent success rates (92-98%) (75).

The most popular and reliable open procedure is cross trigonal reimplantation described by Cohen. The main concern with this procedure is the difficulty of accessing the ureters endoscopically if needed when the child is older. Alternatives are suprahiatal reimplantation (Politano-Leadbetter technique) and infrahiatal reimplantation (Glenn-Anderson technique). If an extravesical procedure (Lich-Gregoir) is planned, cystoscopy should be performed preoperatively to assess the bladder mucosa and the position and configuration of the ureteric orifices. In bilateral reflux, an intravesical antireflux procedure may be considered, because simultaneous bilateral extravesical reflux repair carries an increased risk of temporary postoperative urine retention (76). Overall, all surgical procedures offer very high and similar success rates for correcting VUR.

15.4.2.3 Laparoscopy

There have been a considerable number of case series of transperitoneal extravesical and pneumovesicoscopic intravesical ureteral reimplantation, which have shown the feasibility of the techniques. Today, both conventional and robot-assisted laparoscopic approaches present comparable outcomes to their open surgical counterparts in terms of successful resolution of reflux. Further studies are needed to define the costs and benefits of both approaches.

The major shortcoming of the new techniques seems to be the longer operative times, which hinders their wider acceptance. Also, laparascopic approaches are more invasive than endoscopic correction and their advantages over open surgery are still debated. Therefore, at present, a laparoscopic approach cannot be recommended as a routine procedure. It can be offered as an alternative to the parents in centres where there is enough experience (61,77-83).

15.5 Recommendations for the management of vesicoureteric reflux in childhood

Regardless of the grade of reflux or presence of renal scars, all patients diagnosed within the first year of life should be treated initially with CAP. During early childhood, the kidneys are at higher risk of developing new scars. Immediate, parenteral antibiotic treatment should be initiated for febrile breakthrough infections. Definitive surgical or endoscopic correction is the preferred treatment in patients with frequent breakthrough infections (78).
Surgical correction should be considered in patients with persistent high-grade reflux (grades IV/V). There is no consensus about the timing and type of surgical correction. The outcome of open surgical correction is better than endoscopic correction for higher grades of reflux, whereas satisfactory results can be achieved by endoscopic injection for lower grades.
There is no evidence that correction of persistent low-grade reflux (grades I-III) without symptoms and normal kidneys offers a significant benefit. These patients may be candidates for endoscopic treatment.
In all children presenting at age 1-5 years, CAP is the preferred option for initial therapy. For those with high-grade reflux or abnormal renal parenchyma, surgical repair is a reasonable alternative. In patients with lower grades of reflux and without symptoms, close surveillance without antibiotic prophylaxis may be an option.
A detailed investigation for the presence of LUTD should be performed in all children after toilet-training. If LUTD is found, the initial treatment should always be for LUTD.
If parents prefer definitive therapy to conservative management, surgical correction may be considered. Endoscopic treatment is an option for all children with low grades of reflux.
The traditional approach of initial medical treatment after diagnosis and shifting to interventional treatment in case of breakthrough infections and new scar formation needs to be challenged, because the treatment should be tailored to different risk groups.
The choice of management depends on the presence of renal scars, clinical course, grade of reflux, ipsilateral renal function, bilaterality, bladder function, associated anomalies of the urinary tract, age, compliance, and parental preference (79). Febrile UTI, high-grade reflux, bilaterality, and cortical abnormalities are considered to be risk factors for possible renal damage. The presence of LUTD is an additional risk factor for new scars.
In high-risk patients who already have renal impairment, a more aggressive, multidisciplinary approach is needed.

Table 10: Management and follow-up according to different risk groups

Risk Groups	Presentation	Initial treatment	Comment	Follow-up
High	Symptomatic male or female patients after toilet-training with high-grade reflux (grades IV-V), abnormal kidneys and LUTD	Initial treatment is always for LUTD with CAP; intervention may be considered in cases of BT infections or persistent reflux	Greater possibility of earlier intervention	More aggressive follow-up for UTI and LUTD; full re-evaluation after 6 months
High	Symptomatic male or female patients after toilet-training with high-grade reflux (grade IV-V), abnormal kidneys and no LUTD	Intervention should be considered	Open surgery has better results than endoscopic surgery	Post-operative VCUG on indication only; follow-up of kidney status until after puberty
Moderate	Symptomatic male or female patients before toilet-training, with high-grade reflux and abnormal kidneys	CAP is the initial treatment. Intervention may be considered in cases of BT infections or persistent reflux	Spontaneous resolution is higher in males	Follow-up for UTI/ hydronephrosis; full re-evaluation after 12-24 months
Moderate	Asymptomatic patients (PNH or sibling) with high-grade reflux and abnormal kidneys	CAP is the initial treatment. Intervention may be considered in cases of BT, infections or persistent reflux		Follow-up for UTI/ hydronephrosis; full re-evaluation after 12-24 months

Moderate	Symptomatic male or female patients after toilet-training, with high-grade reflux and normal kidneys with LUTD	Initial treatment is always for LUTD with CAP. Intervention may be considered in cases of BT, infections or persistent reflux	In case of persistent LUTD, despite urotherapy, intervention should be considered. The choice of intervention is controversial	Follow-up for UTI and LUTD, kidney status; full re-evaluation after successful urotherapy
Moderate	Symptomatic male or female patients after toilet-training with low-grade reflux, abnormal kidneys with or without LUTD	Choice of treatment is controversial. Endoscopic treatment may be an option. LUTD treatment should be given if needed.		Follow-up for UTI, LUTD, and kidney status until after puberty
Moderate	All symptomatic patients with normal kidneys, with low-grade reflux, with LUTD	Initial treatment is always for LUTD with or without CAP		Follow-up for UTI and LUTD
Low	All symptomatic patients with normal kidneys, with low-grade reflux, with no LUTD	No treatment or CAP	If no treatment is given, parents should be informed about risk of infection	Follow-up for UTI
Low	All asymptomatic patients with normal kidneys with low-grade reflux	No treatment or CAP in infants	If no treatment is given, parents should be informed about risk of infection	Follow-up for UTI

PNH = prenatal diagnosed hydronephrosis.

16. URINARY STONE DISEASE

16.1 Background

Paediatric stone disease is an important clinical problem in paediatric urology practice. Because of its recurrent nature, every effort should be made to discover the underlying metabolic abnormality so that it can be treated appropriately. Obtaining a stone-free state with interventional management and close follow-up are of utmost importance.

Paediatric stone disease has its own unique features, which are different in both presentation and treatment compared to stone disease in adults. In contrast to adults with stone disease who are more likely to be male, boys and girls are affected almost equally. Most paediatric stones are located in the upper urinary tract. However, bladder stones are still common in underdeveloped areas of the world and are usually ammonium acid urate and uric acid stones, strongly implicating dietary factors (1).

The incidence and characteristics of stones show a wide geographical variation in children. Although urinary stone disease is generally considered to be a relatively rare disease, it is quite common in some parts of the world. Paediatric stone disease is endemic in Turkey, Pakistan and in some South Asian, African and South American states. In the UK and other European countries, 75% of calculi in children are composed of organic matrix and struvite, with many coinciding with Proteus infection and urinary tract anomalies (2).

16.2 Stone formation mechanisms, diagnosis of causative factors and medical treatment for specific stone types

Urinary stone formation is the result of a complex process involving metabolic, anatomical factors and presence of infection.

When supersaturated in urine calcium, oxalate, uric acid and cystine molecules may cause stone formation. A decreased concentration of crystallisation inhibitors (citrate, magnesium, pyrophosphate, macromolecules and glycosaminoglycans) may sometimes be the sole factor playing a role in the formation of urinary stones. Urinary pH changes also affect stone formation.

An impaired flow of urine due to abnormal morphology may facilitate stasis and increase the concentration of stone-forming substances.

16.2.1 ***Calcium stones***

Calcium stones are usually made from calcium oxalate or calcium phosphate. Either supersaturation of calcium (hypercalciuria) and oxalate (hyperoxaluria) or decreased concentration of inhibitors like citrate (hypocitraturia) play a major role in calcium oxalate stone formation.

Hypercalciuria. This is defined by a 24-hour urinary calcium excretion of more than 4 mg/kg/day in a child weighing less than 60 kg. In infants younger than 3 months, 5 mg/kg/day is considered to be the upper limit of normal for calcium excretion (3).

Hypercalciuria can be classified as either idiopathic or secondary. Idiopathic hypercalciuria is diagnosed when clinical, laboratory, and radiographic investigations fail to delineate an underlying cause. Secondary hypercalciuria occurs when a known process produces excessive urinary calcium. In secondary (hypercalcaemic) hypercalciuria, a high serum calcium level may be due to increased bone resorption (hyperparathyroidism, hyperthyroidism, immobilisation, acidosis, metastatic disease) or gastrointestinal hyperabsorption (hypervitaminosis D) (4).

A good screening test for hypercalciuria compares the ratio of urinary calcium to creatinine. The normal calcium-to-creatinine ratio in children is less than 0.2. If the calculated ratio is higher than 0.2, repeat testing is indicated. Neonates and infants have a higher calcium excretion and lower creatinine excretion than older children (3,4). If the follow-up ratios are normal, then no additional testing for hypercalciuria is needed. However, if the ratio remains elevated, a timed 24-hour urine collection should be obtained and the calcium excretion calculated.

The 24-hour calcium excretion test is the criterion standard for the diagnosis of hypercalciuria. If calcium excretion is higher than 4 mg/kg/day (0.1 mmol/kg/day), the diagnosis of hypercalciuria is confirmed and further evaluation is warranted. Further evaluation includes levels of serum bicarbonate, creatinine, alkaline phosphatase, calcium, magnesium, pH, and parathyroid hormone. Freshly voided urine should be measured for pH (3-6).

A 24-hour urine collection should also be collected for measurement of calcium, phosphorus, sodium, magnesium, citrate and oxalate. Meanwhile dietary manipulations should be tried to normalise urine calcium (6).

Initial management is always to increase fluid intake and urinary flow. Dietary modification is a mandatory part of effective therapy. The child should be referred to a dietician to assess accurately the daily intake of calcium, animal protein, and sodium. Dietary sodium restriction is recommended as well as

maintenance of calcium intake consistent with the daily needs of the child (7).

A brief trial of a low-calcium diet can be carried out to determine if exogenous calcium intake is contributing to a high urinary calcium. However, great caution should be used when trying to restrict calcium intake for long periods (LE: 3; GR: B).

Hydrochlorothiazide and other thiazide-type diuretics may be used to treat hypercalciuria at a dosage of 1-2 mg/kg/day (2,8) (LE: 3; GR: C). Citrate therapy is also useful if citrate levels are low or if hypercalciuria persists, despite other therapies (2,9) (LE: 4; GR: C).

Hyperoxaluria. Oxalic acid is a metabolite excreted by the kidneys. Only 10-15% of oxalate comes from diet. Normal school children excrete less than 50 mg (0.57 mmol)/1.73m2/day (2,10), while infants excrete four times as much. Hyperoxaluria may result from increased dietary intake, enteric hyperabsorption (as in short bowel syndrome) or an inborn error of metabolism.

In primary hyperoxaluria, one of the two liver enzymes that play a role in the metabolism of oxalate may be deficient. In primary hyperoxaluria there is increased deposition of calcium oxalate in the kidney and in urine. With increased deposition of calcium oxalate in the kidneys, renal failure may ensue in resulting deposition of calcium oxalate in other tissues. The diagnosis is made upon laboratory findings of severe hyperoxaluria and clinical symptoms. The definitive diagnosis requires liver biopsy to assay the enzyme activity.

