1. INTRODUCTION

1.1 Background

The European Association of Urology (EAU) Guidelines Group for Urological Trauma prepared this guidelines document to assist medical professionals in the management of urological trauma.

The Urological Trauma guidelines are based on a review of the literature, using on-line searches of MEDLINE and other source documents published between 2005 and 2008. A critical assessment of the findings was made, not involving a formal appraisal of the data. There is a paucity of high-powered randomised controlled trials in this area and considerable available data are based on retrospective studies. The panel recognises this limitation.

A level of evidence (LE) and/or grade of recommendation (GR) have been assigned where possible (1). The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given.

Publication history information: The Urological Trauma Guidelines were first published in 2003, with a partial update in 2006 followed by this full text update in 2009. Additionally, a quick reference guide is available. All texts can be viewed and downloaded for personal use at the society website: http://www.uroweb.org/guidelines/online-guidelines/.

Levels of evidence and grade of guideline recommendations*

Table 1: Level of evidence

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

Table 2: Grade of recommendation

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**modified from Sackett et al. (1).*

2. RENAL TRAUMA

2.1 Background

Renal trauma occurs in approximately 1-5% of all trauma cases (1,2). The kidney is the most commonly injured genitourinary and abdominal organ. There is a 3:1 male to female ratio in kidney trauma patients (3-5). Renal trauma can be acutely life-threatening, but the majority of renal injuries can be managed conservatively. Advances in imaging and treatment strategies during the past 20 years have decreased the need for surgical intervention and increased renal preservation (6-8).

2.2 Mode of injury

Renal injuries are classified by their mechanism: blunt or penetrating. In rural settings, blunt trauma can account for the largest percentage (90-95%) (9), while in urban settings the percentage of penetrating injuries can increase to 20% (6) or higher.

Blunt trauma is usually caused by motor vehicle accidents, falls, vehicle-associated pedestrian accidents, contact sports, and assault. Traffic accidents are the major cause of almost half the blunt renal injuries (10). Renal injury in frontal and side-impact collisions appears to occur after direct impact from objects in the vehicle compartment. For frontal crashes, occupant acceleration into the seat belt or steering wheel seems to result in renal injuries. Side impact injuries occur when the vehicle side panel intrudes into the compartment, striking the occupant (11). A 20-year review of renal injuries following free falls found a rate of 16% (12).

Renal lacerations and renal vascular injuries make up only 10-15% of all blunt renal injuries. Isolated renal artery injury following blunt abdominal trauma is extremely rare, and accounts for less than 0.1% of all trauma patients (13).

Renal artery occlusion is associated with rapid deceleration injuries. In theory, the kidney is displaced causing renal artery traction; the resulting tear in the inelastic intima and subsequent haemorrhage into the vessel wall leads to thrombosis. Compression of the renal artery between the anterior abdominal wall and the vertebral bodies may result in thrombosis of the renal artery.

Gunshot and stab wounds represent the most common causes of penetrating injuries. Renal injuries from penetrating trauma tend to be more severe and less predictable than those from blunt trauma. Bullets, because of their higher kinetic energy, have the potential for greater parenchymal destruction and are most often associated with multiple-organ injuries (14).

In wartime, the kidney is the most commonly injured urogenital organ. Most are found to be associated with major abdominal injuries, and the rate of wartime nephrectomies is relatively high (25-33%) (15-17).

*2.2.1 **Injury classification***

Classifying renal injuries helps to standardise different groups of patients, select appropriate therapy, and predict results. A total of 26 classifications for renal injuries have been presented in the literature in the past 50 years (18), but the committee on organ injury scaling of the American Association for the Surgery of Trauma (AAST) has developed a renal-injury scaling system that is now widely used (19). Renal injuries are classified as grade 1 to 5 (Table 3). Abdominal computed tomography (CT) or direct renal exploration is used to classify injuries. Most recent publications in the field of renal trauma have adopted this classification. In a retrospective review, the AAST scaling system was determined as the most important variable predicting the need for kidney repair or removal (20,21). It also predicts for morbidity after blunt or penetrating injury, and for mortality after blunt injury (22).

Table 3: AAST renal injury grading scale (17)

Grade*	Description of injury
1	• Contusion or non-expanding subcapsular haematoma • No laceration
2	• Non-expanding peri-renal haematoma • Cortical laceration < 1 cm deep without extravasation
3	• Cortical laceration > 1 cm without urinary extravasation
4	• Laceration: through corticomedullary junction into collecting system or • Vascular: segmental renal artery or vein injury with contained haematoma, or partial vessel laceration, or vessel thrombosis
5	• Laceration: shattered kidney or • Vascular: renal pedicle or avulsion

**Advance one grade for bilateral injuries up to grade 3.*

2.3 Diagnosis: initial emergency assessment

Initial assessment of the trauma patient should include securing the airway, controlling external bleeding, and resuscitation of shock, as required. In many cases, physical examination is carried out during the stabilisation of the patient. When renal injury is suspected, further evaluation (CT scan, laparotomy) is required for a prompt diagnosis.

2.3.1 History and physical examination

A direct history is obtained from conscious patients. Witnesses and emergency personnel can provide valuable information about unconscious or seriously injured patients. Possible indicators of major renal injury include a rapid deceleration event (fall, high-speed motor vehicle accidents) or a direct blow to the flank. In assessing trauma patients after motor vehicle accidents, the history should include the vehicle's speed and whether the patient was a passenger or pedestrian.

In penetrating injuries, important information includes the size of the weapon in stabbings, and the type and calibre of weapon used in gunshot wounds, as high-velocity projectiles have the potential to cause more extensive damage.

The medical history should be as detailed as possible, as pre-existing organ dysfunction can have a negative effect on trauma patient outcome (23). In the early resuscitation phase, special consideration should be given to pre-existing renal disease (24). Another point of interest is the functioning renal mass of the trauma patient, as there are numerous case reports in the literature about complicated renal trauma in solitary kidneys (25).

Pre-existing renal abnormality makes renal injury more likely following trauma. Pre-existing renal pathology should be noted. Hydronephrosis due to ureteropelvic junction abnormality, renal calculi, cysts, and tumours are the most commonly reported entities that may complicate a minor renal injury (26). The overall percentage of these cases varies from 4% to 22% (27,28).

Haemodynamic stability is the primary criterion for the management of all renal injuries. Shock is defined as a systolic blood pressure of less than 90 mmHg found at any time during an adult patient's evaluation. Vital signs should be recorded throughout diagnostic evaluation.

Physical examination may reveal an obvious penetrating trauma from a stab wound to the lower thoracic back, flanks, and upper abdomen, or bullet entry or exit wounds in this area. In stab wounds, the extent of the entrance wound may not accurately reflect the depth of penetration. Blunt trauma to the back, flank, lower thorax, or upper abdomen may result in renal injury. The following findings on physical examination could indicate possible renal involvement:

- haematuria;
- flank pain;
- flank ecchymoses;
- flank abrasions;
- fractured ribs;
- abdominal distension;
- abdominal mass;
- abdominal tenderness.

2.3.2 Recommendations

	GR
Haemodynamic stability should be decided upon admission.	B
History should be taken from conscious patients, witnesses and rescue team personnel with regard to the time and setting of the incident.	C
Past renal surgery, and known pre-existing renal abnormalities (ureteropelvic junction obstruction, large cysts, lithiasis) should be recorded.	B
A thorough examination should be made of the thorax, abdomen, flanks, and back for penetrating wounds.	B
Findings on physical examination such as haematuria, flank pain, flank abrasions and ecchymoses, fractured ribs, abdominal tenderness, distension, or mass could indicate possible renal involvement.	B

2.3.3 Laboratory evaluation

The trauma patient is evaluated by a series of laboratory tests. Urinalysis, haematocrit, and baseline creatinine are the most important tests for evaluating renal trauma.

Urinalysis is considered the basic test in the evaluation of patients with suspected renal trauma. Haematuria

is the presence of an abnormal quantity of red blood cells in the urine and is usually the first indicator of renal injury. Microscopic haematuria in the trauma setting may be defined as greater than 5 red blood cells per high-power field (rbc/hpf), while gross haematuria is demonstrated by urine in which blood is readily visible.

Haematuria is a hallmark sign of renal injury, but is neither sensitive nor specific enough for differentiating minor and major injuries. It does not necessarily correlate with the degree of injury (29). Major renal injury, such as disruption of the ureteropelvic junction, renal pedicle injuries or segmental arterial thrombosis may occur without haematuria (30). In a study by Eastham *et al.*, 9% of patients with stab wounds and resultant proven renal injury did not manifest haematuria (31). Haematuria that is out of proportion to the history of trauma may suggest pre-existing renal pathology (32). A urine dipstick is an acceptably reliable and rapid test to evaluate haematuria. However, some studies have shown false-negative result rates ranging from 3-10% using the dipstick test for haematuria (33).

Serial haematocrit determination is a method of continuous evaluation of the trauma patient. Initial haematocrit in association with vital signs implies the need for emergency resuscitation. The decrease in haematocrit and the requirement for blood transfusions is an indirect sign of the rate of blood loss and, along with the patient's response to resuscitation, is valuable in the decision-making process.

As most trauma patients are evaluated within 1 hour of injury, creatinine measurement reflects renal function prior to the injury. An increased creatinine usually reflects pre-existing renal pathology.

2.3.4 ***Recommendations***

	GR
Urine from a patient with suspected renal injury should be inspected grossly and then by dipstick analysis.	B
Serial haematocrit measurement indicates blood loss. However, until evaluation is complete, it will not be clear whether it is due to renal trauma and/or associated injuries.	B
Creatinine measurement could highlight patients who had impaired renal function prior to injury.	C

2.3.5 ***Imaging: criteria for radiographic assessment in adults***

Decisions about radiographic imaging in cases of suspected renal trauma are based on the clinical findings and the mechanism of injury. Since the majority of renal injuries are not significant and resolve without any intervention, many attempts have been made to identify which patients could be spared the discomfort, radiation exposure, possible allergic reaction, time, and expense of a radiographic evaluation (34).

Some patients do not require radiographic evaluation following blunt renal trauma. Patients with microscopic haematuria and no shock after blunt trauma have a low likelihood of concealing significant renal injury (35). The indications for radiographic evaluation are gross haematuria, microscopic haematuria and shock, or the presence of major associated injuries (36). However, patients with a history of rapid deceleration injury with clinical indicators of renal trauma or associated injuries also need immediate imaging to rule out ureteral avulsion or renal pedicle injury (12).

Patients with penetrating trauma to the torso have a high incidence of significant renal injuries. If renal injury is clinically suspected on the basis of an entry or exit wound, renal imaging should be performed, regardless of the degree of haematuria (37).

2.3.5.1 Ultrasonography

Ultrasonography (US) is a popular imaging modality in the initial evaluation of abdominal trauma. It provides a quick, non-invasive, low-cost means of detecting peritoneal fluid collections without exposure to radiation (38). However, the usefulness of conventional US in the radiographic evaluation of renal trauma has been widely questioned. Its limitations stem from the difficulty in obtaining good acoustic windows on trauma patients who have sustained numerous associated injuries. The results are also highly dependent on the operator.

Ultrasound scans can detect renal lacerations but cannot definitely assess their depth and extent and do not provide functional information about renal excretion or urine leakage. Despite the drawbacks of the method, US scans can be conveniently used during the primary assessment of renal injuries. During the evaluation of blunt trauma patients, US scans were more sensitive and specific than standard intravenous pyelography (IVP) in minor renal trauma (39). In a study comparing the results of US scans and IVP, the sensitivity of US decreased as the severity of the trauma increased, while that of IVP remained high for all degrees of severity (40).

Another possible role for US may be for serially evaluating stable renal injuries for the resolution of urinomas and retroperitoneal haematomas (41). Ultrasound might be considered suitable for the routine follow-up of renal parenchymal lesions or haematomas in the intensive care unit. Contrast-enhanced sonography is more sensitive than conventional US in the detection of renal injuries. In haemodynamically stable patients, it is

a useful tool in the assessment of blunt injuries (42).

In conclusion, since US scans are used in the triage of patients with blunt abdominal trauma in many centres, they can be helpful in identifying which patients require a more aggressive radiological exploration to obtain a certain diagnosis (43,44). Ultrasound findings do not provide sufficient evidence for a definite answer on the severity of renal injuries.

2.3.5.2 Standard IVP

Standard IVP is no longer the study of choice for the evaluation of renal trauma. In some centres it may be the only study available, in which case IVP should establish the presence or absence of one or both of the kidneys, clearly define the renal parenchyma, and outline the collecting system. In order to stage renal trauma, the IVP should include nephrotomograms, delineate the renal contour, and visualise the excretion of contrast material from both kidneys into the renal pelvis and ureter. Non-visualisation, contour deformity, or extravasation of contrast implies a major renal injury and should prompt further radiological evaluation with CT or, less commonly, angiography if available.

The most significant findings on IVP are non-function and extravasation. Non-function is usually a sign of extensive trauma to the kidney, pedicle injury (vascular avulsion or thrombosis), or a severely shattered kidney. Extravasation of the contrast medium also implies a severe degree of trauma, involving the capsule, parenchyma, and collecting system. Other less reliable signs are delayed excretion, incomplete filling, calyceal distortion, and obscuring of the renal shadow. The sensitivity of IVP is high (> 92%) for all degrees of trauma severity (45).

2.3.5.3 One-shot intraoperative IVP

Unstable patients selected for immediate operative intervention (and thus unable to have a CT scan) should undergo one-shot IVP in the operating theatre. The technique consists of a bolus intravenous injection of 2 mL/kg of radiographic contrast followed by a single plain film taken after 10 minutes. The study is safe, efficient, and of high quality in the majority of cases. It provides important information for decision-making in the critical time of urgent laparotomy concerning the injured kidney, as well as the presence of a normal functioning kidney on the contralateral side (46).

While the majority of experts advocate its use, not all studies have shown one-shot IVP to be necessary. In cases of penetrating abdominal trauma, the positive predictive value of one-shot IVP was only 20% (80% of patients with normal one-shot IVP findings had renal injuries not detected by the IVP) (47). One-shot IVP is of no significant value in assessing penetrating abdominal trauma patients who undergo exploratory laparotomy for associated intra-abdominal injuries, and should be reserved only for patients with a flank wound or gross haematuria following penetrating trauma (48).

2.3.5.4 Computed tomography (CT)

Computed tomography is the gold standard method for the radiographic assessment of stable patients with renal trauma. CT is more sensitive and specific than IVP, ultrasonography or angiography. In a retrospective study, the positive rate during evaluation of 298 patients was 96% by CT, 91% by double-dose intravenous IVP and 79% by US (45).

Computed tomography more accurately defines the location of injuries, easily detects contusions and devitalised segments, visualises the entire retroperitoneum and any associated haematomas, and simultaneously provides a view of both the abdomen and pelvis. It demonstrates superior anatomical detail, including the depth and location of renal laceration and presence of associated abdominal injuries, and establishes the presence and location of the contralateral kidney (49). Computed tomography is particularly useful in evaluating traumatic injuries to kidneys with pre-existing abnormalities (50).

Intravenous contrast should be administered for renal evaluation. A lack of contrast enhancement of the injured kidney is a hallmark of renal pedicle injury. In cases where this typical finding is not demonstrated, central parahilar haematoma increases the possibility of renal pedicle injury. This sign should be considered even if the renal parenchyma is well enhanced (51).

Renal vein injury remains difficult to diagnose with any type of radiographic study. However, the presence on CT of a large haematoma, medial to the kidney and displacing the renal vasculature, should raise the suspicion of venous injury. Newer ‘spiral’ CT provides shorter scanning time and thus fewer artefacts in the examinations of patients who cannot co-operate adequately (52). Three-dimensional post-processing modalities allow assessment of the renal vascular pedicle by CT angiography and improve the demonstration of complex lacerations of the renal parenchyma. However, injury to the renal collecting system may be missed during routine spiral CT. In all cases of suspected renal trauma evaluated with spiral CT, repeat scans of the kidneys should be performed 10-15 minutes after contrast injection (53). Most blunt ureteral and ureteropelvic junction injuries can be identified if delayed excretory CT scans are performed (54). Computed tomography scanning is also safe as part of the diagnostic procedure for patients with gunshot wounds who are being

considered for non-operative management (55).

2.3.5.5 Magnetic resonance imaging (MRI)

Although MRI is not used in the majority of renal trauma patients, Leppäniemi *et al*. investigated the use of high-field strength MRI (1.0 T) in the evaluation of blunt renal trauma (56). MRI scans were accurate in finding peri-renal haematomas, assessing the viability of renal fragments, and detecting pre-existing renal abnormalities, but failed to visualise urinary extravasation on initial examination. The authors concluded that MRI could replace CT in patients with iodine allergy and could be used for initial staging if CT were not available (56).

In a recent study comparing CT and MRI findings, the latter clearly revealed renal fracture with non-viable fragment, and was able to detect focal renal laceration not detected on CT due to peri-renal haematoma (57).

However, MRI is not the first choice in managing patients with trauma because it requires a longer imaging time, increases the cost, and limits access to patients when they are in the magnet during the examination. MRI is therefore useful in renal trauma only if CT is not available, in patients with iodine allergy, or in the very few cases where the findings on CT are equivocal.

2.3.5.6 Angiography

Computed tomography has largely replaced the use of angiography for staging renal injuries, as angiography is less specific, more time-consuming and more invasive. Angiography is, however, more specific for defining the exact location and degree of vascular injuries and may be preferable when planning selective embolisation for the management of persistent or delayed haemorrhage from branching renal vessels (50).

Angiography can define renal lacerations, extravasation, and pedicle injury. Additionally, it is the test of choice for evaluating renal venous injuries. The most common indication for arteriography is non-visualisation of a kidney on IVP after major blunt renal trauma when a CT is not available. Common causes for non-visualisation are:

- total avulsion of the renal vessels (usually presents with life-threatening bleeding);
- renal artery thrombosis;
- severe contusion causing major vascular spasm.

Angiography is also indicated in stable patients to assess pedicle injury if the findings on CT are unclear, and for those who are candidates for radiological control of haemorrhage (31).

2.3.5.7 Radionuclide scans

Radionuclide scans might be helpful for documenting renal blood flow in trauma patients with severe allergy to iodinated contrast material (50), but are not generally used or required.

2.3.6 ***Recommendations***

	GR
Blunt trauma patients with macroscopic or microscopic haematuria (at least 5 rbc/hpf) with hypotension (systolic blood pressure < 90 mmHg) should undergo radiographic evaluation.	B
Radiographic evaluation is also recommended for all patients with a history of rapid deceleration injury and/or significant associated injuries.	B
All patients with any degree of haematuria after penetrating abdominal or thoracic injury require urgent renal imaging.	B
Ultrasonography can be informative during the primary evaluation of polytrauma patients and for the follow-up of recuperating patients, although more data is required to suggest this modality universally.	C
A CT scan with enhancement of intravenous contrast material is the best imaging study for the diagnosis and staging of renal injuries in haemodynamically stable patients.	B
Unstable patients who require emergency surgical exploration should undergo a one-shot IVP with bolus intravenous injection of 2 mL/kg contrast.	C
Formal IVP, MRI, and radiographic scintigraphy are acceptable second-line alternatives for imaging renal trauma when CT is not available.	C
Angiography can be used for diagnosis and simultaneous selective embolisation of bleeding vessels.	B

2.4 Treatment

*2.4.1 **Indications for renal exploration***

The goal in managing patients with renal injuries is to minimise morbidity and to preserve renal function. The need for renal exploration can be predicted with accuracy with a nomogram, which uses the type of injury, transfusion requirements, blood urea nitrogen (BUN), creatinine, and injury grade (58). However, the management of renal injury is usually influenced by the decision to explore or observe associated abdominal injuries (59).

A life-threatening haemodynamic instability due to renal haemorrhage is an absolute indication for renal exploration, irrespective of the mode of injury (60,61). Other indications include an expanding or pulsatile peri-renal haematoma identified at exploratory laparotomy performed for associated injuries (this finding heralds a grade 5 vascular injury and is quite rare). A one-shot intraoperative IVP can provide valuable information. Poor visualisation or any other abnormality of the injured kidney is an indication for exploration.

Grade 5 vascular renal injuries are, by definition, regarded as an absolute indication for exploration, although a single report has suggested that patients who are haemodynamically stable at presentation but with a grade 5 parenchymal injury (shattered kidney) after blunt trauma might be safely treated conservatively (62).

The management of major renal injuries with urinary extravasation and devitalised fragments is controversial. Since these injuries are very uncommon, published series report on small numbers of patients. In recent years, it seems to have been recognised that most major injuries heal with non-operative treatment (63). Moudouni *et al*. suggest that an initially conservative approach is feasible in stable patients with devitalised fragments (64). These injuries are, however, associated with an increased rate of complications and late surgery (65).

Persistent extravasation or urinoma are usually managed successfully with endourological techniques. Inconclusive renal imaging and a pre-existing renal abnormality or an incidentally diagnosed tumour could require surgery even after relatively minor renal injury (32).

*2.4.2 **Operative findings and reconstruction***

The overall exploration rate for blunt trauma is less than 10% (60), and may be even lower as more centres adopt a very conservative approach to the management of these patients (66). The goal of renal exploration following renal trauma is control of haemorrhage and renal salvage. Most experienced authors suggest the transperitoneal approach for surgery (67,68). Access to the renal vascular pedicle is then obtained through the posterior parietal peritoneum, which is incised over the aorta, just medial to the inferior mesenteric vein.

Temporary vascular occlusion before opening Gerota's fascia is a safe and effective method during exploration and renal reconstruction (69). It tends to lower blood loss and the nephrectomy rate, and appears not to increase post-operative azotaemia or mortality (70). Renal reconstruction is feasible in most cases. The overall rate of patients who have a nephrectomy during exploration is around 13%, usually in patients with penetrating injury, and higher rates of transfusion requirements, haemodynamic instability, injury severity scores, and mortality (71). Other intra-abdominal injuries also slightly increase the need for nephrectomy (72). Mortality is associated with the overall severity of the injury and is not often a consequence of the renal injury itself (73). In gunshot injuries caused by a high-velocity bullet, reconstruction can be difficult and nephrectomy is often required (14).

Renorrhaphy is the most common reconstructive technique. Partial nephrectomy is required when non-viable tissue is detected. Watertight closure of the collecting system, if open, might be desirable, although some experts merely close the parenchyma over the injured collecting system with good results. If the renal capsule is not preserved, an omental pedicle flap or peri-renal fat bolster may be used for coverage (74). In a review by Shekarriz and Stoller, the use of fibrin sealant in traumatic renal reconstruction proved to be helpful (75). Newly developed haemostatic agents that have proven useful in open and laparoscopic partial nephrectomy, might also be helpful, but are largely unproven in the trauma setting. In all cases, drainage of the ipsilateral retroperitoneum is recommended to provide an outlet for any temporary leakage of urine.

Renovascular injuries are uncommon. They are associated with extensive associated trauma and increased peri- and post-operative mortality and morbidity. Blunt renal artery injury is rare. Non-operative management should be considered as an acceptable therapeutic option (76).

Following blunt trauma, repair of grade 5 vascular injury is seldom if ever effective (77). Repair could be attempted in those very rare cases in which there is a solitary kidney or the patient has sustained bilateral injuries (78). In all other cases, nephrectomy appears to be the treatment of choice (79). In a recent review, it appears that nephrectomy for main renal artery injury has outcomes similar to those of vascular repair, and it does not worsen post-treatment renal function in the short term. Non-operative management for segmental renal artery injury results in excellent outcomes (80).

Angiography with selective renal embolisation for haemorrhage control is a reasonable alternative to laparotomy provided that no other indication for immediate surgery exists (81). Cure of haematuria after superselective transarterial embolisation is reported as high as 98% (82). Successful haemostasis by

embolisation is reported to be identical in blunt and penetrating injuries (83,84). The complication rate is minimal, and it has been proven effective for grade 4 injuries where conservative therapy failed (85). In our series, embolisation failed when applied to grade 5 injuries (85).

*2.4.3 **Non-operative management of renal injuries***

As the indications for renal exploration become clearer, non-operative management has become the treatment of choice for the majority of renal injuries. In stable patients, supportive care with bed-rest, hydration, and antibiotics is the preferred initial approach (7). Primary conservative management is associated with a lower rate of nephrectomy without any increase in the immediate or long-term morbidity (86). The failure of conservative therapy is low (1.1%) (6).

All grade 1 and 2 renal injuries can be managed non-operatively, whether due to blunt or penetrating trauma. Therapy of grade 3 injuries has been controversial, but recent studies support expectant treatment (87-89). Patients diagnosed with urinary extravasation in solitary injuries can be managed without major intervention and a resolution rate of > 90% (90). Persistent bleeding is the main indication for a reconstruction attempt (91).

The majority of patients with grade 4 and 5 renal injuries present with major associated injuries, and consequently experience high exploration and nephrectomy rates (92), although emerging data indicate that many of these patients can be managed safely with an expectant approach. Although almost all grade 4 patients with penetrating injury require renal exploration, only 20% of those with blunt trauma do (93). Isolated grade 4 renal injuries represent a unique situation to treat the patient based solely on the extent of the renal injury, thus non-operative management is used more frequently. Persistent bleeding represents the main indication for renal exploration and reconstruction. In all cases of severe renal injury, non-operative management should occur only after complete renal staging in haemodynamically stable patients (91).

Penetrating wounds have traditionally been approached surgically. However, stable patients should undergo complete staging to define the full extent of the injury. Renal gunshot injuries should be explored only if they involve the hilum or are accompanied by signs of continued bleeding, ureteral injuries, or renal pelvis lacerations (94).

Low-velocity gunshot and stab wounds of minor degree may be managed conservatively with an acceptably good outcome (95). Tissue damage from high-velocity gunshot injuries, on the other hand, might be more extensive and nephrectomy could be required. Non-operative management of renal gunshot wounds in selected stable patients is associated with a high rate of success (96-98).

If the site of penetration by stab wound is posterior to the anterior axillary line, 88% of such renal injuries can be managed non-operatively (99). Injuries to the flank are more likely to be grade 3, while injuries to the abdomen are more likely to be grade 1. A systematic approach based on clinical, laboratory, and radiological evaluation might minimise negative exploration without increasing morbidity from missed injury (61). Renal stab wounds producing major renal injuries (grade 3 or higher) are more unpredictable and are associated with a higher rate of delayed complications if treated expectantly (100).

*2.4.4 **Recommendations***

	GR
Following grade 1-4 blunt renal trauma, stable patients should be managed conservatively with bed-rest, prophylactic antibiotics, and continuous monitoring of vital signs until haematuria resolves.	B
Following grade 1-3 stab and low-velocity gunshot wounds, stable patients, after complete staging, should be selected for expectant management.	B
Indications for surgical management include: - haemodynamic instability; - exploration for associated injuries; - expanding or pulsatile peri-renal haematoma identified during laparotomy; - grade 5 injury.	
Incidental finding of pre-existing renal pathology requiring surgical therapy.	B
Renal reconstruction should be attempted in cases where the primary goal of controlling haemorrhage is achieved and a sufficient amount of renal parenchyma is viable.	B

*2.4.5 **Post-operative care and follow-up***

Patients who are successfully treated conservatively carry some risk of complications. This risk correlates with increasing grade. Repeat imaging 2-4 days after trauma minimises the risk of missed complications, especially in grade 3-5 blunt renal injuries (101). However, the utility of frequent CT scanning after injury has never been

satisfactorily proven. CT scans should always be performed on patients with fever, unexplained decreasing haematocrit, or significant flank pain.

Nuclear renal scans are useful for documenting and tracking functional recovery in patients following renal reconstruction before discharge from hospital (97). To detect many of the delayed complications, an excretory urogram is recommended within 3 months of major renal injury, although benefit to the patient has not yet been proven in the literature. Follow-up should involve physical examination, urinalysis, individualised radiological investigation, serial blood pressure measurement and serum determination of renal function (60, 64). Follow-up examinations should continue until healing is documented and laboratory findings have stabilised, although checking for latent renovascular hypertension may need to continue for years (102).

The literature is generally inadequate on the subject of the long-term consequences of trauma on renal tissue. It appears that on histopathological evaluation, renal tissue may appear dystrophic following some cases of conservative management of minor renal injuries (103).

2.4.6 ***Recommendations***

	GR
Repeat imaging is recommended for all hospitalised patients within 2-4 days of significant renal trauma (although no specific data exists). Repeat imaging is always recommended in cases of fever, flank pain, or falling haematocrit.	B
Nuclear scintigraphy before discharge from the hospital is useful for documenting functional recovery.	C
Within 3 months of major renal injury, patients' follow-up should involve: 1. physical examination; 2. urinalysis; 3. individualised radiological investigation; 4. serial blood pressure measurement; 5. serum determination of renal function.	C
Long-term follow-up should be decided on a case-by-case basis but should at the very least involve monitoring for renovascular hypertension.	C

2.4.7 ***Complications***

Early complications occur within the first month after injury and can be bleeding, infection, peri-nephric abscess, sepsis, urinary fistula, hypertension, urinary extravasation, and urinoma. Delayed complications include bleeding, hydronephrosis, calculus formation, chronic pyelonephritis, hypertension, arteriovenous fistula, hydronephrosis, and pseudoaneurysms.

Delayed retroperitoneal bleeding usually occurs within several weeks of an injury or procedure and may be life-threatening. Selective angiographic embolisation is the preferred treatment (104). Peri-nephric abscess formation is usually best managed by percutaneous drainage, although open drainage may sometimes be required (60). Percutaneous management of complications may pose less risk of renal loss than re-operation, which may lead to nephrectomy when infected tissues make reconstruction difficult.