Other forms of hyperoxaluria, as mentioned earlier, may be due to hyperabsorption of oxalate in inflammatory bowel syndrome, pancreatitis and short bowel syndrome. Yet, the majority of children who have high levels of oxalate excretion in urine may not have any documented metabolic problem or any dietary cause. This is known as idiopathic 'mild' hyperoxaluria, with urine oxalate levels elevated only mildly in these cases. The treatment of hyperoxaluria consists of the promotion of high urine flow, restriction of dietary oxalate and regular calcium intake. Pyridoxine may be useful in reducing urine levels, especially in primary hyperoxaluria (2,10) (LE: 4; GR: C).

Hypocitraturia. Citrate is a urinary stone inhibitor. Citrate acts by binding to calcium and by directly inhibiting the growth and aggregation of calcium oxalate as well as calcium phosphate crystals. Thus, low urine citrate may be a significant cause of calcium stone disease. In adults, hypocitraturia is the excretion of citrate in urine of less than 320 mg/day (1.5 mmol/day) for adults; this value must be adjusted for children depending on body size (11,12).

Hypocitraturia usually occurs in the absence of any concurrent symptoms or any known metabolic derangements. It may also occur in association with any metabolic acidosis, distal tubular acidosis or diarrhoeal syndromes.

Environmental factors that lower urinary citrate include a high protein intake and excessive salt intake. Many reports emphasize the significance of hypocitraturia in paediatric calcium stone disease. The presence of hypocitraturia ranges from 30% to 60% in children with calcium stone disease.

Due to the increased stone risk in hypocitraturia, the restoration of normal citrate levels is advocated to reduce stone formation. Although some studies have shown that citrate replacement therapy reduces the risk of stone formation in an adult population, there are few relevant studies in children. Hypocitraturia is treated by potassium citrate at a starting dose of 1 mEq/kg, given in two divided doses (12) (LE: 3; GR: B).

16.2.2 ***Uric acid stones***

Uric acid stones are responsible for urinary calculi in 4-8% of children. Uric acid is the end product of purine metabolism. Hyperuricosuria is the main cause of uric acid stone formation in children. A daily output of uric acid of more than 10 mg/kg/day is considered to be hyperuricosuria (2).

The formation of uric acid stones is dependent, mainly on the presence of acidic urinary composition.

Uric acid dissociation and solubility is strongly reduced at pH of less than 5.8. As the pH becomes more alkaline, uric acid crystals become more soluble and the risk of uric acid stone formation is reduced.

In the familial or idiopathic form of hyperuricosuria, children usually have normal serum uric acid levels. In other children, it can be caused by uric acid overproduction secondary to inborn errors of metabolism, myeloproliferative disorders or other causes of cell breakdown. Hyperuricosuria is also caused by high purine and protein intake. Although hyperuricosuria is a risk factor for calcium oxalate stone formation in adults, this does not appear to be a significant risk factor in children.

Uric acid stones are non-opaque stones. Plain X-rays are insufficient to show uric acid stones, and renal sonography and spiral CT are used for diagnosis.

Alkalinisation of urine is the mainstay of therapy and prevention for uric acid stones. Citrate preparations are useful as alkalinising agents. Maintaining a urine pH of 6 to 6.5 is sufficient to prevent uric acid stones (2).

16.2.3 ***Cystine stones***

Cystinuria is the cause of cystine stone formation and accounts for 2-6% of all urinary stones in children. Cystinuria is an incompletely recessive autosomal disorder characterised by failure of renal tubules to reabsorb four basic amino acids: cystine, ornithine, lysine and arginine.

Of these four amino acids, only cystine has poor solubility in urine, so that only cystine stones may form in the case of excessive excretion in urine. Cystine solubility is pH-dependent, with cystine precipitation beginning at pH levels < 7.0. Other metabolic conditions, such as hypercalciuria, hypocitraturia and hyperuricosuria, may accompany cystinuria, so leading to the formation of mixed-composition stones.

Cystine stones are faintly radiolucent and may be difficult to show on regular radiograph studies. They are also hard in texture and more difficult to disintegrate by extracorporeal shock wave lithotripsy (SWL).

The medical treatment for cystine stones aims to reduce cystine saturation in urine and increase its solubility. The initial treatment consists of maintaining a high urine flow and the use of alkalinising agents, such as potassium citrate to maintain urine pH at above 7.0. If this treatment fails, the use of α-mercaptopropionil glycine or D-penicillamine may reduce cystine levels in urine and prevent stone formation. Use of these drugs can be associated with severe side effects, such as bone marrow depression and nephrotic syndrome (13) (LE: 4; GR: C).

16.2.4 Infection stones (struvite stones)

Infection-related stones constitute nearly 5% of urinary stones in children. Bacteria capable of producing urease enzyme (Proteus, Klebsiella, Pseudomonas) are responsible for the formation of such stones.

Urease converts urea into ammonia and bicarbonate, so alkalinising the urine and further converting bicarbonate into carbonate. In the alkaline environment, triple phosphates form, eventually resulting in a supersaturated environment of magnesium ammonium phosphate and carbonate apatite, which in turn leads to stone formation.

In addition to bacterial elimination, stone elimination is essential for treatment, as stones will harbour infection and antibiotic treatment will not be effective. Consideration should be given to investigating any congenital problem that causes stasis and infection. Genitourinary tract anomalies predispose to formation of such stones.

16.3 Clinical presentation

Presentation tends to be age-dependent, with symptoms such as flank pain and haematuria being more common in older children. Non-specific symptoms (e.g. irritability, vomiting) are common in very young children. Haematuria, usually gross, occurring with or without pain, is less common in children. However, microscopic haematuria may be the sole indicator and is more common in children. In some cases, urinary infection may be the only finding leading to radiological imaging in which a stone is identified (14,15).

16.4 Diagnosis

16.4.1 ***Imaging***

Generally, ultrasonography should be used as a first study. Renal ultrasonography is very effective for identifying stones in the kidney. Many radiolucent stones can be identified with a simple abdominal flat-plate examination.

If no stone is found but symptoms persist, spiral CT scanning is indicated. The most sensitive test for identifying stones in the urinary system is non-contrast helical CT scanning. It is safe and rapid, with 97% sensitivity and 96% specificity (16-18) (LE: 2; GR: B).

Intravenous pyelography is rarely used in children, but may be needed to delineate the caliceal anatomy prior to percutaneous or open surgery.

16.4.2 ***Metabolic evaluation***

Due to the high incidence of predisposing factors for urolithiasis in children and high stone recurrence rates, every child with urinary stone should be given a complete metabolic evaluation (1,19,20).

Metabolic evaluation includes:

- Family and patient history of metabolic problems.
- Analysis of stone composition (following stone analysis, metabolic evaluation can be modified according to the specific stone type).
- Electrolytes, BUN, creatinine, calcium, phosphorus, alkaline phosphatase, uric acid, total protein, carbonate, albumin, and parathyroid hormone (if there is hypercalcaemia).
- Spot urinalysis and culture, including ratio of calcium to creatinine.
- Urine tests, including a 24-hour urine collection for calcium, phosphorus, magnesium, oxalate, uric acid citrate, cystine, protein, and creatinine clearance.

Figure 4 provides an algorithm of how to perform metabolic investigations in urinary stone disease in children and to plan medical treatment accordingly.

16.5 Management

With the advance of technology stone management has changed from open surgical approach to endoscopic techniques that are less invasive. Deciding the form of treatment depends on the number, size, location, composition and anatomy of the urinary tract (19,21,22).

Currently, most paediatric stones can easily be managed by SWL. Endoscopic treatment can be applied easily for ureteric and bladder stones. Percutaneous removal of stones is also possible for kidney stones in children. Only a small portion of children will need an open surgical approach.

16.5.1 ***Extracorporeal shock wave lithotripsy (SWL)***

Many reports confirm that shock wave lithotripsy (SWL) can be performed in children with no suspicion of long-term morbidity of the kidney (23-28).

The mean number of shock waves for each treatment is about 1800 and 2000 (up to 4000 if needed) and the mean power set varies between 14 kV and 21 kV. The use of ultrasonography and digital fluoroscopy has significantly decreased the radiation exposure and it has been shown that children are exposed to significantly lower doses of radiation compared to adults (21,29,30). Concerns about anaesthesia do not seem to be a problem any more because of advances in technique and medication, even in the infant period. The type of anaesthesia should be general or dissociative for children under 10 years of age, whereas conventional intravenous sedation or patient-controlled analgesia is an option for older children who are able to co-operate (31) (LE: 2b).

Stone-free rates are significantly affected by various factors. Regardless of the location, as the stone size increases, the stone-free rates decrease and re-treatment rate increases. The stone-free rates for < 1 cm, 1-2 cm, > 2 cm and overall were reported as nearly 90%, 80%, 60% and 80%, respectively. As the stone size increases, the need for additional sessions increases (21,29,30,32-36).