Renal trauma is a rare cause of hypertension, mostly in young men. The frequency of post-traumatic hypertension is estimated to be less than 5% in all published series (105,106). Hypertension may occur acutely as a result of external compression from peri-renal haematoma (Page kidney), or chronically because of compressive scar formation (Goldblatt kidney). Hypertension is usually renin-dependent and associated with parenchymal injury. Renin-mediated hypertension may occur as a long-term complication; aetiologies include renal artery thrombosis, segmental arterial thrombosis, renal artery stenosis (Goldblatt kidney), devitalised fragments and arteriovenous fistulae. Arteriography is informative in cases of post-traumatic hypertension (107). Treatment is required if the hypertension persists, and could include medical management, excision of the ischaemic parenchymal segment, vascular reconstruction, or total nephrectomy (108).

Urinary extravasation after renal reconstruction often subsides without intervention as long as ureteral obstruction and infection are not present. Ureteral retrograde stenting may improve drainage and allow healing (109). Persistent urinary extravasation from an otherwise viable kidney after blunt trauma often responds to stent placement and/or percutaneous drainage as necessary (63).

Arteriovenous fistulae usually present with delayed onset of significant haematuria, most often after penetrating trauma. Percutaneous embolisation is often effective for symptomatic arteriovenous fistulae, but larger ones may require surgery (110).

The development of pseudoaneurysm is a rare complication following blunt renal trauma. In numerous case reports, transcatheter embolisation appears to be a reliable minimally invasive solution (111,112).

Acute renal colic from a retained missile has been reported, and can be managed endoscopically if

possible (113). Other unusual late complications, such as duodenal obstruction, may result from retroperitoneal haematoma following blunt renal trauma (114).

2.4.8 ***Recommendations***

	GR
Complications following renal trauma require a thorough radiographic evaluation.	B
Medical management and minimally invasive techniques should be the first choice for the management of complications.	C
Renal salvage should be the surgeon's aim for patients in whom surgical intervention is necessary.	C

2.4.9 ***Paediatric renal trauma***

Blunt renal trauma is the most common injury seen in children and accounts for more than 90% of renal injuries in the paediatric population (115,116). Children are more susceptible to renal trauma than adults. Differences in anatomy and physiology, as well as the higher incidence of pre-existing renal disease, make children more likely to sustain injury. The kidneys are lower in the abdomen, less well-protected by the lower ribs and muscles of the flank and abdomen, more mobile, have less protective peri-renal fat and are proportionately larger in the abdomen than in adults (117-119).

History and physical examination are very important factors in the evaluation of the paediatric patient with suspected renal trauma. Unlike adults, hypotension is an unreliable sign in children, as an outpouring of catecholamines can maintain blood pressure despite a significant volume of blood loss. Hypotension is less common in children, and significant injury can be present despite stable blood pressures (120). Another important difference from adults is that children with microscopic haematuria or normal urinalyses and stable vital signs may have sustained significant renal injury (121). Haematuria is an important clinical sign of paediatric renal injury and is directly related to the severity of that renal injury and the presence of associated injuries (122).

The radiographic evaluation of children with suspected renal trauma is still controversial. Stein *et al*. proposed that all paediatric patients with any degree of haematuria should be evaluated for renal trauma (123). In contrast, Morey *et al*. concluded that significant injuries are unlikely in the absence of gross or significant microscopic haematuria (> 50 rbc/hpf) (124). Nguyen and Das proposed a low threshold for renal imaging following renal trauma. The instances of its use should include patients with blunt abdominal trauma with any level of haematuria, patients with associated abdominal injury regardless of the findings of urinalysis, and patients with normal urinalyses but in whom the mechanism of injury has a high index of suspicion for renal trauma (i.e. rapid deceleration event, direct flank trauma, falls from a height) (125). After studying 720 paediatric trauma cases, Santucci *et al*. concluded that the decision for imaging based on the adult criteria of gross haematuria, shock and significant deceleration injury is appropriate (126).

Ultrasound is considered a reliable method of screening and following the course of renal injury in paediatric patients with blunt renal trauma in Europe, although it is used much less frequently in the USA (127, 128). Ultrasound is used in some centres, mostly in stable cases with abnormal urinalyses and/or findings suggestive of a major injury (129). The diagnostic accuracy of IVP is superior to that of US, and should be performed as an emergency procedure if CT scan is not available (130).

Computed tomography is the best imaging modality, however, and those with multiple injuries or suspected renal trauma should be evaluated by contrast-enhanced CT if possible (131,132). The use of MRI in paediatric patients with vesicoureteral reflux found that MRI at 1.5 T was better than dimercaptosuccinic acid (DMSA) scans in detecting small renal parenchymal lesions (133), although MRI has little proven use in the acute management of the trauma patient.

Conservative treatment for grade 1-2 renal injuries is clearly defined, and these injuries should be managed expectantly (134). Non-operative management results in an excellent long-term outcome in the majority of cases (135). Non-operative management of high grade renal injuries is effective and is recommended for stable children, but requires close clinical observation, serial CT, and frequent reassessment of the patient's overall condition (136).

The length of hospital stay does not increase with worsening severity of renal injury, but is determined by the severity of non-renal injuries (137). Haemodynamic instability and a diagnosed grade 5 injury are the strongest indications for operative management (59,120,136). Stable patients with urinary extravasation can also be managed expectantly since most urinomas resolve spontaneously. In cases where there is persistent leakage, the placement of a ureteral stent or percutaneous drainage is feasible and curative in most cases. Early placement of a ureteral stent can be considered for paediatric patients with blunt renal trauma who demonstrate an absence of contrast material in the ipsilateral ureter, as clinical indications for stent placement will likely develop (138).

Major kidney trauma has significant consequences on the opposite side. Post-traumatic functional

evaluation by DMSA scintigraphy 8 days after major injury is a valid prognostic indicator of later function, but its clinical utility has never been established.

Children with renal injuries that fail with non-surgical therapy appear to do so in a median time of 4 hours, but the majority of patients fail within the first 24 hours (139). The failure rate of non-surgical management for renal injuries is 3% (140). Buckley and McAninch presented an algorithm for the management of paediatric renal injuries based on the 25 year experience of the San Francisco General Hospital, which is highly recommended (135) (Figure 1).

Mild renal injuries do not require follow-up imaging. Follow-up is only recommended for patients with major injuries as there is an increased risk of delayed complications and loss of renal function (139).

The majority of patients with severe renal injuries develop parenchymal scars. Radionuclide scans such as DMSA can be useful in the early diagnosis of scars and consequent hypertension (141).

2.4.10 ***Recommendations***

	GR
Indications for radiographic evaluation of children suspected of renal trauma include: 1. blunt and penetrating trauma patients with any level of haematuria; 2. patients with associated abdominal injury regardless of the findings of urinalysis; 3. patients with normal urinalysis who sustained a rapid deceleration event, direct flank trauma, or a fall from a height.	B
Ultrasonography is considered a reliable method of screening and monitoring blunt renal injuries by some researchers, but is not universally accepted.	B
CT scanning is the imaging study of choice for staging renal injuries.	B
Haemodynamic instability and a diagnosed grade 5 injury are absolute indications for surgical exploration.	B

2.4.11 ***Renal injury in the polytrauma patient***

Approximately 8-10% of blunt and penetrating abdominal injuries involve the kidneys. The incidence of associated injury in penetrating renal trauma ranges from 77-100%. Gunshot wounds are associated with organ injury more often than are stab wounds. The majority of patients with penetrating renal trauma have associated adjacent organ injuries that may complicate treatment. In the absence of an expanding haematoma with haemodynamic instability, associated multiorgan injuries do not increase the risk of nephrectomy (142).

Blunt and penetrating trauma equally contributed to combined renal and pancreatic injury, as reported by Rosen and McAninch (143). Renal preservation was achieved in most patients, and the complication rate of the series was 15% (143). A similar rate of complications (16%) was reported in patients with simultaneous colon and renal injury. In a report reviewing this combination of injuries over a period of 17 years, 58% of patients underwent an exploration, with nephrectomies performed in 16% of explorations (144).

Renal injuries seem to be rather rare in patients with blunt chest trauma. In a recent study of polytrauma patients, conservative management was safely attempted without increasing morbidity (145). In polytrauma patients undergoing partial or total nephrectomy, there is no increased mortality or renal failure rate (146).

2.4.12 ***Recommendations***

	GR
Polytrauma patients with associated renal injuries should be evaluated on the basis of the most threatening injury.	C
In cases where surgical intervention is chosen, all associated injuries should be evaluated simultaneously.	C
The decision for conservative management should consider all injuries independently.	C

2.5 Iatrogenic renal injuries

2.5.1 ***Iatrogenic vascular injuries***

Iatrogenic main renal artery injuries with perforation or rupture are rare. They are usually reported after renal artery angioplasty or stenting, and have an incidence of 1.6% (147). One case of an iatrogenic renal artery perforation as a complication of cardiac catheterisation has also been reported (148). Since most iatrogenic renal artery lesions occur during endovascular procedures, there are no reports on the clinical symptoms, but

only on the angiographic findings. Arteriovenous fistulae, pseudoaneurysms, arterial dissection, or contrast extravasation are the possible radiological findings in these traumatic vascular lesions.

Traditional therapy for renal perforation has been renal artery ligation followed by bypass grafting or nephrectomy, but nowadays the treatment for acute iatrogenic rupture of the main renal artery is balloon tamponade. However, in case of failure, the immediate availability of a stent graft is vital.

Patients with iatrogenic operative injuries are strikingly different from those with penetrating, blunt, or catheter-related vascular trauma. Renal vessels are vulnerable during oncological procedures. Factors that increase technical difficulty are previous operation, tumour recurrence, radiation exposure, and chronic inflammatory changes.

Renal vein injuries during elective abdominal operations represent a serious complication with significant morbidity. Most patients with operative venous injuries have partial lacerations that can be managed with relatively simple techniques, such as venorrhaphy. Patch angioplasty with autologous vein or polytetrafluoroethylene (ePTFE) graft may be required if venorrhaphy is not possible (149).

Some renal vascular injuries, such as pseudoaneurysms following nephron-sparing surgery, can be managed by transcatheter embolisation (150).

2.5.2 ***Renal transplantation***

The orthotopic kidney is protected from external force by muscles, Gerota's fascia, and peri-nephric fat. A renal graft is located in the lower pelvis in the iliac fossa and is therefore more susceptible to injury, especially from direct blows to the abdomen. The transplanted kidney, unlike the native kidney, is fixed in position by a thick fibrotic capsule that develops post-transplant. Also, the transplant kidney is not suspended by the renal vessels, so deceleration events that cause pedicle injury to a native kidney are less likely to affect a transplanted kidney (151). As transplant recipients return to more active lifestyles, including a significant risk of becoming a trauma victim, a renal graft is liable to be severely affected by trauma that might not cause any injury to a native kidney.

In transplant recipients it is very important to know patients' baseline renal function (152). The knowledge of an abnormal renal baseline may prevent unnecessary extensive diagnostic evaluation. Radiographic evaluation should proceed as for the native kidney. The increased risk for contrast nephrotoxicity can be minimised with adequate hydration.

A CT scan is the test of choice for a stable injured transplant recipient, as it will identify renal and associated intra-abdominal injuries and will also indirectly assess renal blood flow and function. A renal duplex examination can be also very helpful for identifying isolated trauma to the transplanted kidney and for identifying renal blood flow. Radionuclide scans might reveal urine leaks and are good for assessing overall blood flow and renal function, while angiography can assess blood flow and identify specific arterial injuries.

The surgical management of an injured transplanted kidney is complex. A very short vascular pedicle and ureter, dense scarring, and a fibrous capsule may prevent any attempt at the direct repair of the parenchymal, collecting system and vascular pedicle injuries. Grade 1-3 injuries can be managed non-operatively. Grade 4-5 injuries might require exploration with debridement and drainage. Major injuries could require a subcapsular nephrectomy. Renovascular injuries have a poor prognosis. Renal arteriography may be helpful with embolisation of the main artery to stop bleeding, or with more selective embolisation to salvage part of the kidney. When renal graft injury occurs, saving the patient's life is the first priority, but saving the graft is also very important to maintain renal function.

Iatrogenic vascular injuries of renal transplants can be managed by embolisation. Angiographic embolisation often fails, and is associated with a high complication rate and high eventual nephrectomy rate (153). On the other hand, transcatheter embolisation is highly effective for biopsy-related vascular injury in the transplanted kidney.

2.5.3 ***Percutaneous renal procedures***

Percutaneous nephrostomy is achieved in nearly all patients without major complications. Haematuria is common for a few days, but massive retroperitoneal haemorrhage is rare. Small subcapsular renal haematomas resolve spontaneously, while arteriovenous-calyceal fistulae are best managed by angiographic embolisation.

If a nephrostomy catheter is seen to transfix the renal pelvis, the possibility of injury to a large renal artery must be considered. The misplaced nephrostomy catheter should be withdrawn over a guidewire, and renal artery embolisation might enable rapid arrest of a life-threatening haemorrhage (154). In more complex cases, CT could be used to detect possible catheter malposition and successfully guide catheter repositioning into the renal collecting system (155).

Renal pelvis injuries can occur during percutaneous nephrostomy placement. Haemorrhage can be prevented by avoiding puncture in anticoagulated or coagulopathic patients, careful puncture on to target calyceals, and avoidance of medial punctures. A pelvic injury is less likely to happen if the dilator is not

advanced further than the calyx, the peelaway sheaths are handled with care, especially when advanced around the pelviureteric junction, and kinking of the guidewires is avoided (156).

Percutaneous renal biopsy is a relatively safe procedure. Haemorrhage, arteriovenous fistula and renal capsular artery pseudoaneurysm might occur. Arteriovenous fistula might present with severe hypertension and is managed by embolisation (157). A pseudoaneurysm should be suspected if the patient presents with flank pain and decreasing haematocrit without haematuria. Arteriography and transarterial embolisation is the appropriate therapy (158).

Percutaneous nephrolithotomy (PCNL) is a popular procedure in which stones in the renal pelvis are removed via a nephroscope, often after ultrasonic or electrohydraulic disruption. The complications include haemorrhage, extravasation, and absorption of large volumes of irrigation fluid, fever, infection, colonic perforation, arteriovenous fistulae, and pneumothorax.

Extravasation of fluid is often due to a tear in the pelvicalyceal system. A close watch on irrigation fluid input and output is required for early recognition of the complication. Termination of the procedure if the renal pelvis is torn or ruptured is a safe choice. Apart from intraoperative evaluation of serum electrolytes, acid-base status and oxygenation, the monitoring of airway pressure is a good indicator of this complication. Metabolic acidosis, hyponatraemia, hypokalaemia, peritonism, and ileus are due to absorption of large volumes of irrigation fluids. Management of this complication requires close monitoring, placement of an abdominal or retroperitoneal drain, correction of acidosis and supportive measures (159).

The diagnosis of a colon injury during or after percutaneous renal surgery can be elusive because symptoms are often variable. An unrecognised or untreated colon injury can result in abscess formation, septicaemia, and/or nephrocolic or colocutaneous fistula. Surgical exploration is inevitable when the patient experiences haemorrhage, pneumoperitoneum, and peritonitis.

The majority of these cases can be successfully managed conservatively. The consistent application of proper techniques, avoidance of puncturing the kidney lateral to the posterior axillary line, and puncture of the upper pole calyx when feasible, will help prevent the injuries.

Vascular injuries with renal bleeding are quite frequent and can occur at any stage of the percutaneous procedure, requiring transfusion in 1-11% of cases. A high number of punctures and incorrect choice of puncture site (access that is too medial or direct puncture of the renal pelvis) have been suggested as the cause of vascular lesions after percutaneous procedures. Renal bleeding can arise from both venous and arterial lesions. Bleeding from venous vessels could be profuse at the end of a procedure, but is generally controlled by simple measures, such as placing the patient supine to reduce abdominal compression, positioning a nephrostomy catheter, and forcing diuresis through hydration and parenteral administration of mannitol after clamping of the nephrostomy catheter. In the case of major venous trauma with massive haemorrhage, patients with concomitant renal insufficiency can be treated without open exploration or angiographic embolisation using a Council balloon catheter (160).

Arterial lesions may induce acute or late post-operative bleeding. Severe acute bleeding usually arises from injury to the anterior or posterior segmental arteries. Delayed bleeding is usually caused by interlobar and lower pole artery lesions, often arteriovenous fistulae and post-traumatic aneurysms. Duplex US and CT angiography can diagnose vascular injuries.

Hyperselective renal embolisation is considered the most appropriate technique for the treatment of iatrogenic vascular lesions. It is essential to identify the precise site of the lesion so as to be as selective as possible and reduce the risk of renal dysfunction. Hyperselective catheterisation of the renal artery branches is achieved by means of either hydrophilic 5 French catheters or coaxial systems with low profile microcatheters (2.6 French). The use of an embolic agent helps in performing a distal and irreversible occlusion with complete haemostasis. A variety of embolic materials have been used; microcoils, homologous clots, detachable balloons, polyvinyl alcohol particles, gelfoam, silicone rubber, cotton pellets, and silk filaments. The choice of the embolic agent is dependent mainly on the blood flow entity at the level of the lesion, the vessel size and the operator's experience.

Finally, complications of endopyelotomy can be classified as major (vascular injury) and minor (infection, urinoma) (161). Preventive steps, along with proper patient selection, minimise the risk for these complications.

2.5.4 *Recommendations*

	GR
Iatrogenic rupture of the main renal artery should be treated with balloon tamponade and, in case of failure, with a stent graft.	C
Surgical venous injuries should be managed with venorrhaphy or patch angioplasty.	C
The transplanted kidney should be evaluated on the basis of renal function, type of injury and the patients' condition.	C
Hyperselective embolisation may control arterial bleeding during percutaneous procedures.	C

2.6 Suggestions for future research studies

Among the topics that would be useful subjects for future research studies are:

- blunt trauma grade 5 patients, as it appears that some of them may benefit from non-surgical management;
- the necessity and nature of follow-up imaging;
- the value of the administration of antibiotics in low-grade renal injuries selected for conservative management.

2.7 Algorithms

Figure 1 is an algorithm for the management of renal trauma in children. Figures 2 and 3 show the suggested treatment of blunt and penetrating renal injuries in adults.

Figure 1: Algorithm for the management of paediatric renal trauma (119)

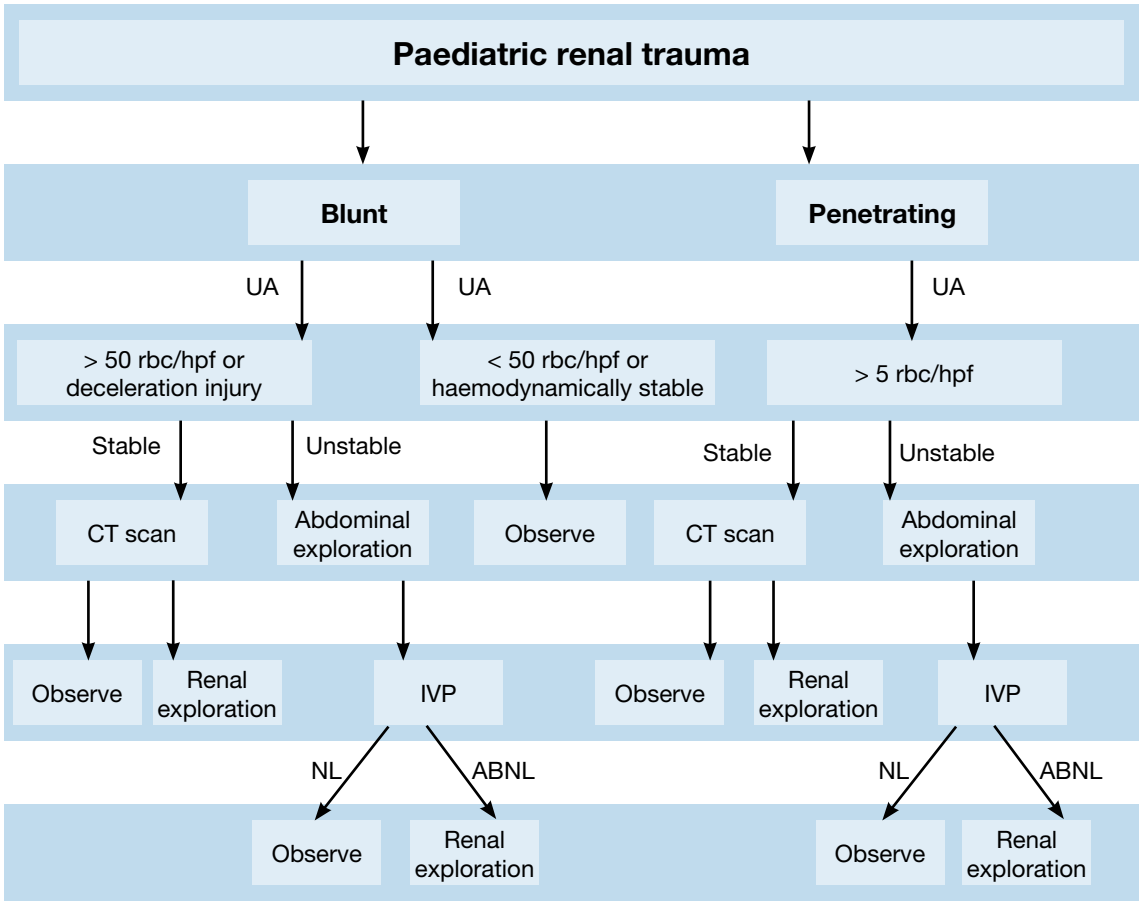

Figure 2: Evaluation of blunt renal trauma in adults

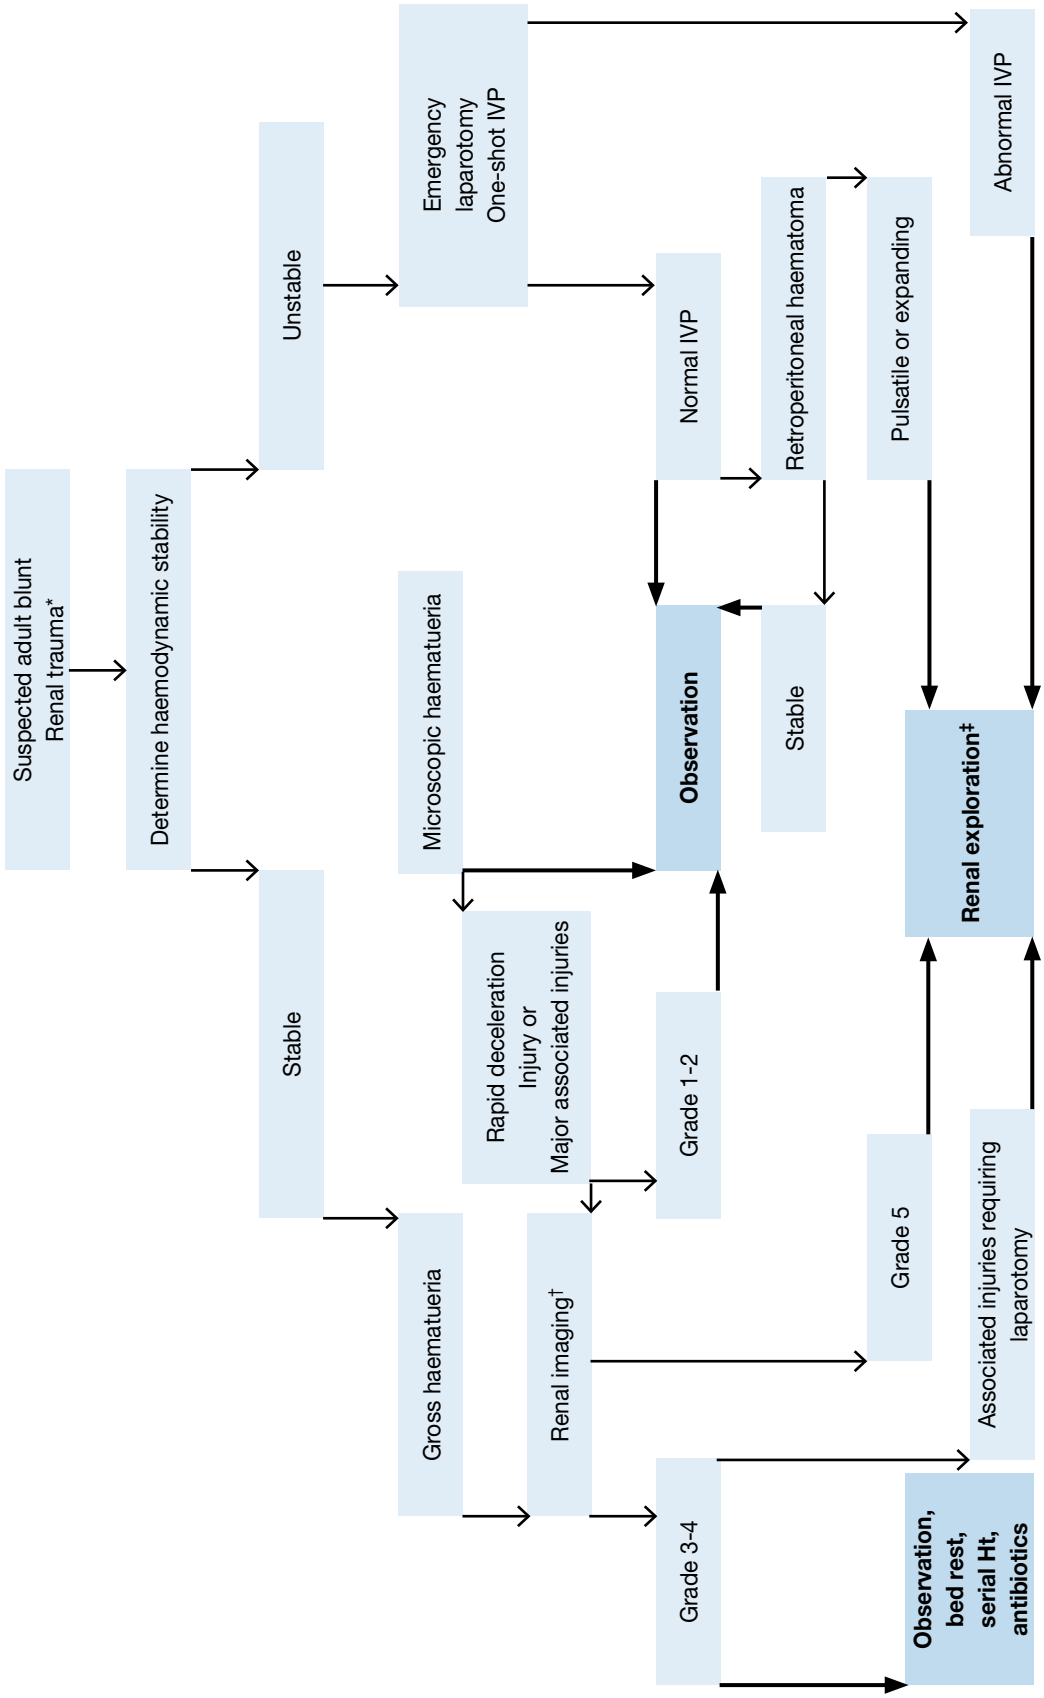
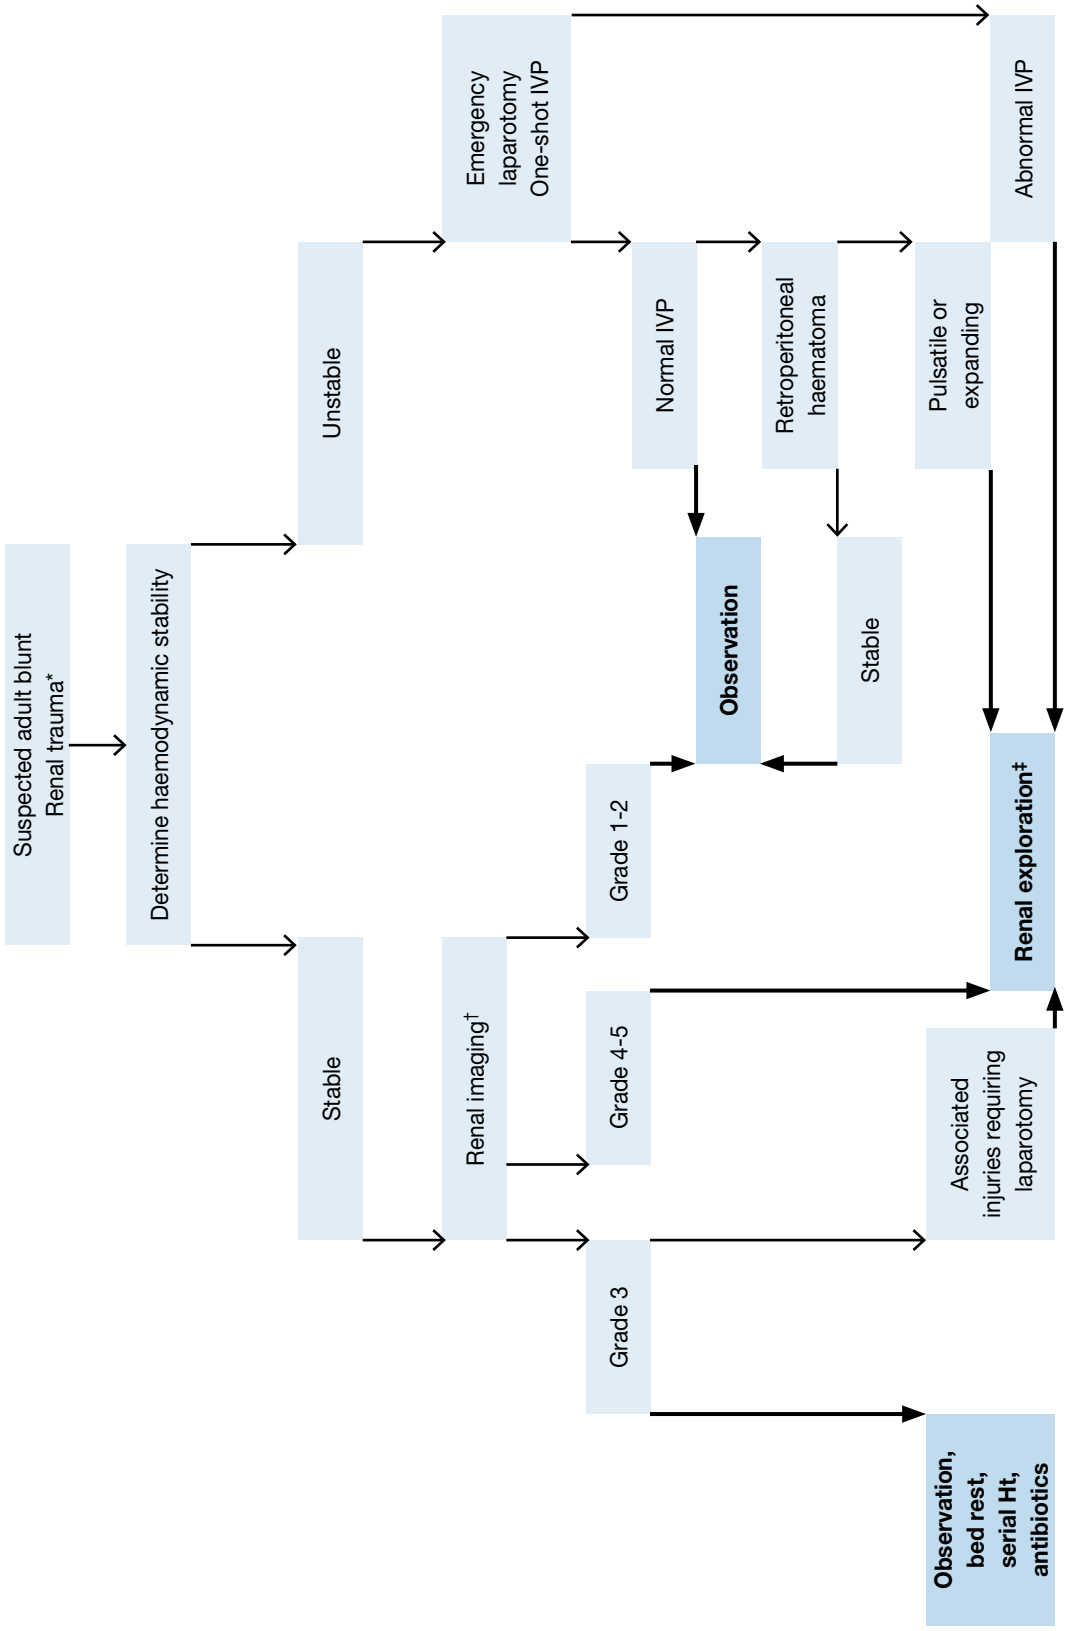