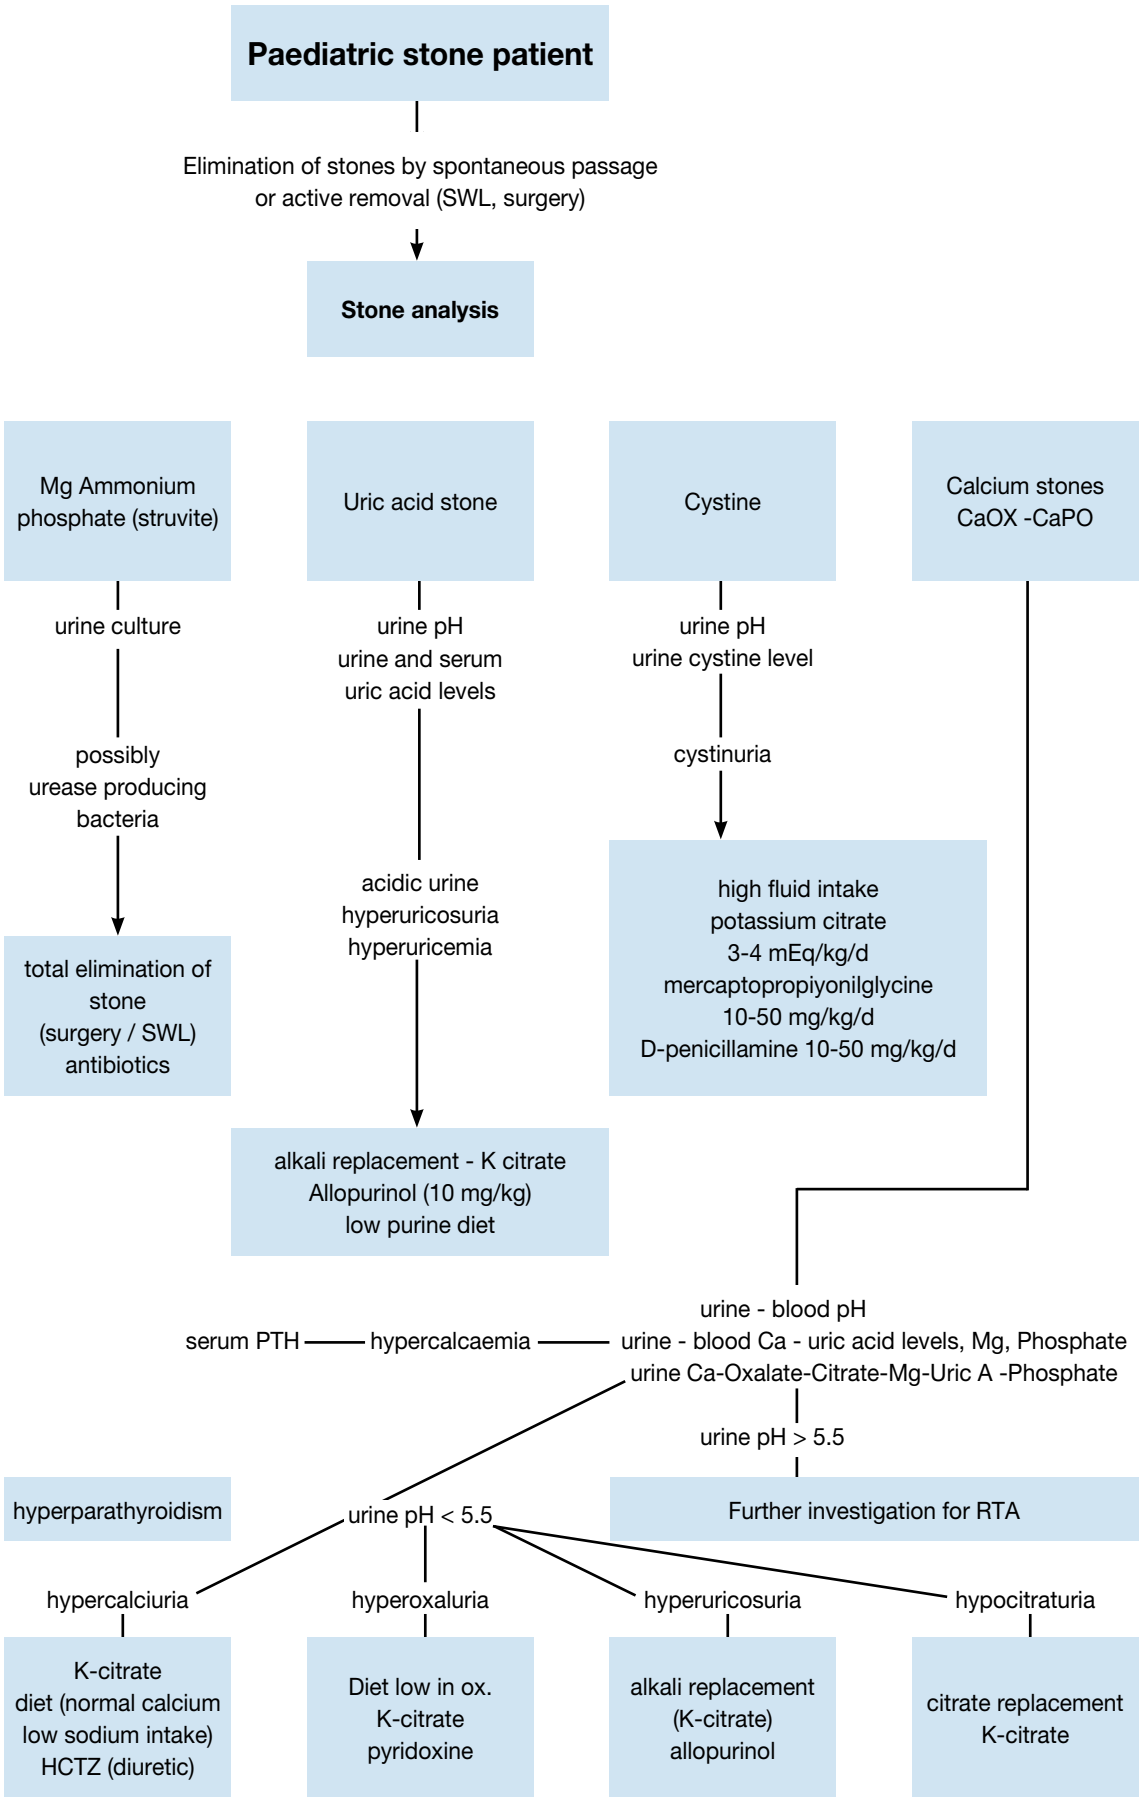
Localisation of the calculi has been described as a significant factor affecting the success rates in different studies. Stones in renal pelvis and upper ureter seem to respond better to SWL. In these mentioned sites, the stone clearance rates are nearly 90%. However, SWL was found to be less effective for caliceal stones particularly the lower caliceal stones. Several studies reported stone-free rates for isolated lower caliceal stones varying between 50% and 62% (37-40).

SWL treatment can also be used to treat ureteral calculi. However, this is a more specific issue and with controversies. The success rates with SWL are less for distal ureteric stones. There may also be technical problems with localisation and focusing of ureteric stones in children (37,39,40-42).

The type of machine used has a strong effect on success rates and complications. First-generation machines can deliver more energy to a larger focal zone, resulting in higher fragmentation rates in a single therapy. However, general anaesthesia is usually required due to the intolerable discomfort associated with a first-generation machine. Later-generation machines have a smaller focal zone and deliver less energy, and have a lower risk of pulmonary trauma. However, additional treatments may be needed with later-generation machines. The success rate is higher in younger children (35).

Although stenting does not affect stone clearance, overall complication rates are higher and hospital stay is longer in the unstented patient (34,35). Stenting is essential in solitary kidneys undergoing SWL treatment. Children with a large stone burden have a high risk of developing Steinstrasse and urinary obstruction and should be followed more closely for the risk of prolonged urinary tract obstruction after SWL. Post-SWL stent or nephrostomy tube placement may be needed in prolonged obstruction (20,36).

Figure 4: Algorithm for metabolic investigations in urinary stone disease in children



SWL = extracorporeal shockwave lithotripsy; HCTZ = hydrochlorothiazide; PTH = parathyroid hormone; RTA = renal tubular acidosis.

SWL in children may have complications, but these are often self-limiting and transient. The most frequently observed complications are:

- Renal colic;
- Transient hydronephrosis;
- Dermal ecchymosis;
- Urinary tract infection;
- Formation of Steinstrasse;
- Sepsis;
- Rarely, haemoptysis.

In children with sterile pre-operative urine cultures, antibiotic prophylaxis to decrease the infectious complications is not recommended (43). However, every effort should be made to sterilise the urine before performing ESWL, ureteroscopy (URS), or percutaneous nephrolithotomy.

16.5.2 ***Percutaneous nephrolithotomy***

SWL is the first choice for treating most renal paediatric stones. However, percutaneous renal surgery can be used for larger and complex stones. Pre-operative evaluation, indication and surgical technique are similar in children compared to adults. PCNL is used as monotherapy in most cases, but is also used as an adjunctive procedure to other therapies.

The use of adult-sized instruments, in association with an increased number of tracts and sheath size, seems to increase the blood loss. However, small-calibre instruments have now been developed and there are some advantages for PCNL in children (particularly smaller children), such as smaller skin incision, single-step dilation and sheath placement, good working access for paediatric instruments, variable length, and lower cost (43,44). Now that appropriate-size instruments are available, age is no longer a limiting factor for PCNL.

As monotherapy, PCNL is considerably effective and safe. The reported stone-free rates in the recent literature are between 86.9% and 98.5% after a single session. These rates increase with adjunctive measures, such as second-look PCNL, SWL and URS. Even in complete staghorn cases, a clearance rate of 89% has been achieved following a single session (45-48,50,51).

The most frequently reported complications of PCNL in children are bleeding, post-operative fever or infection, and persistent urinary leakage. Bleeding requiring transfusion is reported in 0.4% to 23.9% and is closely associated with stone burden, operative time, sheath size and number of tracts. Post-operative fever and infection has been reported up to 29.3% and 5.5%, respectively; the origin of fever is not thought to be the infection (49-56).

The mean post-operative hospital stay is similar to adults. It is reported as 3 to 4 days in all the previously mentioned studies and is much shorter than open surgery. The less invasive nature of this technique has made it a promising alternative to open surgery for treating renal stones in children (LE: 2; GR: B).

16.5.3 ***Ureterorenoscopy***

The increasing availability of smaller size endourological equipment has made it possible to manage paediatric ureteral stones using endoscopic techniques.

The technique used in children is similar to the one used in adults. It is strongly recommended that guide wires are used and the procedure is performed using direct vision. Routine balloon dilation of ureterovesical junction and ureteral stenting are controversial. In general, ureteric dilatation is being done less and less and only in selected cases. The general tendency is to use hydrodilation more as it is shown to be as effective (57-60,43,61-63) (LE: 3; GR: B).

Different lithotripsy techniques, including ultrasonic, pneumatic and laser lithotripsy, have all been shown to be safe and effective. Because of the smaller size of the probes, laser energy is easier to use in smaller instruments and is more useful for paediatric cases (50,58,60,64-70).

All studies reporting the use of endoscopy for ureteric stones in children have clearly demonstrated that there is no significant risk of ureteric strictures or reflux with this mode of therapy (LE: 1; GR: A).

A multi-institutional study on the use of semi-rigid ureteroscopy for ureteral calculi in children has revealed that the procedure is effective with a 90% stone-free rate and efficacy quotient. The study also focused on the factors affecting the complication rates. The authors found that although operating time, age, institutional experience, orifice dilation, stenting and stone burden were significant on univariate analysis, multivariate analysis revealed that operating time was the only significant parameter affecting the complication rate (71).

A recent literature review contains a growing number of case series on the use of flexible ureterorenoscopic interventions in children. Both intrarenal and ureteric stones can be treated using this approach (72-76). In these series, the authors generally did not use active orifice dilation, but attempted to use a ureteral sheath where possible. However, an important problem was the inability to obtain retrograde access to the ureter

in approximately half of the cases (74,75). This problem can be overcome by stenting and leaving the stent indwelling for passive dilation of the orifice, and performing the procedure in a second session. The success rates varied between 60 and 100%, with a negligible number of complications (72-74,76). The need for additional procedures was related to stone size (72). Although the use of flexible instruments seems feasible for the present time, more data are needed for comparison with other endourological modalities in children.

*16.5.4 **Open stone surgery***

Most stones in children can be managed by SWL and endoscopic techniques. Yet in some situations, open surgery is inevitable. Good candidates for open stone surgery include very young children with large stones and/or a congenitally obstructed system which also requires surgical correction. Severe orthopaedic deformities may limit positioning for endoscopic procedures. Open surgery would also be a necessity for such children.

Bladder stones in children can usually be managed by endoscopic techniques. Open surgery may also be used for very large bladder stones or for bladder stones caused by an anatomical problem.

Recommendations for interventional management are given in Table 11.

Table 11: Recommendations for interventional management in paediatric stones

Stone size and localisation*	Primary treatment option	LE	Secondary treatment options	Comment
Staghorn stones	PCNL	2b	Open/SWL	Multiple sessions and accesses with PCNL maybe needed Combination with SWL may be useful
Pelvis < 10 mm	SWL	1a	RIRS/PCNL	
Pelvis 10-20 mm	SWL	2b	PCNL/Open	Multiple sessions with SWL may be needed PCNL has similar recommendation grade
Pelvis > 20 mm	PCNL	2b	SWL/Open	Multiple sessions with SWL may be needed
Lower pole calix < 10 mm	SWL	2c	RIRS/PCNL	Anatomical variations are important for complete clearance after SWL
Lower pole calix > 10 mm	PCNL	2b	SWL	Anatomical variations are important for complete clearance after SWL
Upper ureteric stones	SWL	2b	PCNL/URS/ Open	
Lower ureteric stones	URS	1a	SWL/Open	Additional intervention need is high with SWL
Bladder stones	Endoscopic	2b	Open	Open is easier and with less operative time with large stones

** Cystine and uric acid stones excluded.*
PCNL = percutaneous nephrolithostomy; SWL = shock-wave lithotripsy; RIRS = retrograde intrarenal surgery; URS = ureteroscopy.

17. OBSTRUCTIVE PATHOLOGY OF RENAL DUPLICATION: URETEROCELE AND ECTOPIC URETER

17.1 Background

Ureterocele and ectopic ureter are the two main anomalies associated with complete renal duplication, but they also occur in a single system. At present, antenatal ultrasonography detects both conditions in the majority of cases if associated with obstruction, and diagnosis is confirmed after birth by further examination. Later in life, these anomalies are revealed by clinical symptoms: UTI, pain, calculus formation, disturbances of micturition, and urinary incontinence. There is a wide variation of symptoms in patients with ureterocele (from the asymptomatic patient to urosepsis, urinary retention and upper tract dilatation after birth).