**Suspected renal trauma results from reported mechanism of injury and physical examination.*

† Renal imaging: CT scans are the gold standard for evaluating blunt and penetrating renal injuries in stable patients. In settings where the method is not available, the urologist should rely on other imaging modalities (IVP, angiography, radiographic scintigraphy, MRI).

‡ Renal exploration: Although renal salvage is a primary goal for the urologist, decisions concerning the viability of the organ and the type of reconstruction are made during the operation.

Figure 3: Evaluation of penetrating renal trauma in adults



**Suspected renal trauma results from reported mechanism of injury and physical examination.*

3. URETERAL TRAUMA

3.1 Introduction

The ureter is the sole conduit for urinary transport between the kidney and the bladder. Thus, any ureteral injury can threaten the function of the ipsilateral kidney. This small, mobile, worm-like, peristalsing, urothelial-lined tube runs inferiorly from the renal pelvis in the retroperitoneal space. It lies anterior to the muscles of the posterior abdominal wall and lateral to the vertebral column, before descending into the bony ring of the pelvis to enter the bladder. Any external injury to the flank or back and any calamity within the bony pelvis therefore places the ureter at risk. Perhaps because of its protected location, its small size, and its mobility, trauma to the ureter is relatively rare and accounts for only 1% of all urinary tract trauma. Thus, there is a relatively small volume of published clinical experience upon which to base recommendations of management.

3.2 Aetiology

The largest and most contemporary review of ureteral trauma in the European literature is from Dobrowolski *et al*. in Poland (1). These authors retrospectively analysed the records of patients with upper urinary tract injuries presenting to 61 urology departments between 1995 and 1999. They identified 452 ureteral injuries. Of these, 340 (75%) were iatrogenic, 81 (18%) were from blunt trauma, and 31 (7%) were from penetrating trauma. Of the 340 iatrogenic injuries, 247 (73%) were gynaecological in origin, 46 (14%) were general surgical, and 47 (14%) were urological. It is therefore important to note that ureteral injury is much more likely to occur from activity within a hospital rather than from injuries sustained outside. Dobrowolski *et al*. estimate the frequency of ureteral injury during gynaecological pelvic surgical procedures to be 1.6 per 1000 (1). Of the total ureteral injuries identified, the injury was in the upper third in 60 cases (13%), in the middle third in 61 cases (13%), and in the lower third in 331 (74%). The median time to diagnosis was 3.3 h.

The most common diagnostic investigation was intravenous urography (IVU), which was used in 244 patients; retrograde ureteropyelography was used in 98 patients; and ureteral catheterisation was used in 125. The diagnosis was also established at open surgery in 104 patients. This snapshot of ureteral trauma in a modern European setting is similar to that seen in the USA (2).

3.3 Diagnosis

*3.3.1 **Clinical diagnosis***

There are no classic clinical symptoms and signs associated with acute ureteral trauma caused by external injury (3). In view of this, the diagnosis must be one of suspicion. Ureteral trauma should be suspected in all cases of penetrating abdominal injury, especially gunshot wounds, and also in cases of blunt deceleration

trauma, in which the kidney and renal pelvis can be torn away from the ureter. This deceleration injury is more likely to occur in children because of their hyperextensible vertebral column (4). Haematuria is also a poor indicator of injury, as it is present in only half of those with ureteral trauma (5).

It is possible for isolated ureteral injuries to be missed. Such patients tend to present with subsequent evidence of upper tract obstruction, urinary fistula formation and sepsis (6). After gynaecological pelvic surgery, any woman who complains of flank pain, develops vaginal leakage of urine or becomes septic should also be suspected of having injury to the ureter or bladder and should be investigated appropriately. At surgery, when the ureter is explored to exclude injury, the use of intravenous indigo carmine or methylene blue is to be recommended. This will help reveal the site of injury by leakage of blue-stained urine. This is especially important in partial tears.

*3.3.2 **Radiological diagnosis***

Ureteral injury may cause radiological signs of upper urinary tract obstruction but the sine qua non of ureteral injury is extravasation of radiological contrast material (3). This sign can be produced by the use of IVP, giving 2 mg of contrast material per kilogram of body weight. However, because of the increasing use of CT scanning in polytraumatised patients, the diagnosis is increasingly made with this modality.

If a high suspicion of ureteral injury exists and the CT scan is non-diagnostic, then a 'poor man's IVP' can be obtained by taking a plain kidney-ureter-bladder (KUB) film 30 minutes after intravenous injection of CT contrast medium. If this is also non-diagnostic and a suspicion of injury still exists, then retrograde pyelography should be undertaken as the gold standard investigation.

3.4 Classification

The AAST has classified ureteral injuries as shown in Table 4 (7).

Table 4: Classification of ureteral injury

Grade	Description of injury
I	Haematoma only
II	Laceration < 50% of circumference
III	Laceration > 50% of circumference
IV	Complete tear < 2 cm of devascularisation
V	Complete tear > 2 cm of devascularisation

3.5 Management

*3.5.1 **Partial injuries***

These can be defined as grade I to II lesions. Once recognised, they can be managed with ureteral stenting or by placement of a nephrostomy tube to divert urine (3). There is no prospective clinical trial comparing outcomes between these techniques. We believe that ureteral stenting is probably superior because a stent across the injury will allow secure drainage of the kidney, as well as providing canalisation and stabilisation of the injury. We believe that this will reduce the subsequent risk of stricture. The stent may be placed in an antegrade or retrograde fashion. In all cases, fluoroscopy and ureteropyelography with radio-opaque contrast should be used to guide stent placement.

The procedure should commence with the passage of a hydrophilic atraumatic guidewire across the damaged segment of ureter. Once across the site of the injury, an access catheter can be backloaded over the wire and passed across the injury. The hydrophilic wire can then be exchanged for a 0.038-inch wire, and the stent deployed. If this technique is utilised, a bladder catheter should be left in place for 2 days to limit stent reflux during voiding until mucosal healing has begun. The stent should be left in place for at least 3 weeks. The patient should have a follow-up dynamic renogram and IVP between 3 and 6 months, or sooner if lateralising flank pain develops. If there is evidence of stricture, then this should be managed by endo-urological or open surgical techniques, as appropriate.

If a grade II or III injury is encountered during immediate surgical exploration of an iatrogenic injury, then primary closure of the ureteral ends over a stent may be recommended, with placement of an external, non-suction drain adjacent to the injury.

3.5.2 Complete injuries

These are grade III to V injuries. Successful repair should utilise the principles outlined in Table 5.

Table 5: Principles of repair of complete injury

Debridement of ureteral ends to fresh tissue
Spatulation of ureteral ends
Placement of internal stent
Watertight closure of reconstructed ureter with absorbable suture
Placement of external, non-suction drain
Isolation of injury with peritoneum or omentum

The type of reconstructive repair procedure chosen by the surgeon depends on the nature and site of the injury (3). The options are depicted in Figure 4.

Figure 4: Diagram of the options for repair of complete injuries, based on the site of the injury

Upper third: Uretero-ureterostomy
Transuretero-ureterostomy
Ureterocalycostomy

Middle third: Uretero-ureterostomy
Transuretero-ureterostomy
Boari flap and reimplantation

Lower third: Direct reimplantation
Psoas hitch
Blandy cystoplasty

Complete: Ileal interposition
Autotransplantation

3.5.3 ***Sterile surgery***

3.5.3.1 Uretero-ureterostomy

Using the principles outlined above, the ureteral ends are debrided and freshened. The ends are spatulated. An internal double J-stent is inserted and the ends are closed over the stent using an interrupted 4/0 vicryl suture. An external, non-suction drain is placed at the site of the injury, and a catheter is left in the bladder. The bladder catheter can be removed after 2 days. The wound drain can be removed 2 days later if drainage is low. The stent should be removed after 6 weeks, and a follow-up renogram and IVP should be obtained after 3 months to assess the patency of the repair.

3.5.3.2 Ureterocalycostomy

In cases were the pelvi-ureteral junction has been destroyed, the lower pole of the affected kidney can be amputated to expose the lower pole infundibulum and calyces. The distal ureteral end can then be debrided and spatulated, and anastomosed to the lower pole calyx, over an internal stent, using an interrupted 4/0 vicryl suture. An external, non-suction drain is placed at the site of the injury and a catheter is left in the bladder. The bladder catheter can be removed after 2 days. The wound drain can be removed 2 days later if drainage is low. The stent should be removed after 6 weeks and a follow-up renogram and IVP should be obtained after 3 months to assess the patency of the repair.

3.5.3.3 Transuretero-ureterostomy

The distal end of the injured ureter is ligated with an absorbable suture. The proximal end is debrided and spatulated. This end is then transposed across the midline through a retroperitoneal window above the level of the inferior mesenteric artery. A 1.5 cm ureterotomy is made on the medial aspect of the contralateral ureter. A stent is placed from the ipsilateral kidney, through the anastomosis, and down the distal contralateral ureter into the bladder. A watertight anastomosis is fashioned using an interrupted 4/0 vicryl suture. An external, nonsuction drain is placed at the site of the injury, and a catheter is left in the bladder. The bladder catheter can be removed after 2 days. The wound drain can be removed 2 days later if drainage is low. The stent should be removed after 6 weeks, and a follow-up renogram and IVP should be obtained after 3 months to assess the patency of the repair.

3.5.3.4 Ureteroneocystostomy with Boari flap

The proximal ureteral end is debrided and spatulated. A traction suture is placed. The distal ureteral end is ligated with an absorbable suture. The bladder is filled with 200-300 ml of normal saline via a urethral catheter, and controlling stay sutures are placed on the bladder. The L-shaped flap is raised, its base being approximately four times wider than the width of the ureter to be implanted. The ureter is pulled through a submucosal tunnel in the flap and secured to the bladder mucosa using an interrupted 4/0 vicryl suture. Anchoring sutures can be placed at the serosal aspect of the ureter to secure it to the bladder. A stent is placed across the neo-ureterocystostomy, and a suprapubic catheter is placed in the bladder. The bladder is then closed in two layers with 2/0 vicryl sutures. An external, non-suction drain should be placed at the site of the reimplant; it can be removed after 2 days. The urethral catheter can be removed at the same time. The suprapubic catheter can be removed after a cystogram at 2 weeks, and the stent can be removed after 6 weeks. An IVP and renogram should be obtained 3 months thereafter to confirm the patency of the neocystostomy.

3.5.3.5 Ureterocystostomy and psoas hitch

The proximal ureteral end is debrided and spatulated. A traction suture is placed. The distal ureteral end is ligated with an absorbable suture. The fundus of the bladder is mobilised, and the contralateral superior vesical pedicle may be divided to improve fundal mobility. The bladder is filled with 200-300 ml of normal saline via a urethral catheter, and controlling stay sutures are placed. A cystotomy (Blandy) is performed perpendicular to the line of the ureter. Two fingers are placed inside the bladder to stretch it gently towards the ipsilateral psoas tendon. Three non-absorbable 2/0 sutures are placed between the bladder wall and the tendon, with care being taken to avoid the genitofemoral nerve.

Ureteroneocystostomy is then undertaken using either the Leadbetter-Politano or Lich-Gregoire techniques. A double J-stent is placed across the reimplant, and a suprapubic catheter is placed in the bladder. The bladder is then closed in two layers with 2/0 vicryl in the line of the ureter, thus providing extra length to the hitch. The anastomosis is thus under no tension. An external, non-suction drain should be placed at the site of the reimplant, and can be removed after 2 days. The urethral catheter can be removed at the same time. The suprapubic catheter can be removed after a cystogram at 2 weeks, and the stent can be removed after 6 weeks. An IVP and renogram should be obtained 3 months thereafter to confirm the patency of the neocystostomy.

3.5.3.6 Ileal interposition graft

In cases of long segment ureteral destruction, the ureter can be totally replaced using the distal ileum. This should be avoided in patients with coincidental gastrointestinal disease, such as Crohn's disease, and in patients with impaired renal function. A 25-cm length of ileum is taken out of bowel continuity about 20 cm proximal to the ileocaecal valve. Gastrointestinal continuity is restored with an ileo-ileal anastomosis using interrupted 3/0 seromuscular vicryl. The mesenteric is repaired using 2/0 vicryl. The ileal segment is placed in the isoperistaltic orientation between the renal pelvis and the bladder. Ileo-pelvic and cysto-ileal end-to-end anastomoses are fashioned using 2/0 vicryl. A nephrostomy tube should be inserted into the ipsilateral kidney to decompress the affected upper tract. A catheter should be placed in the bladder. External, non-suction drains should cover the proximal and distal anastomoses. Lastly, the reconstruction should be wrapped in omentum.