17.1.1 ***Ureterocele***

Ureterocele is 4-7 times more frequent in female than in male patients; the overall incidence in autopsies is around 1 in 4,000 children. Around 80% is associated with the upper pole ureter in duplicated systems and 20% in single systems. About 10% of ureteroceles are bilateral (1).

17.1.2 ***Ectopic ureter***

Ectopic ureter is less frequent than ureterocele (10 in 19,046 autopsies), but is also more common in female patients (male to female ratio, 1:5). Some remain asymptomatic, therefore, the true incidence is difficult to determine (2). Eighty per cent of ectopic ureters are associated with complete renal duplication, however, in male patients, most ectopic ureters are associated with a single system (3,4).

17.2 Definition and classification

17.2.1 ***Ureterocele***

Ureterocele is a cystic dilatation that develops in the intravesical part of the submucosal ureter. The aetiology remains unclear (5-7). A single-system uretereocele is associated with a kidney with one ureter, and in duplex systems, the ureterocele belongs to the upper pole.

Ureteroceles usually cause obstruction of the upper pole, but the degree of obstruction and functional impairment is variable according to the type of ureterocele and upper pole dysplasia. In the orthotopic form, there is often no or only mild obstruction, and frequently the function of the moiety is normal or slightly impaired, and the corresponding ureter may be dilated. Cystic renal dysplasia is also associated with a single system ureterocele (8,9). Vesicoureteral reflux can be observed in 50% on the ipsilateral side and 20% on the contralateral side. Reflux into the ureterocele is uncommon (10).

In the ectopic form, the upper pole is altered, frequently dysplastic, and hypo-functional or non-functional (11,12). The corresponding ureter is a megaureter. In the caeco-ureterocele (see definition below), the upper pole of the renal duplication is dysplastic and non-functional.

17.2.1.1 Ectopic (extravesical) ureterocele

If any portion of the ureterocele extends into the bladder neck or urethra, it is called an ectopic ureterocele. Ectopic ureterocele is the most common form of ureterocele (> 80%). It can be voluminous, dissociating the trigone and slipping into the urethra, and may prolapse through the urethral meatus (caeco-ureterocele). The ureterocele orifice is tight, and located in the bladder itself or below the neck. The ureter corresponding to the lower pole moiety is raised by the ureterocele and is frequently refluxing or compressed by the ureterocele, leading to an obstructive megaureter. A contralateral renal duplication is associated in 50% of cases. Occasionally, large ureteroceles are responsible for reflux or obstruction of the contralateral upper tract.

17.2.1.2 Orthotopic (intravesical) ureterocele

The intravesical or orthotopic ureterocele is completely located in the bladder. Intravesical ureteroceles are mostly combined with a single kidney system and account for about 15% of cases. It is seen more in older children or adults.

17.2.2 ***Ectopic ureter***

The term ectopic ureter describes a ureter with the orifice located at the bladder neck, in the urethra, or outside the urinary tract. The ureter can drain the upper pole of a duplex or single system. There is a fundamental difference between the sexes. In boys, the ectopic orifice is never below the external sphincter.

In girls, the ureteral orifice may be located (13):

- in the urethra, from the bladder neck to the meatus (35%)
- in the vaginal vestibule (34%)
- in the vagina (25%)
- in the uterus and Fallopian tube (6%).

In boys, the ureteral orifice may be located (13):

- in the posterior urethra (47%)
- in the prostatic utricle (10%)
- in the seminal vesicles (33%)
- in the vas deferens or ejaculatory ducts (10%).

17.3 Diagnosis

17.3.1 ***Ureterocele***

Prenatal ultrasound easily reveals voluminous obstructive ureteroceles (14,15). In cases with a small upper pole or a slightly obstructive ureterocele, prenatal diagnosis is difficult. If prenatal diagnosis is impossible, the following clinical symptoms, besides incidental findings, can reveal the congenital anomaly at birth or later:

- At birth, a prolapsed and sometimes strangulated ureterocele may be observed in front of the urethral orifice. In a newborn boy, it might cause acute urinary retention, simulating urethral valves.
- The early symptom of pyelonephritis in either sex may lead to the diagnosis.
- Later symptoms can include dysuria, recurrent cystitis and urgency.

In cases of prenatal diagnosis at birth, ultrasonography confirms the ureteral dilatation that ends at the upper pole of a renal duplication. It also demonstrates the presence of a ureterocele in the bladder, with a dilated ureter behind the bladder.
At this point, it is important to assess the function of the upper pole using nuclear renography of the region of interest. This is best assessed with DMSA (16-18). Magnetic resonance urography may visualise the morphological status of the upper pole and lower moieties and of the contralateral kidney. Based on the prevalence of high-grade reflux, VCUG is mandatory for identifying ipsilateral or contralateral reflux, and assessing the degree of intraurethral prolapse of the ureterocele (19).

Urethrocystoscopy may reveal the pathology in cases where it is difficult to make the differential diagnosis between ureterocele and ectopic megaureter.

17.3.2 ***Ectopic ureter***

Most of the ectopic megaureters are diagnosed primarily by ultrasonography. In some cases, clinical symptoms can lead to diagnosis:

- In neonates: dribbling of urine, pyuria, and acute pyelonephritis.
- In young girls: permanent urinary incontinence besides normal voiding, or significant vaginal discharge as the equivalent of incontinence; an ectopic orifice may be found in the meatal region (20).
- In pre-adolescent boys: epididymitis is the usual clinical presentation and the seminal vesicle may be palpable.

Ultrasonography, radionuclide studies (DMSA), VCUG, magnetic resonance urography, high-resolution MR imaging, and cystoscopy are the diagnostic tools to assess function, to detect reflux and rule out ipsilateral compression of the lower pole and urethral obstruction (21). In some cases, the large ectopic ureter presses against the bladder and can look like a pseudo-ureterocele (22,23).

Girls who present with lifelong minimal urinary incontinence, never being dry, normal bladder function, complete emptying, and normal ultrasound are very suspicious for ectopic ureter. This needs to be excluded or confirmed by further imaging (e.g. MRI). Filling the bladder with methylene blue and checking for clear urine output from the vagina can give clear evidence of extrasphincteric ureteral ectopia. This test is also helpful in confirming a vesicovaginal fistula (in this case blue fluid is drained from the vagina).

17.4 Treatment

17.4.1 ***Ureterocele***

The management is controversial with a choice between a conservative approach, endoscopic decompression, partial nephroureterectomy, or complete primary reconstruction (24-29). The choice of a therapeutic modality depends on the following criteria: clinical status of the patient (e.g. urosepsis); patient age; function of the upper pole; presence of reflux or obstruction of the ipsilateral or contralateral ureter; presence of bladder neck

obstruction caused by ureterocele; intravesical or ectopic ureterocele; and parents' and surgeon's preferences (30).

17.4.1.1 Early treatment

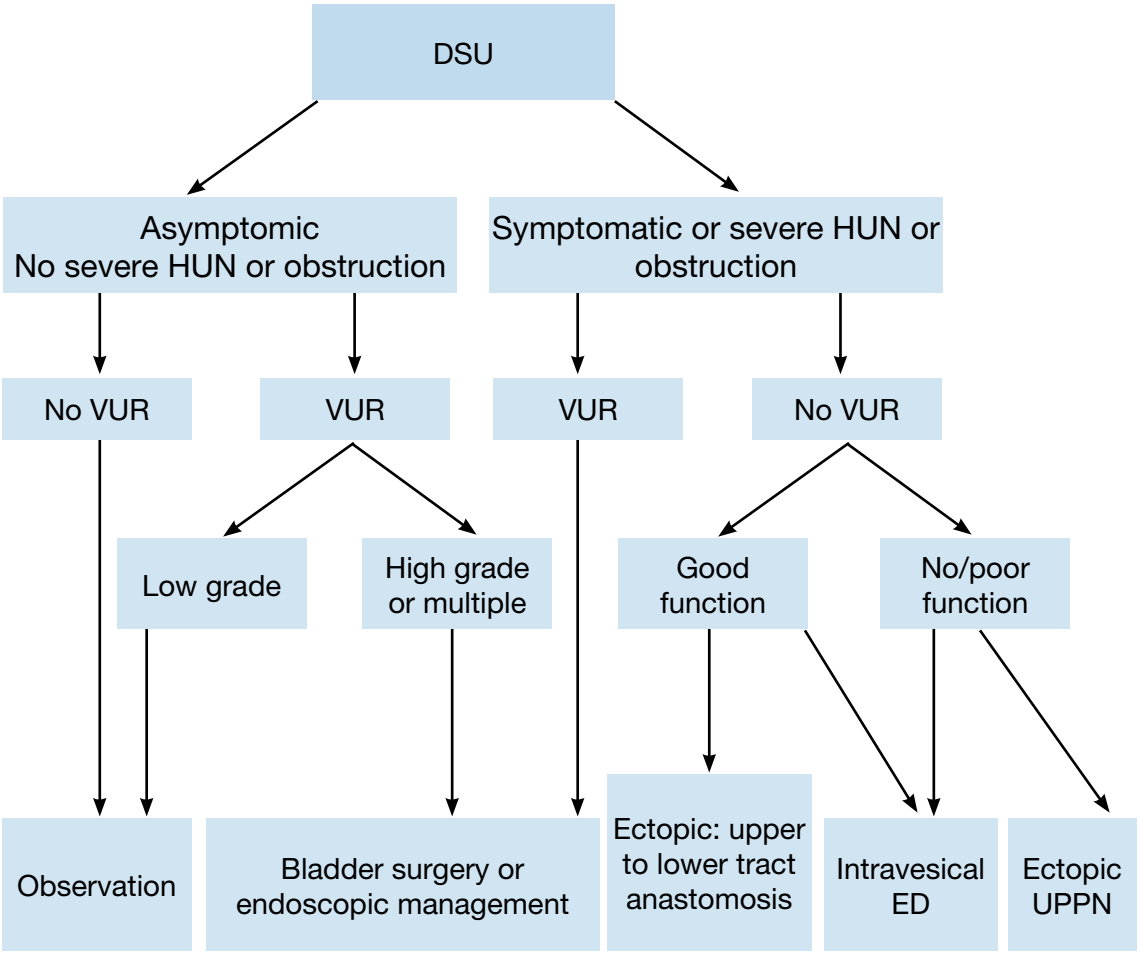
In the presence of febrile infection or obstruction at the bladder neck, immediate endoscopic incision or puncture of the ureterocele is recommended. In a clinically asymptomatic child with a ureterocele and a non- or hypofunctional upper pole, without significant obstruction of the lower pole and without bladder outlet obstruction, prophylactic antibiotic treatment is given until follow-up procedures are instigated.

17.4.1.2 Re-evaluation

Conservative treatment may be adopted in asymptomatic patients without any bladder outlet obstruction, without severe hydroureteronephrosis of the ureterocele moiety or high-grade (over grade III) reflux (30,31).

If decompression is effective and there is no reflux (~25% of cases and more often in intravesical ureterocele), the patient is followed-up conservatively. After an endoscopic incision, most of the children with an extravesical ureterocele (50-80%) need a secondary procedure, compared with only 18% of those with an intravesical ureterocele (32). Secondary surgery is necessary if decompression is not effective, significant reflux is present, or there is obstruction of the ipsi- or contralateral ureters, and/or bladder neck obstruction. Surgery may vary from upper pole nephrectomy to complete unilateral reconstruction (10,26,33-40). In an ectopic ureterocele with severe hydroureteronephrosis and without reflux, the primary upper tract approach without endoscopic decompression (partial upper-pole nephroureterectomy, pyelo/uretero-pyelo/ureterostomy and upper-pole ureterectomy) gives up to an 80% chance of being the definitive treatment (30,41).

Figure 5: Algorithm for the management of duplex system ureteroceles after the first 3-6 months of life (30)



DSU = duplex system ureterocele; ED = endoscopic decompression; HUN = hydroureteronephrosis; MCUG = micturating cystourethrography; UPPN = upper pole partial nephrectomy; VUR = vesicoureteric reflux.

Obstruction is considered to be the presence of non-refluxing dilatation of non-ureterocele-bearing moieties

(especially of the lower pole) or of an obstructive drainage pattern on diuretic renography. Endoscopic management includes decompression of ureterocele and endoscopic or conservative management of VUR.

17.4.2 ***Ectopic ureter***

In the majority of cases, the upper pole is dysplastic and heminephro-ureterectomy should be considered. Ureteral reconstruction (ureteral reimplantation/ ureteroureterostomy/ureteropyelostomy and upper-pole ureterectomy) is a therapeutic option in cases in which the upper pole has function worth preserving. Both procedures can be performed through an open or laparoscopic approach (42-44). In patients with bilateral single ectopic ureters (a very rare condition), an individual approach depending on the sex and renal and bladder function is necessary. Usually the bladder neck is insufficient in these patients (45-48).

18. DISORDERS OF SEX DEVELOPMENT

18.1 Background

The formerly called ‘intersex disorders’ were recently the subject of a consensus document in which it was decided that the term ‘intersex’ should be changed to ‘disorders of sex development’ (DSD) (1,2).

The new classification has arisen because of advances in knowledge of the molecular genetic causes of abnormal sexual development, controversies inherent to clinical management and ethical issues. Controversial and pejorative terminology, e.g. ‘pseudohermaphroditism’ and ‘hermaphroditism’, have been renamed according to the new pathophysiological insights. Furthermore, some conditions presenting with severe male genital malformation, such as penile agenesis, cloacal exstrophy, which could not be categorised, have also been included. The term ‘disorders of sex development’ is proposed to indicate congenital conditions with atypical development of chromosomal, gonadal or anatomical sex.

We refer to the consensus document as a general guideline, while this chapter will focus on what is relevant for the practising paediatric urologist. As the urologist is likely to be involved in both surgical and nonsurgical neonatal work, this chapter will discuss the neonatal emergency and the diagnostic and therapeutic role of the paediatric urologist.

Overall, there is a low evidence base for the published literature on DSD. There are no randomised controlled trials and most studies are based on retrospective clinical descriptive studies (grade 4 level of evidence) or are expert opinion. An exception is the risk of gonadal cancer, for which the level of evidence is higher.

Disorders of sex development require a multidisciplinary approach to diagnosis and treatment, which should include geneticists, neonatologists, paediatric and adult endocrinologists, gynaecologists, psychologists, ethicists and social workers. Each team member should be specialised in DSD and a team should have enough new patients to ensure experience.

18.2 The neonatal emergency

The first step is to recognise the possibility of DSD (Table 12) and to refer the newborn baby immediately to a tertiary paediatric centre, fully equipped with neonatal, genetics, endocrinology and paediatric urology units. At the paediatric centre, the situation should be explained to the parents fully and kindly. Registering and naming the newborn should be delayed as long as necessary.

18.2.1 Family history and clinical examination

A careful family history must be taken followed by a thorough clinical examination (Table 13).

Table 12: Findings in a newborn suggesting the possibility of DSD (adapted from the American Academy of Pediatrics)

Apparent male
Severe hypospadias associated with bifid scrotum
Undescended testis/testes with hypospadias
Bilateral non-palpable testes in a full-term apparently male infant
Apparent female
Clitoral hypertrophy of any degree, non-palpable gonads
Vulva with single opening
Indeterminate
Ambiguous genitalia

Table 13: Diagnostic work-up of neonates with ambiguous genitalia

History (family, maternal, neonatal)
Parental consanguinity
Previous DSD or genital anomalies
Previous neonatal deaths
Primary amenorrhoea or infertility in other family members
Maternal exposure to androgens
Failure to thrive, vomiting, diarrhoea of the neonate
Physical examination
Pigmentation of genital and areolar area
Hypospadias or urogenital sinus
Size of phallus
Palpable and/or symmetrical gonads
Blood pressure
Investigations
Blood analysis: 17-hydroxyprogesterone, electrolytes, LH, FSH, TST, cortisol, ACTH
Urine: adrenal steroids
Karyotype
Ultrasound
Genitogram
hCG stimulation test

Androgen-binding studies
Endoscopy

LH = luteinizing hormone; FSH = follicle stimulating hormone; TST = testosterone; ACTH = adrenocorticotropic hormone; hCG = human chorionic gonadotrophin.

18.2.2 ***Choice of laboratory investigations***

The following laboratory investigations are mandatory:

- Karyotype;
- Plasma 17-hydroxyprogesterone assay;
- Plasma electrolytes;
- Ultrasonography to evaluate the presence of Müllerian duct structures.

These investigations will provide evidence of congential adrenal hyperplasia (CAH), which is the most frequently occurring DSD. If this evidence is found, no further investigation is needed. If not, then the laboratory work-up should proceed further.

The hCG stimulation test is particularly helpful in differentiating the main syndromes of 46XYDSD by evaluating Leydig cell potential. When testosterone metabolism is evaluated, the presence or absence of metabolites will help to define the problem. An extended stimulation can help to define phallic growth potential and to induce testicular descent in some cases of associated cryptorchidism.

18.3 Gender assignment

This is a very complicated task. It should take place after a definitive diagnosis has been made. The idea that an individual is sex-neutral at birth and that rearing determines gender development is no longer the standard approach. Instead, gender assignment decisions should be based upon:

- age at presentation;
- fertility potential;
- size of the penis;
- presence of a functional vagina;
- endocrine function;
- malignancy potential;
- antenatal testosterone exposure;
- general appearance;
- psychosocial well-being and a stable gender identity.

Each patient presenting with DSD should be assigned a gender as quickly as a thorough diagnostic evaluation permits.

18.4 Role of the paediatric urologist

The role of the paediatric urologist can be divided into a diagnostic role and a therapeutic role (Table 14). Each of these roles will be discussed briefly.

Table 14: Role of the paediatric urologist

Diagnostic role

- Clinical examination
- Ultrasound
- Genitography
- Cystoscopy
- Diagnostic laparoscopy

Therapeutic role

- Masculinising surgery
- Feminising surgery
- Gonadectomy

18.4.1 ***Diagnosis***

18.4.1.1 Clinical examination

A good clinical examination in a neonate presenting with ambiguous genitalia is important. As well as a good description of the ambiguous genitalia, some detailed information should be given on palpability and localisation of the gonads. Information gathered by the various examinations described below should help the team to come to a final diagnosis.

Palpable gonad. It must be remembered that if it is possible to feel a gonad, it is almost certainly a testis; this

clinical finding therefore virtually excludes 46XXDSD.

Medical photography can be useful but requires sensitivity and consent (3).

Phallus. The phallus should be measured. A cotton bud placed at the suprapubic base of the implant of the stretched phallus allows for a good measurement of phallic length.

Urogenital sinus opening. The opening of the urogenital sinus must be well evaluated. Is there only one opening visible? Can a hymenal ring be seen? What does the fusion of the labioscrotal folds look like; do the folds show rugae or some discolouration?

18.4.1.2 Investigations
Ultrasound can help to describe the palpated gonads or to detect non-palpated gonads. However, the sensitivity and specificity are not high. On ultrasound, the Mülllerian structures can be evaluated. Is there a vagina? Are there some abdominal gonads? Is there a vaginal or utriculur structure visible? (4,5).

Genitography can provide some more information on the urogenital sinus. How low or how high is the confluence? Is there any duplication of the vagina? How does the urethra relate to the vagina?

General anaesthesia. In some cases, further examinations under general anaesthesia can be helpful. On cystoscopy, the urogenital sinus can be evaluated and the level of confluence between the bladder neck and the bladder. Cystoscopy can also be used to evaluate the vagina or utriculus, e.g. the presence of a cervix at the top of the vagina can be important information.

Laparoscopy is necessary to obtain a final diagnosis on the presence of impalpable gonads and on the presence of Müllerian structures. If indicated, a gonadal biopsy can be performed (6,7).

18.5 Management

Referring to the consensus document (1,2), it is clear that the timing of surgery is much more controversial than it used to be.
The rationale for early surgery includes:

- beneficial effects of oestrogen on infant tissue;
- avoiding complications from anatomical anomalies;
- minimising family distress;
- mitigating the risks of stigmatisation and gender-identity confusion (8).

However, adverse outcomes have led to recommendations to delay unnecessary surgery to an age when the patient can give informed consent. Surgery that alters appearance is not urgent. Early surgery should be reserved for those patients with high confluent urogenital tracts, girls with severely masculinised genitalia and boys with undervirilised genitals. Vaginoplasty should be delayed until puberty and milder forms of masculinisation should not be treated surgically.

18.5.1 ***Feminising surgery***

Clitororeduction. Reduction of an enlarged clitoris should be done with preservation of the neurovascular bundle. Clitoral surgery has been reported to have an adverse outcome on sexual function and clitoral surgery should therefore be limited to severely enlarged clitorises (9,10). Informed parental consent should be obtained. Although some techniques that conserve erectile tissue have been described, the long-term outcome is unknown (11).

Separation of the vagina and the urethra is preserved for high confluence anomalies. Many techniques for urogenital sinus repair have been described, but their outcome has not been evaluated prospectively (12,13).

Vaginoplasty should be performed during the teenage years. Every technique (self dilatation, skin or bowel substitution) has its specific advantages and disadvantages (14). All carry a potential for scarring that would require further surgery before sexual function was possible.

Aesthetic refinements. The goals of genital surgery are to maximise anatomy to allow sexual function and romantic partnering. Aesthetics are important in this perspective. The reconstruction of minor labiae from an enlarged clitoral hood is an example of aesthetic refinement.

18.5.2 ***Masculinising surgery***

Hormone therapy early in life is advocated by many doctors. The level of evidence is low for restoration of normal penile size.

Hypospadias surgery. See section on hypospadias (Chapter 6).

Excision of Mullerian structures. In the DSD patient assigned a male gender, Müllerian structures should be excised. There is no evidence about whether utricular cysts need to be excised.

Orchiopexy. See section on orchidopexy (Chapter 3).

Phalloplasty. The increasing experience of phalloplasty in the treatment of female to male transsexual patients has led to reports about the reliability and feasibility of this technique. It has therefore become available to treat severe penile inadequacy in DSD patients.

Aesthetic refinements. These include correction of penoscrotal transposition, scrotoplasty and insertion of testicular prostheses.

Gonadectomy. Germ cell malignancy only occurs in patients with DSD who have Y-chromosomal material. The highest risk is seen in patients with gonadal dysgenesis and in patients with partial androgen insensitivity with intra-abdominal gonads (LE: 2). Intra-abdominal gonads of high-risk patients should be removed at the time of diagnosis (15) (GR: A).

19. POSTERIOR URETHRAL VALVES

19.1 Background

Posterior urethral valves (PUV) are one of the few life-threatening congenital anomalies of the urinary tract found during the neonatal period. Despite optimal treatment, PUV in children may result in renal insufficiency in nearly 35% of cases. PUV are found in 1 in 1,250 in a population undergoing foetal ultrasound screening (1). An incidence of PUV of 1 in 5,000-12,500 live-births has been estimated (2,3). In one report, up to 46% of foetuses with a PUV diagnosis were terminated (4), indicating a possible decrease in incidence.

19.2 Classification

*19.2.1 **Urethral valve***

Despite recent attempts to introduce new classification terms, such as 'congenital obstructive posterior urethral membrane (COPUM)' (5), the original classification by Hugh Hampton Young remains the most commonly used (6).