The wound drains can be removed after 2 days. A nephrostogram should be performed after 3 weeks; if no leakage is demonstrated, the nephrostomy can be clamped and then removed. Finally, the urinary catheter can be removed. Follow-up should include IVP and renography at 3 months, together with testing for the levels of serum creatinine, chloride, bicarbonate, and base excess, looking for evidence of hyperchloraemic metabolic acidosis.

3.5.3.7 Autotransplantation

If complete ureteral disruption should occur in the presence of coincidental gastrointestinal disease or impaired renal function, then autotransplantation of the affected renal unit can be undertaken. The renal artery and vein are divided long at the aorta and cava. The kidney is moved to the pelvis, and vascular continuity is restored using 5/0 prolene for the artery and 4/0 prolene for the vein. A Lich-Gregoire extravesical neoureterocystostomy can then be fashioned to re-establish urinary drainage. This need not be stented. A covering external, non-suction drain should be placed, and a catheter inserted in the bladder. The drain can be removed after 2 days, if dry, and the catheter removed after a cystogram at 2 weeks. Again, follow-up at 3 months with IVP and renogram is recommended.

3.5.3.8 Nephrectomy

There is one circumstance in which immediate nephrectomy should be undertaken. This is when ureteral injury complicates the repair of an abdominal aortic aneurysm or other vascular procedure in which a vascular prosthesis is to be implanted. We feel that immediate excision of the corrupted renal unit and its damaged ureter leads to less chance of urinary leak, urinoma, sepsis, and graft infection.

4. BLADDER TRAUMA

4.1 Background

Among abdominal injuries that require surgical repair, 2% involve the bladder (1). Blunt or penetrating trauma account for 67-86% and 14-33% of bladder ruptures, respectively (2-4). Motor vehicle accidents are the most common cause (90%) of bladder rupture by blunt trauma (5-7). In the setting of blunt trauma, bladder rupture may be classified as either extraperitoneal with leakage of urine limited to the perivesical space, or intraperitoneal, in which the peritoneal surface has been disrupted, with concomitant urinary extravasation.

Bladder trauma: facts and figures

- 70-97% of patients with bladder injuries caused by blunt trauma have associated pelvic fractures (3,8,9).
- Pubic symphysis diastasis, sacroiliac diastasis, and sacral, iliac, and pubic rami fractures are significantly associated with bladder rupture, whereas isolated acetabular fractures are not (10,11).
- > 50% of the associated pelvic fractures are of the pubic ramus (12).
- Up to 30% of patients with pelvic fractures will have some degree of bladder injury (13).
- Major bladder injury occurs in only 5-10% of patients who have pelvic fracture(s) (7,14).
- > 85% of patients with pelvic fractures have associated injuries in other organ systems (8), with a mortality rate of 22-44% (12,13,15).
- Approximately 25% of intraperitoneal bladder ruptures occur in patients who do not have pelvic fracture(s) (7).

During a motor vehicle accident, traumatic forces can be transferred to the bladder by the seatbelt; injuries usually occur in patients with a full bladder. The degree of distension of the bladder with urine determines its shape and, to some degree, the injury it sustains. A fully distended bladder can be ruptured by a light blow; however, an empty bladder is seldom injured, except by crushing or penetrating wounds. Pelvic scars or pre-existing pelvic pathology can influence susceptibility to injury (16).

Combined intra- and extraperitoneal rupture may occur in 2-20% of cases (7,17-19). Simultaneous bladder and prostate-membranous urethra ruptures occur in 10-29% of male patients (10). Several studies investigating pelvic fractures and associated injuries in paediatric patients reported a lower incidence of urogenital injury (7-14%) (20-23), than in comparative adult series (7,13,14). In seven paediatric series (20-26), the average rate of bladder injury in patients with pelvic fractures was 4%. Motor vehicle accidents were the cause of the trauma in 97% of cases (26).

4.1.1 ***Iatrogenic trauma***

During lower abdominal operations, the bladder is the most frequently injured genitourinary organ (27). Most iatrogenic injuries occur during:

- open abdominal or pelvic surgery (85%);
- anterior vaginal surgery (9%);
- laparoscopy (6%).

The majority (92%) of these injuries are graded as III-IV, using the AAST scale (27). Most injuries occur during obstetric and gynaecological procedures (52-61%), followed by urological (12-39%) and general surgical (9-26%) interventions (27,28). Of the general surgical operations that result in iatrogenic injury to the bladder, most involve resection of bowel as a result of malignancy, diverticulitis, or inflammatory diseases (27,28).

Bladder injury occurs during gynaecological operations in 0.3-8.3% of cases (29-34). Concurrent anti-incontinence surgery significantly increases the risk of injury to the bladder (13% vs 3%; P= 0.049) (34). Most cases of urological iatrogenic trauma occur during vaginal operations and laparoscopy (27,28). The incidence of bladder wall perforation is generally low (1%) during transurethral resection of bladder tumours, and most (88%) can be managed by catheter drainage (35,36). Transurethral resection of the prostate is also associated with low injury rates (37).

Routine cystoscopy is an important adjunct to the major gynaecological procedures, and its omission may result in underestimation of iatrogenic bladder injury. An extensive review of the literature indicated that in studies not involving routine cystoscopy, the frequency of bladder injury varied from 0.2/1000 to 19.5/1000, with an overall frequency of 2.6/1000. Only 52% of bladder injuries were identified and managed intraoperatively (31). In studies involving routine cystoscopy, the frequency of bladder injury varied from 0.0/1000 to 29.2/1000, with an overall frequency of 10.4/1000. Up to 85% of unsuspected bladder injuries were identified with the use of cystoscopy and were managed successfully intraoperatively (31). Routine cystoscopy is recommended after any type of incontinence surgery as it enables identification of unsuspected bladder injury in 85% of patients (31,32,34,38).

Surgical procedures for the correction of stress urinary incontinence can also result in bladder trauma. The rate of bladder injury is below 3% in Burch colposuspension (39-41). Bladder injury is the most common complication of the tension-free vaginal tape (TVT) procedure, with an incidence of 2.0-11.5% (42-47) and up to 19% in patients with prior failed incontinence surgery (48).

The transobturator tape (TOT) procedure minimises the retropubic needle passage, and the incidence of bladder injury is expected to be low. Although during early experience with this technique rates of injury were similar to those associated with the TVT procedure (39), a recent meta-analysis indicated a lower incidence of bladder injuries (odds ratio: 0.12; 95% confidence interval: 0.05-0.33) with TOT procedures (49).

4.2 Classification

Table 6: Bladder injury scale[1]

Grade*	Description	
I	Hematoma	Contusion, intramural hematoma
	Laceration	Partial thickness
II	Laceration	Extraperitoneal bladder wall laceration < 2 cm
III	Laceration	Extraperitoneal (> 2 cm) or intraperitoneal (< 2 cm) bladder wall laceration
IV	Laceration	Intraperitoneal bladder wall laceration > 2 cm
V	Laceration	Intraperitoneal or extraperitoneal bladder wall laceration extending into the bladder neck or ureteral orifice (trigone)

**Advance one grade for multiple injuries up to grade III.*
[1] Adapted from the AAST.

4.3 Risk factors

Individuals who are driving under the influence of alcohol are likely to have a distended bladder and a motor vehicle accident. Driving after drinking alcohol is therefore a risk factor for bladder injury (19) (LE: 3).

Concurrent anti-incontinence surgery during gynaecological procedures results in a fourfold increased risk of bladder injury, and is therefore a risk factor for iatrogenic bladder trauma (34) (LE: 3).

4.4 Diagnosis

The most common signs and symptoms in patients with major bladder injuries are gross haematuria (82%) and abdominal tenderness (62%) (3). Other findings may include inability to void, bruises over the suprapubic region, and abdominal distension (6). Extravasation of urine may result in swelling in the perineum, scrotum, and thighs, as well as along the anterior abdominal wall within the potential space between the transversalis fascia and the parietal peritoneum.

*4.4.1 **Macroscopic (gross) haematuria***

Gross haematuria indicates urological trauma (LE: 3). Traumatic bladder rupture is strongly correlated with the combination of pelvic fracture and gross haematuria. Morey *et al*. reported gross haematuria in all their patients with bladder rupture, and 85% had pelvic fractures (50). Thus, the classic combination of pelvic fracture and gross haematuria constitutes an absolute indication for immediate cystography in patients who have blunt trauma (3,7,13,50) (LE: 3).

The presence of gross blood at the urethral meatus is diagnostic of a urethral injury (LE: 3). A Foley catheter should not be inserted before a retrograde urethrogram has been carried out to ensure urethral integrity (51). Although grossly clear urine in a trauma patient without a pelvic fracture virtually eliminates the possibility of bladder rupture, 2-10% of patients with bladder rupture may have only microhaematuria or no haematuria at all (5,51).

In a retrospective review of more than 8000 paediatric trauma patients, of those cases with pelvic fractures, only one patient (0.5%) had an extraperitoneal bladder rupture (26). Lower urogenital injury occurred in six patients (2.8%). The absence of gross haematuria ruled out serious injury in this cohort.

Based on this data, no further work-up was recommended in paediatric patients with pelvic fractures without gross haematuria. It is recommended that patients with gross haematuria, multiple associated injuries, or significant abnormalities found on physical examination should be further evaluated with retrograde urethrography and cystography (LE: 3).

*4.4.2 **Microscopic haematuria***

In the trauma patient with a pelvic ring fracture, microscopic haematuria might indicate bladder laceration, and further investigation is warranted (LE: 3). However, the exact quantity of blood in the urine that should trigger investigation is controversial.

- Morgan *et al*. reported that no ruptures were seen in patients with < 25 red blood cells/high-power field (rbc/hpf) (10).
- Werkman *et al*. (52) concluded that if cystography had been restricted to patients with > 35-50 rbc/hpf, no perforation would have been missed in their series.
- Fuhrman *et al*. (53) believe that cystography in blunt trauma should be restricted to patients with gross haematuria, which they defined as > 200 rbc/hpf. They also thought that a retrograde urethrogram should be carried out first.

Existing data do not support lower urinary tract imaging in all patients with pelvic fracture or microscopic haematuria alone. Hochberg and Stone (54) concluded that cystography might be safely reserved for those patients with pelvic fracture considered to be high risk for bladder injury (significant pubic arch involvement, gross haematuria and/or haemodynamic instability), as 90% of patients in their series with pelvic fracture did not have a bladder rupture.

These observations do not appear to be valid for paediatric trauma patients. Abou-Jaoude *et al*. (55) reported a threshold for radiological evaluation of ≥ 20 rbc/hpf would miss 25% of cases with bladder injury. In contrast with other reported series (26), they suggested that lower urogenital tract evaluation in paediatric trauma patients, especially in the presence of pelvic fractures, should be based as much on clinical judgment as on the presence of haematuria (55) (LE: 3).

4.4.3 ***Cystography***

Retrograde cystography is the standard diagnostic procedure in the evaluation of bladder trauma (7,13,56-58) (LE: 3). This is the most accurate radiological study to identify bladder rupture. When bladder filling and post-void images are obtained, cystography has an accuracy rate of 85-100% (5,7,59,60). Bladder rupture is usually diagnosed when the contrast is identified outside the bladder. Adequate distension of the urinary bladder is crucial to demonstrating perforation, especially in cases of penetrating trauma, as most instances of a false-negative retrograde cystography were found in this situation (56).

Cystography requires plain film, filled film, and post-drainage films (as a minimum) (LE: 3); half-filled film and obliques are optional. For the highest diagnostic accuracy, the bladder must be distended using instillation of at least 350 mL of contrast medium by gravity. Bladder injury may be identified only on the post-drainage film in approximately 10% of cases (7). False-negative findings may result from incorrectly performed studies with less than 250 mL of contrast instillation or omission of a post-drainage film (61) (LE: 3). Only a correctly performed cystography should be used to exclude bladder injury (7).

4.4.4 ***Excretory urography IVP***

An IVP is inadequate for evaluation of the bladder and urethra after trauma, not only because of dilution of the contrast material within the bladder, but also because resting intravesical pressure is simply too low to demonstrate a small tear (16,62). An IVP has a low accuracy (15-25%) (15), and clinical studies have indicated that IVP has an unacceptably high false-negative rate (64-84%), which precludes its use as a diagnostic tool in bladder injuries (52,59,63) (LE: 3).

4.4.5 ***Ultrasound (US)***

Although, the use of US in bladder rupture has been described (64), it is not routine for evaluation of bladder injury. Free peritoneal fluid in the presence of normal viscera, or failure to visualise the bladder after transurethral saline instillation, are highly suggestive of bladder rupture (66) (LE: 3). Practically, however, US is not definitive in bladder or urethral trauma and is almost never used.

4.4.6 ***Computed tomography (CT)***

Computed tomography is clearly the method of choice for the evaluation of patients with blunt or penetrating abdominal and/or pelvic trauma (LE: 3). However, routine CT is not reliable in the diagnosis of bladder rupture, even if an inserted urethral catheter is clamped. CT demonstrates intraperitoneal and extraperitoneal fluid, but cannot differentiate urine from ascites.

As with IVP, the bladder is usually inadequately distended to reveal extravasation through a bladder laceration or perforation during routine abdominal and pelvic studies. Thus, a negative study cannot be entirely trusted, and routine CT cannot exclude bladder injury (12,16,65).

In a review of the cystograms and CT scans (CT cystography) of 25 patients who underwent both investigations during the initial evaluation of blunt abdominal trauma, five patients were found to have bladder rupture, three of which were extraperitoneal and two intraperitoneal (66); all of the injuries were detected by both studies. It was concluded that delayed imaging or contrast instillation could provide the adequate bladder distention needed to demonstrate contrast extravasation from the injury site. Similarly, in a series of 316 patients, 44 cases were diagnosed with bladder ruptures (60). In patients who underwent a formal surgical repair, 82% had operative findings that exactly matched the CT cystography interpretation. Either retrograde cystography or CT cystography are diagnostic procedures of choice for suspected bladder injury (51).

Computed tomography cystography can be used in place of conventional cystography (overall sensitivity 95% and specificity 100%) (LE: 3), especially in patients undergoing CT scanning for other associated injuries (60). However, this procedure should be performed using retrograde filling of the bladder with a minimum of 350 mL of dilute contrast material (7,66,67).

In conclusion, CT cystographic features may lead to accurate classification of bladder injury and allow prompt, effective treatment without further radiation exposure and the additional cost of conventional cystography (70) (LE: 3).

4.4.7 *Angiography*

Angiography is seldom, if ever, indicated. It can be useful in identifying an occult source of bleeding and can guide its subsequent therapeutic embolisation (16).