Hampton Young described three categories: type I, type II and type III. However, today, only type I and type III are found to be obstructive. As type II seems to be more like a fold and not obstructive, it is no longer referred to as a valve. Hampton Young's descriptions of type I and III are as follows:

Type I (90-95%). 'In the most common type there is a ridge lying on the floor of the urethra, continuous with the verumontanum, which takes an anterior course and divides into two fork-like processes in the region of the bulbo-membranous junction. These processes are continued as thin membranous sheets, direct upward and forward which may be attached to the urethra throughout its entire circumference. It is generally supposed that the valves have complete fusion anteriorly, leaving only an open channel at the posterior urethral wall. Yet the fusion of the valves anteriorly may not be complete in all cases, and this point a slight separation of the folds exist' (6).

Type III. 'There is a third type which has been found at different levels of the posterior urethra and which apparently bears no such relation to the verumontanum. This obstruction was attached to the entire circumference of the urethra, with a small opening in the centre' (6).

The transverse membrane described has been attributed to incomplete dissolution from the urogenital portion of the cloacal membrane (7). The embryology of the urethral valves is poorly understood. The membrane may be an abnormal insertion of the mesonephric ducts into the foetal cloaca (8).

19.3 Diagnosis

An obstruction above the level of the urethra affects the whole urinary tract in varying degrees.

- The prostatic urethra is distended and the ejaculatory ducts may be dilated due to urinary reflux. The bladder neck is hypertrophied and rigid.
- The hypertrophied bladder occasionally has multiple diverticula.
- Nearly all valve patients have dilatation of both upper urinary tracts. This may be due to the valve itself and the high pressure in the bladder, or due to obstruction of the uretereovesical junction by the

hypertrophied bladder.

- If there is secondary reflux, the affected kidney functions poorly in most cases.

During prenatal ultrasonography screening, bilateral hydroureteronephrosis and a distended bladder are suspicious signs of a urethral valve. If a dilated posterior urethra and a thick-walled bladder ('keyhole' sign) are seen, a PUV is likely. In the presence of increased echogenity of the kidney, dilatation of the urinary tract and oligohydramnion, the diagnosis of a PUV should strongly be considered.

A voiding cysturethrography (VCUG) confirms a PUV diagnosis. This study is essential whenever there is a question of an infravesical obstruction, as the urethral anatomy is well outlined during voiding. A secondary reflux is observed in at least 50% of patients with PUV (9). Reflux is consistently associated with renal dysplasia in patients with PUV. It is generally accepted that reflux in the renal units acts as a 'pressure pop-off valve', which would protect the other kidney, leading to a better prognosis (10). Other types of pop-off mechanism include bladder diverticula and urinary extravasation, with or without urinary ascites (11). However, in the long-term, a supposed protective effect did not show a significant difference compared to other patients with PUV (12,13).

Nuclear renography with split renal function is important to assess kidney function. Creatinine, blood urea nitrogen and electrolytes should be monitored closely during the first few days. A nadir creatinine of 80 µmol/L is correlated with a better prognosis (14).

19.4 Treatment

19.4.1 ***Antenatal treatment***

About 40-60% of PUV are discovered before birth (15). The intrauterine obstruction leads to a decreased urine output, which could result in an oligohydramnios. Amnion fluid is necessary for normal development of the lung and its absence may lead to pulmonary hypoplasia, causing a life-threatening problem. Intrauterine attempts have been made to treat a foetus with PUV.

As renal dysplasia is not reversible, it is important to identify those foetuses with good renal function. A sodium level below 100 mmol/L, a chloride value of < 90mmol/L and an osmolarity below 200 mOsm/L found in three foetal urine samples gained on three different days are associated with a better prognosis (16).

The placing of a vesicoamniotic shunt has a complication rate of 21-59%, dislocation of the shunt occurs in up to 44%, mortality lies between 33% and 43%, and renal insufficiency is above 50% (16-18). Although shunting is effective in reversing oligohydramnios, it makes no difference to the outcome and longterm results of patients with PUV (17,18).

19.4.2 ***Postnatal treatment***

Bladder drainage. If a boy is born with suspected PUV, drainage of the bladder and, if possible, an immediate VCUG is necessary. A neonate can be catheterised with a 3.5-5 F catheter. A VCUG is performed to see if the diagnosis is correct and whether the catheter is within the bladder and not in the posterior urethra. An alternative option is to place a suprapubic catheter, perform a VCUG and leave the tube until the neonate is stable enough to perform an endoscopic incision or resection of the valve.

Valve ablation. When the medical situation of the neonate has stabilised and the creatinine level decreased, the next step is to remove the intravesical obstruction. Small paediatric cystoscopes and resectoscopes are now available either to incise or to resect the valve at the 4-5, 7-8 or 12 o'clock position, or at all three positions, depending on the surgeon's preference. It is important to avoid extensive electrocoagulation as the most common complication of this procedure is stricture formation.

Vesicostomy. If the child is too small and/or too ill to undergo endoscopic surgery, a vesicostomy is used to drain the bladder temporarily. If initially a suprapubic tube has been inserted, this can be left in place for 6-12 weeks. Otherwise, a cutaneous vesicostomy provides an improvement or stabilisation of upper urinary tracts in over 90% of cases (19). Although there has been concern that a vesicostomy could decrease bladder compliance or capacity, so far there are no valid data to support these expectations (20-22).

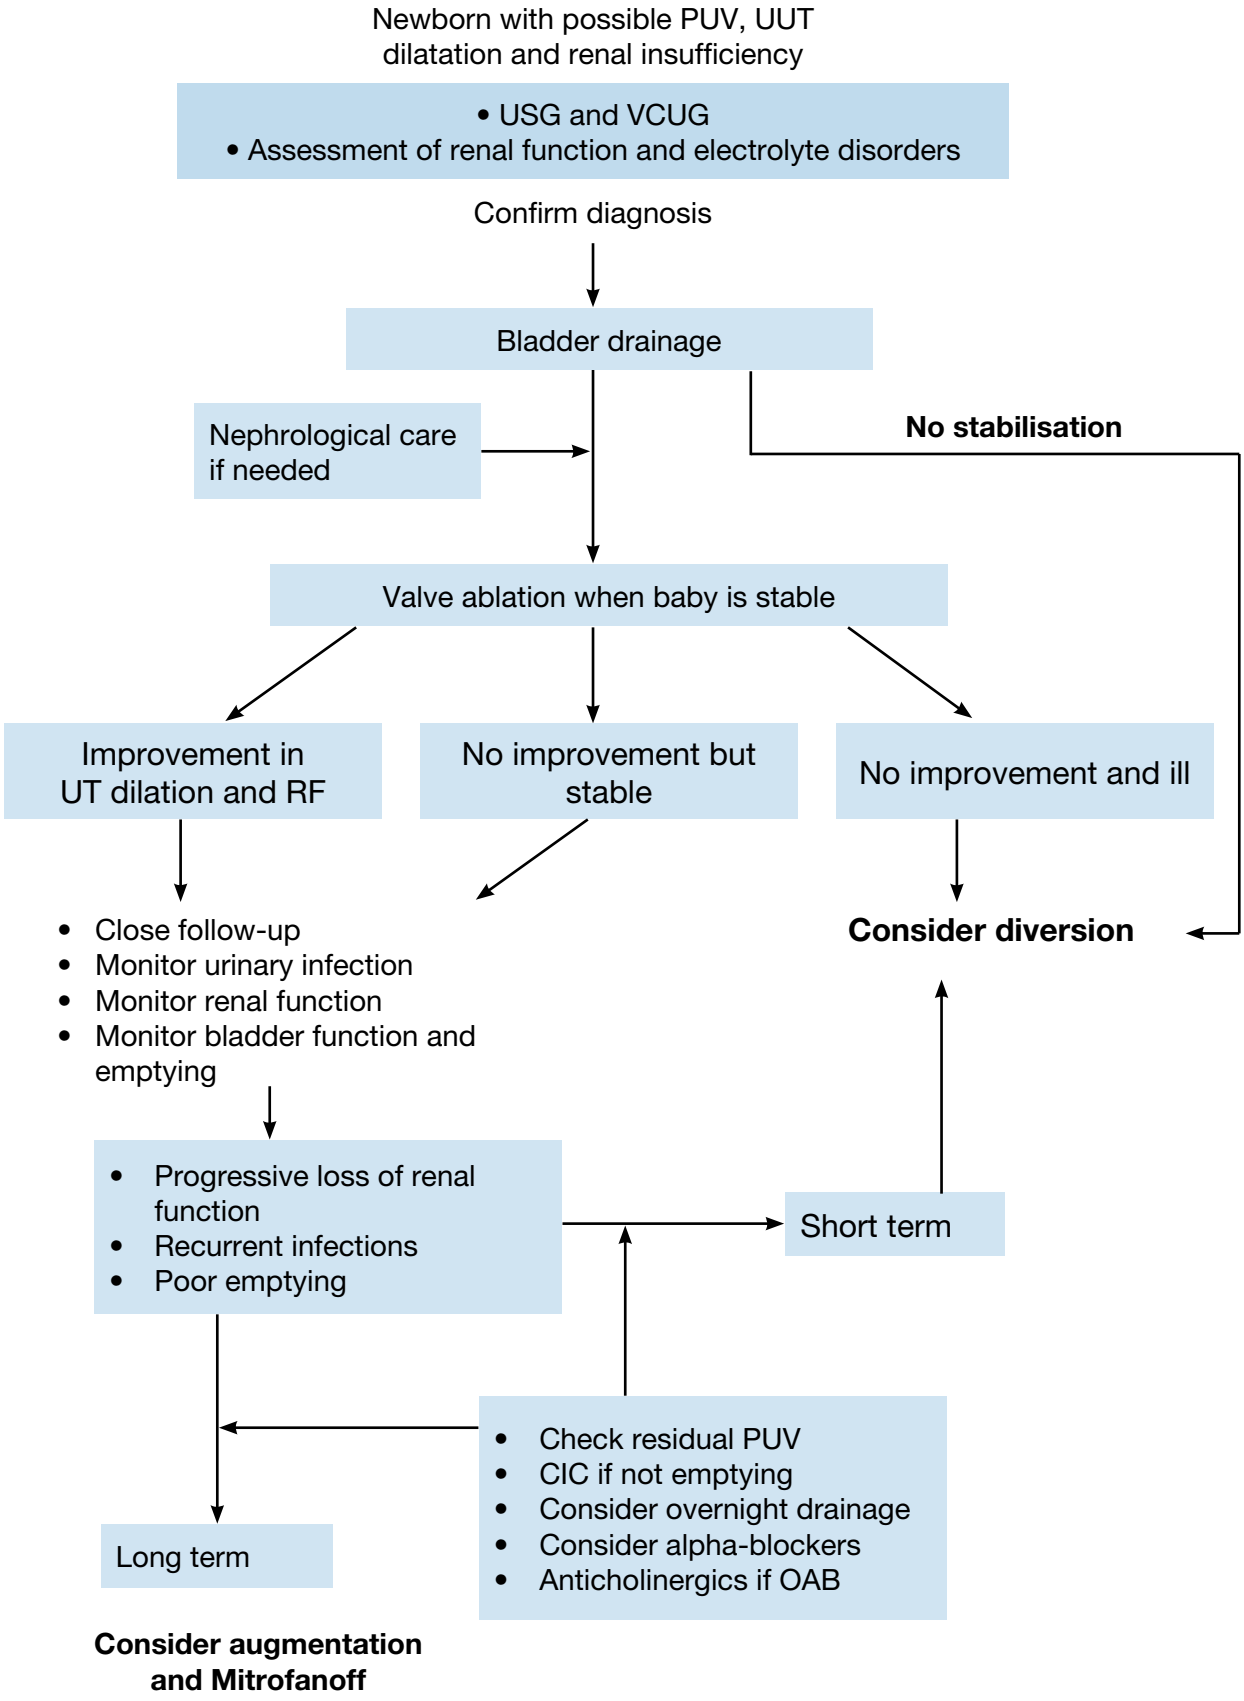
High diversion. If bladder drainage is insufficient to drain the upper urinary tract, high urinary diversion should be considered. Diversion may be suitable if there are recurrent infections of the upper tract, no improvement in renal function and/or an increase in upper tract dilatation, despite adequate bladder drainage. The choice of urinary diversion depends on the surgeon's preference for high loop ureterostomy, ring ureterostomy, end ureterostomy or pyelostomy, with each technique having advantages and disadvantages (23-25). Reconstructive surgery should be delayed until the upper urinary tract has improved as much as can be expected.

Reflux is very common in PUV patients (up to 72%) and it is described bilaterally in up to 32% (26).

High-grade reflux is mostly associated with a poor functioning kidney. However, early removal of the renal unit seems to be unnecessary, as long as it causes no problems. It may be necessary to augment the bladder and in this case the ureter may be used (27).

Life-long monitoring of these patients is mandatory, as bladder dysfunction is not uncommon and the delay in day- and night-time continence is a major problem (9, 14). Poor bladder sensation and compliance, detrusor instability and polyuria (especially at night) and their combination are responsible for bladder dysfunction. Between 10% and 47% of patients may develop end-stage renal failure (14,28). Renal transplantation in these patients can be performed safely and effectively. Deterioration of the graft function is mainly related to lower urinary tract dysfunction (29,30).

Figure 6: An algorithm providing information on assessment, treatment and follow up of newborns with possible PUV



PUV = posterior urethral valve; UUT = upper urinary tract; USG = urinary specific gravity; VCUG = voiding cystourethrogram; UT = urinary tract; RF = renal function; CIC = clean intermittent catheterisation; OAB = overactive bladder.

20. POST-OPERATIVE FLUID MANAGEMENT

20.1 Background

It is often stated that children are not simply small adults, and have specific metabolic features. Children are growing and developing organisms that have a different total body fluid distribution, changing renal physiology, different electrolyte requirements and weaker cardiovascular compensation mechanisms as compared to adults (1). Additionally, developing children have a high metabolic rate and low body stores of fat and other nutrients, and are therefore, susceptible to metabolic disturbances due to surgical stress (2). The metabolic response to anaesthesia and surgery in infants and children is related to the severity of the operation (3).

20.2 Pre-operative fasting

Pre-operative fasting has been advocated for elective surgery to avoid the complications associated with pulmonary aspiration during induction of anaesthesia. Current guidelines of pre-operative fasting for elective surgery are indicated in Table 15 (4,5).

Table 15: Preoperative fasting times for elective surgery

Ingested material	Minimum fasting period (h)
Clear liquids	2
Breast milk	4
Infant formula	4 (< 3 months old) to 6 (> 3 months old)
Non-human milk	6
Light meal	6

Although hypoglycaemia is considered to be an important issue for children, later studies have demonstrated that hypoglycaemia is uncommon if children are fed until 4 h before anaesthesia induction (6). Low glycogen

stores and impaired gluconeogenesis are common problems in newborns. Limiting the period of preoperative starvation and use of glucose-containing solutions are recommended. Therefore, monitoring of blood glucose and continuous adjustment of glucose supply appear to be necessary in neonates and children who are small for their age, to avoid excessive fluctuations in blood glucose levels (7).

20.3 Maintenance therapy and intraoperative fluid therapy

Typically, intraoperative management is the responsibility of the anaesthetist, whereas surgeons write the postoperative instructions. The goal of intraoperative fluid management is to sustain homeostasis by providing the appropriate amount of parenteral fluid to maintain adequate intravascular volume, cardiac output and oxygen delivery to tissues at a time when normal physiological functions are altered by surgical stress and anaesthetic agents (7).

The fluids for maintenance therapy do not take into account blood loss or third-space loss of fluid into the interstitial space or gut, and replaces losses from two sources: insensible (evaporative) and urinary loss. The principle formulae for calculating the daily maintenance water requirement has not changed for the past 50 years (Table 16) (8). Previous calculations have shown that there is good agreement in fluid requirements between non-operated and anaesthetised children (9). Thus, the combination of maintenance fluid and electrolyte requirements results in a hypotonic electrolyte solution. Conventionally, the usual intravenous maintenance fluid given to children by paediatricians is a quarter to a third strength saline (4,10).

Table 16: Hourly and daily fluid requirements according to body weight

Body weight	Hourly	Daily
< 10 kg	4 mL/kg	100 mL/kg
10-20 kg	40 mL + 2 mL/kg; > 10 kg	1000 mL + 50 mL/kg; > 10 kg
>20 kg	60 mL + 1 mL/kg; > 20 kg	1500 mL+ 20 mL/kg; > 20 kg

Fasting deficit is calculated by multiplying the hourly maintenance fluid requirement by the number of hours of restriction. Replacement of 50% of the fasting deficit in the first hour and 25% in the second and third hours is recommended (11). However, Berry et al. have proposed simplified guidelines for fluid administration according to the child's age and severity of surgical trauma (12) (Table 17).

Table 17: Intraoperative fluid management adapted for children fasted for 6-8 h following the classical recommendation "nil per oral after midnight"

The amount of fluid given during the first hour should be reduced if children are fasting for a shorter period of time, or if the child is already receiving intravenous fluid before surgery.

Furman (11)			
Hour of fluid replacement	**Maintenance fluid**	**Fasting deficit replacement**	**Persistent losses**
First hour	As Table 16	50%	Third space + blood loss replacement
Second hour	As Table 16	25%	Third space + blood loss replacement
Third hour	As Table 16	25%	Third space + blood loss replacement
Berry (12)			
First hour	≤ 3 years: 25 mL/kg ≥ 4 years: 15 mL/kg		Blood replacement 1:1 with blood or colloid or 3:1 with crystalloids
All other hours	Maintenance volume = 4 mL/kg/h Maintenance + mild trauma = 6 mL/kg/h Maintenance + moderate trauma = 8 mL/kg/h Maintenance + severe trauma = 10 mL/kg/h		Blood replacement 1:1 with blood or colloid or 3:1 with crystalloids

Five percent dextrose with a quarter- to half-normal saline is frequently used as maintenance fluid, and balanced salt solution or normal saline as replacement fluid. Blood losses are replaced with either 1:1 ratio of blood or colloid, or 3:1 ratio for crystalloid. However, the administration of a large volume of normal saline can cause dilutional acidosis or hyperchloraemic acidosis, whereas a large volume of balanced salt solution, such as lactated Ringer's solution, can decrease serum osmolality, which is not beneficial in patients with

decreased intracranial compliance. Albumin, plasma, synthetic colloids, and blood are administered where appropriate (7). Third-space losses may vary from 1 mL/kg/h for a minor surgical procedure to 15-20 mL/kg/h for major abdominal procedures, or even up to 50 ml/kg/h for surgery of necrotising enterocolitis in premature infants. Third-space losses should be replaced with crystalloids (normal saline or Ringer's lactate) (4). Most of the fluids required during surgery are needed for replacing fasting deficit or third-space losses. Both losses consist mainly of extracellular fluids. Thus, hydrating solutions should contain high sodium and chloride and a low concentration of bicarbonate, calcium and potassium. Intraoperative hypoglycaemia is rare in children. In contrast, hyperglycaemia is commonly encountered during anaesthesia and surgery. The replacement fluid should be free of dextrose or should not have > 1% dextrose. The present recommendations include the use of low-dextrose-containing solutions for maintenance fluid therapy (except for patients who are at greatest risk for hypoglycaemia) (1,10). Intraoperative administration of glucose-free isotonic hydrating solutions should be the routine practice for most procedures in children over 4-5 years of age. In infants and young children, 5% dextrose solutions should be avoided, but 1% or 2% dextrose in lactated Ringer's solution is appropriate (4).

20.4 Post-operative fluid management

During the postoperative period, the basic principle is to estimate the function of the gut and to continue oral or enteral nutrition as much as possible (2). However, it should be taken into consideration that withholding oral fluids postoperatively from children undergoing day surgery reduces the incidence of vomiting (13). For minor surgical procedures, the intraoperative administration of large volumes of crystalloids is associated with a reduced incidence of postoperative nausea and vomiting after anaesthesia in paediatric and adult patients (14). Thus, Berry's guidelines seem appropriate for minor surgical cases provided that either lactated ringer polyionique B66, which has an osmolarity similar to plasma (15) is administered during surgery. It is not obligatory to check serum chemistry after uncomplicated surgery in children with normal preoperative renal and hepatic functions. However, if oral intake is postponed for > 24 h (e.g. intestinal surgery), there is an increased risk for electrolyte abnormalities that require further assessment and subsequent management, particularly for potassium. Postoperative findings such as decreased bowel movements and ileus may be signs of hypokalemia, which might be corrected with a solution including 20 mmol/L potassium with an infusion rate not more than 3 mmol/kg/day. In these cases, fluid therapy should be administered via peripheral venous access if the duration of infusion is not expected to exceed 5 days, or via central venous access when long-term parenteral nutrition is necessary.

Fluid therapy should provide basic metabolic requirements, and compensate for gastrointestinal and additional losses. If hypovolemia is present, it should be treated rapidly. Hyponatremia is the most frequent electrolyte disorder in the postoperative period (15,16). Therefore, hypotonic fluid should not be routinely administered to hospitalised children because they have several stimuli for AVP production, and are at high risk for developing hyponatremia (4,15,17-20). The preferred fluids for maintenance therapy are 0.45% saline with dextrose or isotonic fluids, in the absence of a specific indication for 0.25% saline. Moreover, it is advised to administer isotonic fluids intraoperatively and also immediately postoperatively, albeit at two-thirds of the calculated maintenance rate in the recovery room. Fluid composition should balance high sodium requirements, energy requirements and osmolarity of the solution. The extra losses from gastric or chest tubes should be replaced with lactated Ringer's solution. Fluid administration to dilute the medications also should be taken into account (4).

Children who undergo interventions to relieve any kind of obstructive diseases deserve particular attention. The risk of polyuria due to post-obstructive diuresis has to be assessed. In cases in which polyuria develops, fluid intake and urine output should be followed, as well as renal function and serum electrolytes. When necessary, clinicians should not feel any hesitation in consulting with a paediatric nephrologist.

20.5 Post-operative fasting

Although some previous studies have reported that fasting reduces the risk of vomiting by up to 50% (13,21,22), a recent study has revealed that, if children were freely allowed to drink and eat when they felt ready or requested, the incidence of vomiting did not increase, the children felt happier, and were significantly less bothered by their pain than those in the fasting group (23). The mean times until first drink and eating in the free group were 108 and 270 min, respectively, which were 4 and 3 h earlier than in the fasting group.

Previous studies have implied that gastric motility returns to normal 1 h after emergence from anaesthesia in children who have undergone non-abdominal surgery (24), and first oral intake in children 1 h after emergence from anaesthesia for minor surgery does not appear to cause an increase in the incidence of vomiting, as long as the fluid ingested is at body temperature (25). Therefore, panel members recommend encouraging early fluid intake for children who undergo minor or non-abdominal urological surgery.

21. POST-OPERATIVE PAIN MANAGEMENT IN CHILDREN: GENERAL INFORMATION

21.1 Introduction

Adequate pain control requires proper pain evaluation, accurate choice of drug and route of administration, and consideration of age, physical condition and type of surgery and anaesthesia (1). However, there is still no standardised algorithm for management of postoperative pain in children (2). The authors emphasise the need for a postoperative pain management protocol in children, and state that the frequency of pain assessment, use of parenteral opioids, introduction of regional anaesthesia, and application of rescue analgesics are far from what they should be (3).

The recent understanding of maturation of the pain system, pain assessment methods, clinical consequences of pain in neonates, and the traditional medical beliefs that neonates are incapable of experiencing pain have now been abandoned (4-8). Many studies have shown that deficiency or insufficiency in proper analgesia might be the cause of future behavioural and somatic sequelae (9-13). The current understanding fully depends on the belief that all children irrespective of age deserve adequate treatment.