4.4.8 *Magnetic resonance imaging (MRI)*

It is extremely difficult to monitor a seriously injured patient in a strong magnetic field; MRI therefore has little place in the evaluation of acute bladder (16). The use of MRI has been described for later evaluation of urethral injury (69-71).

4.4.9 *Cystoscopy*

Mainly useful in iatrogenic trauma, routine cystoscopy identifies 85% of the unsuspected injuries to the bladder that would otherwise go unnoticed (31,34,39). Thus, it must be used as an adjunct to major gynaecological operations as well as surgical interventions for incontinence (LE: 3).

4.5 Treatment

The first priority in the treatment of bladder injuries is stabilisation of the patient and treatment of associated life-threatening injuries (LE: 3).

4.5.1 *Blunt trauma: extraperitoneal rupture*

Most patients with extraperitoneal rupture can be managed safely by catheter drainage alone, even in the presence of extensive retroperitoneal or scrotal extravasation (61) (LE: 3). Obstruction of the catheter by clots or tissue debris must be prevented for healing to occur. A success rate of 90% was reported with this approach in extraperitoneal rupture (5): 87% of the ruptures were healed in 10 days, and virtually all were healed in 3 weeks (57). However, bladder neck involvement (2), the presence of bone fragments in the bladder wall, or entrapment of the bladder wall will necessitate surgical intervention (19) (LE: 3).

4.5.2 *Blunt trauma: intraperitoneal rupture*

Intraperitoneal ruptures occurring after blunt trauma should always be managed by surgical exploration (LE: 3). This type of injury involves a high degree of force and, because of the severity of associated injuries, carries a high mortality (20-40%) (72). Lacerations are usually large in these cases, with the potential risk of peritonitis due to urine leakage if left untreated (61). Abdominal organs should be inspected for possible associated injuries and urinoma must be drained, if present.

4.5.3 *Penetrating injuries*

All bladder perforations resulting from penetrating trauma should undergo emergency exploration and repair (61) (LE: 3).

4.5.4. *Iatrogenic injuries*

Iatrogenic bladder perforations can occur during any pelvic, abdominal, or vaginal procedure (27). Prompt intraoperative recognition is extremely important to ensure a successful repair. Generally, suture repair is satisfactory, limiting unnecessary extravesical dissection (LE: 3). Most (> 95%) of urinary bladder injuries sustained during gynaecological operations are detected and can be managed during surgery (73). Repair can be performed either transvaginally or abdominally. Simple catheter drainage is sufficient in most cases of bladder perforation during transurethral resection of prostate or bladder tumours (36-38) (LE: 3).

4.6 Recommendations

4.6.1 *General*

	GR
Stabilisation of the patient is always the priority in cases with associated injuries.	B

4.6.2 *Diagnosis*

	GR
Immediate cystography is required in the presence of haematuria and pelvic fracture.	B
Diagnosis should be made with retrograde cystography with a minimum of 350 mL of gravity-filled contrast medium.	B
For cystography, the minimum requirement includes a plain film, filled film, and post-drainage film. Half-filled film and obliques are optional.	B
CT cystography can be used with equal efficacy if the patient is undergoing CT scanning for associated injuries.	B
Routine cystoscopy is recommended after major gynaecological operations and/or incontinence surgery.	B

4.6.3 *Treatment*

	GR
In the absence of bladder neck involvement and/or associated injuries that require surgical intervention, extraperitoneal bladder ruptures caused by blunt trauma are managed by catheter drainage alone.	B
Intraperitoneal bladder ruptures by blunt trauma, and any type of bladder injury by penetrating trauma, must be managed by emergency surgical exploration and repair.	B
The technique of surgical repair used depends on the surgeon's preference, but a two-layer closure with absorbable sutures achieves a safe repair of the bladder wall.	B

5. URETHRAL TRAUMA

5.1 Anatomical and aetiological considerations

The male urethra is divided into the anterior and posterior sections by the urogenital diaphragm. The posterior urethra consists of the prostatic and the membranous urethra. The anterior urethra consists of the bulbar and penile urethra. Only the posterior urethra exists in the female; the anterior urethra corresponds to the labia minora, which results from persistent separation of the urethral folds on the ventral surfaces of the genital tubercle.

*5.1.1 **Posterior urethral injuries***

Road traffic accidents, falls, and crush injuries can cause pelvic fractures, which result in injuries to the posterior urethra. About two-thirds (70%) of pelvic fractures occur because of motor vehicle accidents. The incidence of pelvic fracture is 20% in survivors of motor accidents where fatalities have occurred. The incidence is nearly 50% in fatal pedestrian accidents. Twenty-five per cent of cases result from a fall from a height (1,2).

Altogether, blunt trauma accounts for more than 90% of urethral injuries (3). Overall, the male posterior urethra is injured in 4-19% and the female urethra in 0-6% of all pelvic fractures (2,4-12). The female urethra is rarely injured, except by contusion or laceration by bone fragments.

During crush or deceleration impact injury, the severe shearing forces necessary to fracture the pelvis are transmitted to the prostatomembranous junction, resulting in disruption of the prostate from its connection to the anterior urethra at the prostatic apex. Retrograde urethrography and MRI correlates to this location of the injury (13,14). Cadaveric studies suggest that in most cases the membranous urethra is torn distally to the urogenital diaphragm (15).

An accurate knowledge of the functional anatomy of the sphincter mechanism is essential to the success of posterior urethral surgery. Continence after anastomotic reconstruction of subprostatic pelvic fracture urethral distraction defects depends upon the function of the bladder neck and of the distal urethral sphincter mechanism, each of which is competent and independently capable of maintaining continence in the absence of the other (16).

Unstable pelvic fractures (8,11,17-21), bilateral ischiopubic rami fractures ('straddle fracture'), and symphysis pubis diastasis have the highest likelihood of injuring the posterior urethra. In particular, the combination of straddle fractures with diastasis of the sacroiliac joint has the highest risk of urethral injury; the odds ratio is about 7 times higher than for either straddle injuries or sacroiliac ('Malgaigne') fractures alone (Table 7) (2).

Table 7: Odds ratio of suffering urethral injury with different types of pelvic fracture

Type of fracture	Odds ratio
Single ramus	0.6
Ipsilateral rami	0.8
Malgaigne's (vertical shear)	3.4
Straddle	3.9
Straddle plus sacroiliac	24.0

Lower urinary tract injury has been reported in about 16% of patients with unilateral rami fractures and in 41% of patients with bilateral rami fractures (22). Anteroposterior compression injuries from frontal crushes produce more severe pelvic fractures, major retroperitoneal bleeding and more frequent injury to the lower urinary tract than do lateral crashes (23).

Prostatomembranous urethral injuries can vary from simple stretching (25%) to partial rupture (25%) or complete disruptions (50%) (2). The more severe injuries result in prostatourethral displacement, with progressive scar formation encompassing the rupture defect. The incidence of double injuries involving the urethra and the bladder ranges between 10% and 20% in males, and may be intraperitoneal (17-39%), extraperitoneal (56-78%), or both (2,7).

Urethral injuries, by themselves, are never life-threatening, except as a consequence of their close association with pelvic fractures and multiple organ injuries, which occur in about 27% of cases. Initially, the assessment and management of other associated injuries is usually more important than the assessment and management of the urethral injury (24).

The American Association for Surgery of Trauma has proposed the classification given in Table 8.

Table 8: Organ injury scaling III classification of urethral injuries (25)

Grade	Description	Appearance
I	Contusion	Blood at the urethral meatus; Normal urethrogram
II	Stretch injury	Elongation of the urethra without extravasation on urethrography
III	Partial disruption	Extravasation of contrast at injury site with contrast visualised in the bladder
IV	Complete disruption	Extravasation of contrast at injury site without visualisation in the bladder; < 2 cm of urethral separation
V	Complete disruption	Complete transection with > 2 cm urethral separation or extension into the prostate or vagina

New classifications provide an anatomical classification and a means of comparing treatment strategies and outcomes (26,27). The classification shown in Table 9 combines the best of previous classifications and has direct implications in clinical management.

Table 9: Classification of blunt anterior and posterior urethra

Grade	Description	Appearance
I	Stretch injury	Elongation of the urethra without extravasation on urethrography
II	Contusion	Blood at the urethral meatus No extravasation on urethrography
III	Partial disruption of anterior or posterior urethra	Extravasation of contrast at injury site with contrast visualised in the proximal urethra or bladder
IV	Complete disruption of anterior urethra	Extravasation of contrast at injury site without visualisation of proximal urethral or bladder
V	Complete disruption of posterior urethra	Extravasation of contrast at injury site without visualisation of bladder
VI	Complete or partial disruption of posterior urethra with associated tear of the bladder neck or vagina	

Clinical management is according to the injury grade:

- grade I no treatment required;
- grades II and III can be managed conservatively with suprapubic cystostomy or urethral catheterisation;
- grades IV and V will require open or endoscopic treatment, primary or delayed;
- grade VI requires primary open repair.

5.1.1.1 Urethral injuries in children

Urethral injuries in children are similar to those in adults. The only significant difference is that straddle pelvic fractures, Malgaigne's fractures or the association of straddle plus sacroiliac joint fracture is more common in children than in adults. In addition, posterior urethral injuries can involve the prostatic urethra and the bladder neck, as well as the membranous urethra. The tear is often in the prostatic urethra or at the bladder neck because of the rudimentary nature of the prostate, and is more likely to be a complete rupture (69% versus 42%). Urethral stretching is less common than in adults. The more proximal the injury, the greater the risk of incontinence, impotence, and stricture (2,24,28,29).

5.1.1.2 Urethral injuries in women

These are rare events since the female urethra is short and mobile, without any significant attachments to the pubic bone. They usually occur in children. They are often accompanied by severe pelvic fractures, where bony fragments of the fractured pelvis can lacerate the urethra. Urethral injuries in females frequently extend into the bladder neck or vagina, and often disrupt the normal continence mechanism (4,12). Injury to the female urethra is usually a partial tear of the anterior wall and is rarely a complete disruption of the proximal or distal urethra (29).

5.1.1.3 Penetrating injuries to the perineum

These can occur after external violence such as gunshot or stab wounds, or as iatrogenic injuries caused by endoscopic instruments or during surgery for vaginal repair. In developing countries, urethral and bladder neck damage occur quite often as a result of ischaemic injury during obstructed labour.

5.1.2 ***Anterior urethral injuries***

Anterior urethral injuries result from blunt trauma more frequently than from penetrating trauma (Table 10).

Table 10: Aetiology of anterior urethral injuries

Cause	Example
Blunt trauma	• Vehicular accidents • Fall astride (straddle) • Kicks in the perineum • Blows in the perineum from bicycle handlebars, tops of fences, etc.
Sexual intercourse	• Penile fractures • Urethral intraluminal stimulation
Penetrating trauma	• Gunshot wounds • Stab wounds • Dog bites • External impalement • Penile amputations
Constriction bands	• Paraplegia
Iatrogenic injuries	• Endoscopic instruments • Urethral catheters/dilators

5.1.2.1 Blunt trauma

Vehicular accidents, falls, or blows cause most anterior urethral injuries. In contrast to posterior urethral trauma, they are rarely associated with pelvic fractures. They are usually straddle-type injuries caused by blows of blunt objects against the perineum, such as bicycle handlebars or the top of a fence. In this type of accident, the relatively immobile bulbar urethra is trapped and compressed by a direct force on it against the inferior surface of the symphysis pubis. These injuries are more common in children than in adults (28).

5.1.2.2 Intercourse-related trauma

A less common cause of blunt anterior urethral trauma is penile fracture. This rupture of the corpus cavernosum usually occurs during intercourse. In these injuries, the urethra is involved in 20% of the cases (30). Intraluminal stimulation of the urethra with foreign objects has also been reported to cause anterior urethral trauma. Most are short and incomplete, and occur in the distal penile urethra.

Surgery is rarely indicated and depends on the degree and extent of injury to the urethra.

5.1.2.3 Penetrating trauma

Penetrating injuries to the anterior urethra usually result from gunshot wounds and involve the pendulous and bulbar urethral segments equally. These injuries are associated with penile and testicular injury. These can involve the rectum, which may result in pelvic abscesses and the formation of fistulae (31,32). Other less frequent causes of external anterior urethral injuries include stab wounds, penile amputation, and impalement.

5.1.2.4 Constriction band-related trauma

Individuals with paraplegia who use a constriction device for urinary incontinence and forget to release the band because of the lack of sensation can cause severe ischaemic injuries involving the penis and urethra.

5.1.2.5 Iatrogenic trauma

Iatrogenic urethral injuries caused by instruments are by far the most common cause of urethral trauma. Urethral ischaemic injuries related to cardiac bypass procedures are not infrequent and can result in long and fibrotic strictures. A separate section in this chapter discusses iatrognic trauma in more detail (see section 4.6).

5.2 Diagnosis: initial emergency assessment

*5.2.1 **Clinical assessment***

The initial management of urethral injury is resuscitation of the patient. In the absence of blood at the meatus or genital haematoma, a urological injury is very unlikely and is excluded by catheterisation. Maintain airway and respiratory function, secure the cervical spine if necessary, and address blood loss if present. This is particularly important in posterior urethral injuries because of their close association with pelvic fractures.

The next step includes taking a complete history and carrying out physical, laboratory, and radiographic evaluations in order to identify all injuries accurately. A diagnosis of acute urethral trauma should be suspected from the history. A pelvic fracture, or any external penile or perineal trauma, can be suggestive of urethral trauma (33,34).

For penetrating injuries, the type of weapon used, including the calibre of the bullet, is helpful in assessing potential tissue damage. In a conscious patient, a thorough voiding history should be obtained to establish the time of last urination, the force of the urinary stream, whether urination is painful and whether haematuria is present. The following clinical indicators of acute urethral trauma warrant a complete urethral evaluation.

5.2.1.1 Blood at the meatus

This is present in 37-93% of patients with posterior urethral injury, and in at least 75% of patients with anterior urethral trauma (35,36). When blood is present at the urethral meatus, do not attempt urethral instrumentation until the entire urethra is imaged. In an unstable patient, attempt to pass a urethral catheter, but if there is any difficulty, place a suprapubic catheter and perform a retrograde urethrogram when appropriate.

It is extremely unlikely that gentle passage of a urethral catheter will do any additional damage (37,38), although it has been suggested that this may convert a partial tear into one that is complete (39). There are no convincing data indicating a higher rate of infection or urethral stricture after a single attempt at catheterisation (3). Indeed, if a urethral injury is suspected, urethrography prior to attempted catheterisation is the most prudent approach.

5.2.1.2 Blood at the vaginal introitus

This is present in more than 80% of female patients with pelvic fractures and co-existing urethral injuries (4).

5.2.1.3 Haematuria

Although non-specific, haematuria on a first-voided specimen may indicate urethral injury. The amount of urethral bleeding correlates poorly with the severity of the injury, as a mucosal contusion or small partial tear may be accompanied by copious bleeding, while total transection of the urethra may result in little bleeding (40).

5.2.1.4 Pain on urination or inability to void

The inability to void suggests urethral disruption.