21.2 Assessment of pain

Assessment of pain is the first step of pain management. Validated pain assessment tools are needed for this purpose and selecting the appropriate pain assessment technique is important. There are several pain assessment tools that have been developed according to the child's age, cultural background, mental status, communication skills and physiological reactions (14,15).

One of the most important topics in paediatric pain management is informing and involving the patient and parents during this process. Parents and patients can manage postoperative pain at home or in hospital if provided with the correct information. Parents and patients, if they are old enough, can actively take part in pain management, even in patient-family-controlled analgesia applications (16-21).

21.3 Drugs and route of adminstration

Pre-emptive analgesia is an important concept that aims to induce suppression of pain before neural hypersensitisation occurs (22), and local anaesthetics or non-steroidal analgesics are given intraoperatively to delay postoperative pain and decrease postoperative analgesic consumption. Analgesics must be titrated until an appropriate response is achieved. Opioids can be administered to children by the oral, mucosal, transdermal, subcutaneous, intramuscular or intravenous routes (18). The combination of opioids with non-steroidal anti-inflammatory drugs (NSAIDs) or local anaesthetics (balanced or multimodal analgesia) might be used to increase the quality of analgesia and decrease undesired effects related to opioids (23). The same combination of local anaesthetics, opioids, and non-opioid drugs used in adults can also be used in children with respect to their age, body weight and individual medical status.

Table 18: List of several drugs used in postoperative pain management in children (5,13,19,25-27)

Name	Route of administration	Dose	Side effects	General remarks	Caution
Non-narcotics					
Acetaminophen	Rectal Oral Intravenous	40 mg/kg loading, 20 mg/kg/dose 4 times/day 15-40 mg/kg, followed by 30 mg/kg/8 h Propacetamol (prodrug)	Nephrotoxicity, hepatotoxicity (neonates)	Most common used analgesic, Antipyretic effect Opioid sparing effect Wide safety range	Slow onset time and variable absorption via rectal route, dividing the vehicle not recommended. Total dose should not exceed 100 mg/kg for children; 75 mg/kg for infants; 60 mg/kg for term and preterm neonates > 32 weeks post-conceptual age; and 40 mg/kg for preterm neonates < 32 weeks post-conceptual age
Ibuprofen	Oral, rectal	4-10 mg/kg/dose 3-4 times/day		Better analgesic that paracetamol	Safety not established for infants < 6 months old
Diclofenac	Tablet, syrup, suppository	1-1.5 mg/kg 2-3 times/day	Nephrotoxicity, GI disturbances	Better than ibuprofen	> 6 years old
Ketorolac	Oral IV, IM	0.2-0.5 mg/kg every 6 h (48 h) Total dose < 120 mg/day		Opioid sparing effect	
Ketamine	Oral, rectal, IM, SC, IV and intraspinal	< 2 mg/kg (IM) < 1 mg/kg (IV, epidural)			
Metamizole, dipyrone	Oral IM drop	10-15 mg/kg/dose (max 40 mg/kg total) 10-15 mg/kg 1 drop/kg/dose, max 4 times	Risk of agranulocytosis, not clarified definitely	Very effective antipyretic	Not approved in some countries including USA, Sweden, Japan and Australia
Narcotics					
Opioids			Nausea, vomiting, dyspepsia, constipation, urinary retention, respiratory depression, drowsiness, euphoria		
Tramadol (weak opioid)	Oral, rectal, IV, IM (dose can be repeated 4-6 times/day)	2-3 mg/kg/dose (oral, drop) 1-2 mg/kg/dose (oral, tablet) 1.5-3 mg/kg/dose (rectal) 0.75-2 mg/kg/dose (IM) 2-2.5 mg/kg/dose (IV) 0.1-0.25 mg/kg/h (continuous)	nausea, vomiting, pruritus and rash	Does not inhibit prostaglandin synthesis	IM injection not recommended, Slow IV infusion, Be careful in patients under psychoactive medications and with seizures

Codeine	Oral	1 mg/kg, single dose	Respiratory depression not seen after single dose	Both antitussive and analgesic effect	
Morphine	IM, IV	6-12 months: 0.1 mg/kg (IM), 0.05 mg/kg (IV)		Most common used but not the most suitable opioid for pain relief in children	IM injection not recommended < 2 months old: be careful
Nalbuphine	IV	< 3 months old: 0.05 mg/kg/dose > 3 months old: 0.05-0.10 mg/kg/ dose (4-6 times/day)			
Piritramide	IV	0.05-0.10 mg/kg/dose (4-6 times/ day)			
Dextromethorphan	Oral, syrup	1 mg/kg			
Pethidine/ meperidine	IM, IV	1.5-2 mg/kg IM as premedicant 1 mg/kg IV analgesic	No advantage over morphine		
Fentanyl	IV	1-2 µg/kg	Not so popular		
Buprenorphine	IV	3-5 mg/kg			
Pentazocine	IV, IM	1 mg/kg IM or 0.5-0.75 mg/kg IV	In small infants, observe respiration after IV administration		
Regional (local) anaesthetics					
bupivacaine		Maximum single bolus dose: 2.5-3.0 mg/kg. Maximum infusion: 0.4-0.5 mg/ kg/h (10-20 mg/kg/day) in older infants and children, and 0.2-0.25 mg/kg/h (5-6 mg/kg/day) in neonates	Cardiotoxicity, convulsion		
Levobupivacaine	IV, IM	0.2-0.25% 1-2.5 mg/kg for single shot epidural intravenous continuous administration 0.2-0.4 mg/kg/h		Less toxic than bupivacaine	
Ropivacaine	IV,IM	0.2-0.25% 1-2.5 mg/kg for single shot epidural intravenous continuous administration 0.2-0.4 mg/kg/h		Less toxic than levobupivacaine	

The World Health Organization's "pain ladder" is a useful tool for the pain management strategy (24). A three-level strategy seems practical for clinical use. Postoperative management should be based on sufficient intraoperative pre-emptive analgesia with regional or caudal blockade followed by balanced analgesia. Paracetamol and NSAIDs are the drugs of choice at the first level. As they become insufficient to prevent pain, weak and strong opioids are added to oral drugs to achieve balanced analgesia. Every institute must build their own strategy for postoperative analgesia. A proposed strategy for postoperative analgesia may be as follows:

1. Intraoperative regional or caudal block
2. Paracetamol + NSAID
3. Paracetamol + NSAID + weak opioid (e.g. tramadol or codeine)
4. Paracetamol + NSAID + strong opioid (e.g. morphine, fentanyl, oxycodone or pethidine)

21.4 Circumcision

Circumcision without anaesthesia, irrespective of age, is not recommended and it needs proper pain management (28). Despite this, adequate pain management is still below expectations (29). Potential analgesic interventions during circumcision include use of dorsal penile nerve block (DPNB) or ring block, topical anaesthetics (e.g. lidocaine-prilocaine cream, or 4% liposomal lidocaine cream), a less painful clamp (e.g., Mogen clamp), a pacifier, sucrose, and swaddling, preferably in combination (30-35). Although DPNB and topical anaesthetics seem to have a similar postoperative analgesic affect, DPNB is still the most preferred method (33) (LE: 1A). Ultrasonographic guidance may improve the results, with an increase in procedural time (36,37). Caudal blockade methods have similar efficacy compared to DPNB. However, parents should be informed about the more frequent incidence of postoperative motor weakness and micturition problems (38-43).

21.5 Penile, inguinal and scrotal surgery

Caudal block is the most studied method for post-hypospadias surgery analgesia. Several agents with different doses, concentrations and adminstration techniques have been used with similar outcomes (44-58). Both single and combined use of these agents has been shown to be effective (46,48,53,54,56,57).

Penile blocks can be used for postoperative analgesia and have similar postoperative analgesic properties as caudal blocks (59). Two penile blocks at the beginning and conclusion of surgery seems better (60). Severe bladder spasms due to the presence of the bladder catheter may sometimes cause more problems than pain, which necessitates antimuscarinic medications.

For inguinoscrotal surgery, all anaesthetic methods, such as caudal blocks (61-65), nerve block (66,67), wound infiltration or instillation, as well as irrigation with local anaesthetics (68-70), have been shown to have adequate postoperative analgesic properties. Combinations may improve the results (71).

21.6 Bladder and kidney surgery

Continuous epidural infusion of local anaesthetics (72-74), as well as systemic (intravenous) application of analgesics (75), has been shown to be effective.

Ketorolac is an underutilised although effective agent that has been shown to decrease frequency and severity of bladder spasms, as well as the length of postoperative hospital stay and costs (76-81).

Open kidney surgery is particularly painful because all three muscle layers are cut during conventional loin incision. Dorsal lumbotomy incision may be a good alternative because of the shorter postoperative hospital stay and earlier return to oral intake and unrestricted daily activity (82).

Caudal blocks plus systemic analgesics (83), and continuous epidural analgesia have been shown to be effective in terms of decreased postoperative morphine requirement after renal surgery (84,85). However, when there is a relative contraindication to line insertion, a less experienced anaesthetist is available, or parents prefer it (86), non-invasive regimens composed of intraoperative and postoperative analgesics may be the choice. Particularly in this group of patients, stepwise analgesia protocols can be developed (87). For laparoscopic approaches, intraperitoneal spraying of local anaesthetic before incision of perirenal fascia may be beneficial (88).

Table 19: A simple pain management strategy for paediatric urological surgery

Intensity of surgery	First step	Second step	Third step
Mild (inguinal, scrotal, penile)	Paracetamol and wound infiltration with local anaesthetics	NSAIDs	Regional block/weak opioid or intravenous strong opioid with small increments as rescue analgesia (nalbuphine, fentanyl, meperidine, morphine etc.)
Moderate (lower abdominal)			Peripheral nerve block (single shot or continuous infusion)/opioid injection (IV PCA)
Severe (upper abdominal or lombotomy)			Epidural local/major peripheral nerve/plexus block/opioid injection (IV PCA)

IV PCA = intravenous patient-controlled analgesia.

22. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

AGS	adrenogenital syndrome
ACTH	adrenocorticotropic hormone
AMH	anti-Müllerian hormone
ARM	anorectal malformation
CAH	congenital adrenal hyperplasia
CIC	clean self-intermittent catheterisation
CNS	central nervous system
COPUM	congenital obstructive posterior urethral membrane
CRP	C-reactive protein
DDAVP	desmopressine
CT	computed tomography
DHTST	dihydrotestosterone
DMSA	dimercaptosuccinic acid
EMG	electromyography
ESR	erythrocyte sedimentation rate
FSH	follicle stimulating hormone
GnRH	gonadotrophin-releasing hormone
hCG	human chorionic gonadotrophin
IC	intermittent catheterisation
ICCS	International Children's Continence Society
IVU	intravenous urogram
LH	luteinizing hormone
LHRH	luteinizing hormone releasing hormone
LUTD	lower urinary tract dysfunction
LUT(S)	lower urinary tract (symptoms)
MRI	magnetic resonance imaging
NDSD	neurogenic detrusor-sphincter dysfunction
OAB	overactive bladder
PNL	percutaneous litholapaxy
RCT	randomised controlled trial
RN	reflux nephropathy
RNC	radionuclide cystography
RTA	renal tubular acidosis
SWL	(extracorporeal) shockwave lithotripsy
Tc-MAG3 (99m)	technetium-99m mercaptoacetyltriglycine (MAG3)
TIP	tubularised incised plate urethroplasty
TST	testosterone
UPJ	ureteropelvic junction
URS	ureterorenoscopy
US	ultrasound
UTIs	urinary tract infections
VCUG	voiding cystourethrography
VR	vesicorenal reflux
VUR	vesicoureteral reflux
VUS	voiding urosonography

Conflict of interest

All members of the Paediatric Urology Guidelines writing panel have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on Urological Trauma