5.2.1.5 Haematoma or swelling

With anterior urethral trauma, the pattern of the haematoma can be useful in identifying the anatomical boundaries violated by the injury. Extravasation of blood or urine in a sleeve distribution along the penile shaft indicates that the injury is confined by Buck's fascia. Disruption of Buck's fascia results in a pattern of extravasation limited only by Colles' fascia, and can extend to the coracoclavicular fascia superiorly and the fascia lata inferiorly. This results in a characteristic butterfly pattern of bruising in the perineum. In female

patients with severe pelvic fractures, the presence of labial swelling may be an indicator of urethral injury. It can be caused by urinary extravasation and warrants immediate attention.

5.2.1.6 High-riding prostate

This is a relatively unreliable finding in the acute phase since the pelvic haematoma associated with pelvic fractures often precludes the adequate palpation of a small prostate, particularly in younger men (3). A boggy mass is usually palpated without recognition of a prostate gland (41). Rectal examination is more important as a tool to screen for rectal injuries, which can be associated with pelvic fractures. Blood on the examination finger is suggestive of a rectal injury. Assessment of concomitant genital injuries is mandatory in every case of external urethral trauma.

*5.2.2 **Radiographic examination***

Retrograde urethrography is the gold standard for evaluating urethral injury (5,29). A scout film should be performed first to assess the radiographic technique, and to detect pelvic fractures and foreign bodies, such as bullets. This is performed using a Foley catheter in the fossa navicularis, with the balloon inflated using 1-2 mL of saline to occlude the urethra. Then, 20-30 mL of contrast material is injected while films are taken in a 30° oblique position. When severe pelvic fractures and associated patient discomfort are present, the oblique position may not always be possible. The radiographic appearance of the urethra permits classification of the injury and facilitates the subsequent management.

If posterior urethral injury is suspected, a suprapubic catheter is inserted. Later on, a simultaneous cystogram and ascending urethrogram can be carried out to assess the site, severity and length of the urethral injury. This is usually done after 3 months if a delayed repair is considered.

When the proximal urethra is not visualised in a simultaneous cystogram and urethrogram, either MRI of the posterior urethra (42) or endoscopy through the suprapubic tract is used to define the anatomy of the posterior urethra. Since manipulation in the bladder can cause the bladder neck to open and give the false impression of incompetence, the endoscopic appearance of the bladder neck should be noted immediately on placing the scope into the bladder (43).

After assessing the endoscopic appearance of the bladder neck, the flexible endoscope can be advanced through the bladder neck into the posterior urethra to the level of obstruction. If there is a question about the length of the distraction, a simultaneous retrograde urethrogram can be performed while the endoscope is in the posterior urethra. The radiographic appearance of the bladder neck is important, but is not as reliable an indicator of continence as the endoscopic appearance is. Furthermore, there are patients who, despite evidence of an open or scarred bladder neck, will have acceptable continence after reconstruction. For this reason, the need for concomitant bladder neck surgery at the time of urethral reconstruction is debatable (43,44).

Ultrasonography is not a routine investigation in the initial assessment of urethral injuries but can be very useful in determining the position of pelvic haematomas, or the exact location of the bladder when a suprapubic catheter is indicated.

Computed tomography and MRI have no place in the initial assessment of urethral injuries. However, they are useful in defining distorted pelvic anatomy after severe injury and assessing associated injuries of penile crura, bladder, kidneys, and intra-abdominal organs (14,45).

*5.2.3 **Endoscopic examination***

Urethroscopy does not have any role in the initial diagnosis of urethral trauma in males. In females, however, where the short urethra precludes adequate retrograde urethrography, urethroscopy is an important adjunct to the physical examination for the identification and staging of urethral injuries (46).

5.3 Management

The management of urethral injuries remains controversial because of the variety of injury patterns, associated injuries and treatment options available. In addition, urethral injuries are relatively uncommon, hence the limited experience of most urologists worldwide and the absence of randomised prospective studies.

*5.3.1 **Anterior urethral injuries***

5.3.1.1 Blunt injuries

Partial tears can be managed with a suprapubic catheter or with urethral catheterisation (29,37,47). Suprapubic cystostomy has the advantage that it not only diverts the urine away from the site of injury, but also avoids urethral manipulation (48), as well as allowing for a simultaneous study to be carried out at a later date.

If the bladder is not easily palpable suprapubically, transabdominal sonography should be used to guide the placement of the catheter. The cystostomy tube is maintained for approximately 4 weeks to allow urethral healing. Voiding cystourethrography is then performed. Remove the suprapubic tube if normal voiding

can be re-established and neither contrast extravasation nor stricture is present.

The potential early complications of acute urethral injuries include strictures and infections.

Extravasated blood or urine from the urethral tear produces an inflammatory reaction that can progress to the formation of an abscess. The extent of the infection depends on the fascial planes violated (see section 4.2). The potential sequelae of these infections include urethrocutaneous fistulae, peri-urethral diverticulae and, rarely, necrotising fasciitis. Prompt urinary diversion coupled with the appropriate administration of antibiotics decreases the incidence of these complications.

After the patient has adequately recovered from any associated injuries, and the urethral injury has stabilised, the urethra can be thoroughly re-evaluated radiographically. When necessary, the appropriate reconstructive procedure is planned.

Blunt anterior urethral injuries are associated with spongiosal contusion, which makes it more difficult to evaluate the limits of urethral debridement in the acute phase. Acute or early urethroplasty is therefore not indicated, and the best management is simply suprapubic diversion.

Satisfactory urethral luminal recanalisation occurs in approximately 50% of partial anterior urethral disruptions (47,49). Short and flimsy strictures are managed with optical urethrotomy or urethral dilatation. Denser strictures require formal urethral reconstruction. Anastomotic urethroplasty is indicated in strictures of less than 1 cm in length.

Longer strictures of the anterior urethra should not be repaired by an end-to-end anastomosis, in order to avoid chordee. In these cases, flap urethroplasty is indicated. Almost all complete ruptures of the anterior urethra require anastomotic or patch urethroplasty at 3-6 months. The only exception to this is urethral injury associated with penile fracture; this usually results in partial urethral disruption and can be repaired at the time of cavernosal closure.

5.3.1.2 Open injuries

5.3.1.2.1 Male urethral injuries

Stab wounds, gunshot wounds and dog bites to the urethra often involve the penis and testes and often require immediate exploration. During surgery, the urethral injury can be surgically evaluated and repaired as needed. Urethral strictures form in fewer than 15% of these patients (50).

Primary urethral suturing involves direct visualisation of the severed urethral ends and creation of a watertight, tension-free repair. The patient should be in a supine position. Use a circumferential subcoronal incision to deglove the penis.

In complete disruptions, the corpus spongiosum is mobilised at the level of the injury and the urethral ends dissected distally and proximally. Urethral ends are spatulated, and end-to-end anastomosis is fashioned over a 14 French Foley catheter. Suture small lacerations with fine absorbable material. Careful overclosure of the corpus spongiosum and skin prevents the subsequent formation of fistulae (24). Keep urethral debridement to a minimum since the spongiosum is well vascularised and will usually heal well.

As with any surgery, give pre-operative antimicrobial prophylaxis. Some experts recommend the post-operative continuation of prophylactic antibiotics, but we are not aware of any data that prove that they help. After 10-14 days, obtain a peri-catheter retrograde urethrogram with the urethral catheter in situ. Provided there is no leakage at the anastomotic site, remove the urethral catheter. If there is leakage, leave the catheter in and repeat the cystourethrogram 1 week later.

If the urethra is so extensively disrupted that primary anastomosis is not feasible, then primary repair should be aborted. This occurs with defects of more than 1-1.5 cm in length. One should marsupialise the urethra preparatory to a two-stage urethral repair, and consider a suprapubic urinary diversion. Perform a delayed elective procedure a minimum of 3 months after injury. There is no role for acute placement of a graft or flap in the initial management of any urethral injury, since contamination or decreased blood supply can compromise such a repair (33).

5.3.1.2.2 Female urethral injuries

Most female urethral disruptions can be sutured primarily. These injuries often occur together with bladder ruptures. Frequently, if the bladder injury is going to be repaired primarily, the urethral disruption can be repaired at the same time. For proximal urethral injuries, urethral exposure is best obtained transvesically. Distal urethral injuries can be approached vaginally (29). Early repair of post-traumatic urethral fistulae can also be accomplished transvaginally (4,12).

5.3.2 ***Posterior urethral injuries***

It is important to distinguish between inflammatory or iatrogenic posterior urethral strictures and true pelvic fracture urethral distraction defects as the principles of their surgical management are entirely different. Urethral stricture indicates a narrowing of the urethral lumen. In urethral distraction defects, there is a gap between the two otherwise normal ends of the urethra. The dismembered ends of the urethra retract, and the

space between them fills with fibrous tissue. There is no urethral wall in the scarred space, and any lumen represents merely a fistulous tract between the urethral stumps. A further difference between inflammatory strictures and distraction defects is that the urethral stumps are usually not fibrotic and can be re-anastomosed without tension after distraction injury. Once anastomosed, they usually heal without stricture (51).

Erectile dysfunction occurs in 20-60% of patients after traumatic posterior urethral rupture (51-55). The most important determining factor associated with impotence is the severity of the initial injury. The incidence of erectile dysfunction being caused by the open surgical repair itself is 5% or less (51,56). Erectile dysfunction seems to be a direct result of the pelvic fracture plus urethral injury. King reported an incidence of 42% in cases of pelvic fracture and urethral injury, but only 5% when the urethra was not injured (53). Barbagli *et al*. reported an incidence of 60% in patients with posterior urethral injury, compared with 14% in patients with bulbar injury (57).

Factors that correlate with the development of impotence are age, defect length, and the type of fracture. Bilateral pubic rami fractures are the most frequent cause of impotence. Impotence is most commonly neurogenic, due to bilateral damage of the cavernous nerves at the prostatomembranous urethra behind the symphysis pubis (58,59). Associated vasculogenic erectile failure may occur in up to 80% of cases (60). Dixon *et al*. presented evidence that impotence may also be a consequence of avulsion of the corporus cavernosum from the ischium (14). In this series, five out of six patients with avulsion of the corpus cavernosum off the inferior pubic ramus, were impotent. Spontaneous return of potency may occur up to 2 years after injury (42). Gibson reported an incidence of improved sexual function after 18 months in 21% of patients (52).

5.3.2.1 Partial urethral rupture

Manage partial tears of the posterior urethra with a suprapubic or urethral catheter. Perform urethrography at 2-weekly intervals until healing has occurred (29,37). They may heal without significant scarring or obstruction if managed by diversion alone (48,61). Manage residual or subsequent stricture with urethral dilatation or optical urethrotomy if short and flimsy, and with anastomotic urethroplasty if dense or long (24,37).

5.3.2.2 Complete urethral rupture

Acute treatment options include:

- primary endoscopic realignment;
- immediate open urethroplasty (**which should be considered experimental** and rarely or never used in patients without associated rectal or bladder neck injury).

Delayed treatment options include:

- 'delayed primary urethroplasty' (which implies primary repair 2 weeks after injury and for **which there is a lack of supporting evidence in male patients**);
- delayed formal urethroplasty at 3 months after injury **(the most standard approach);**
- delayed endoscopic incision of the scar tissue between the urethral ends (so-called 'cut-to-the-light' or similar procedures).

5.3.2.3 Primary realignment

The management of complete posterior rupture of the urethra has changed in recent years. There is now more active orthopaedic management of pelvic fractures with immediate external and internal fixation. This has led to the option of early repair of urethral injuries (37).

In the absence of indications for immediate exploration, posterior urethral disruption can be managed in a delayed primary fashion. Primary realignment requires placement of a suprapubic tube at the time of initial injury, with repair undertaken when the patient is stable, usually within 7 days. At this time, patients are stable, and most pelvic bleeding has resolved. The aim of internal realignment is to correct severe distraction injuries rather than to prevent a stricture occurring, although it will also ensure that it is easily treated if it does occur (62).

Open realignment has been described (63), but it should be performed only in patients who undergo open abdominal or pelvic surgery for associated injuries or internal bone fixation. Haematomas that prevent adequate pelvic descent can be evacuated at this point in these cases.

Concomitant bladder neck or rectal injuries should usually be repaired immediately, and open or endoscopic urethral realignment over a catheter at the same time might be advisable. The reasons for immediate repair of bladder neck and rectal injury are:

1. Unrepaired bladder neck injury risks incontinence and infection of the pelvic fractures.
2. Unrepaired rectal injury carries the obvious risk of sepsis and fistula, and early exploration is indicated to evacuate contaminated haematomas and perform colostomy.
3. Urethral realignment over a stenting catheter is appropriate in such cases (29,40,64-66).

The overall condition of the patient and the extent of the associated injuries greatly affect the decision to proceed with primary realignment. Most patients with pelvic crush injuries have multiple organ injuries.

Associated lower extremity fractures can prevent placement in the lithotomy position, which may be required for primary realignment (although bedside flexible cystoscopy can be used). Head injuries increase the adverse risks of anaesthesia. If these conditions are controlled, such that a haemodynamically stable patient can safely undergo a lengthier anaesthesia and can be placed in the lithotomy position, endoscopic urethral realignment could be considered during the first 2 weeks after trauma.

The proposed benefits of primary alignment are:

1. A lower stricture rate than with suprapubic catheter placement alone (69% versus 10%) (6), which avoids a second operation for urethral reconstruction in about one-third of patients (3).
2. If scarring occurs, restoration of urethral continuity is simplified and may be accomplished by endoscopic procedures or dilatation.
3. If urethroplasty is required later, it is technically easier when the prostate and urethra are well aligned; the disadvantage might be a higher incidence of erectile dysfunction and incontinence when compared with delayed reconstruction (6,67).

The great variation of techniques used for primary realignment procedures confuses any comparison with delayed repair procedures (68-71). Primary realignment techniques include:

- simple passage of a catheter across the defect (70);
- catheter realignment using flexible/rigid endoscopes and biplanar fluoroscopy (72,73);
- use of interlocking sounds ('railroading') or magnetic catheters to place the catheter (71,74);
- pelvic haematoma evacuation and dissection of the prostatic apex (with or without suture anastomosis) over a catheter;
- catheter traction or perineal traction sutures to pull the prostate back to its normal location (75).

Realignment may be insufficient to join the margins of the severed urethra completely, and 1.5-4.0 cm defects have been observed even after catheter realignment (76). This finding agrees with experimental animal data, which show that when the urethra is transacted and an apparently good urethral junction is achieved by catheter traction, there is no evidence of epithelialisation of the mucosal gap, but rather that the intervening area is filled with fibrous tissue (77).

Traction on the catheter might not improve the healing of the urethra, and could in fact harm continence. Sustained traction on the Foley balloon catheter can damage the remaining sphincter mechanism at the bladder neck as a result of pressure necrosis (3,64). Series that use immediate urethral realignment with minimal traction without suture repair bolsters report the most favourable results (Table 11).

Endoscopic primary realignment fulfils these criteria and should be used when a primary procedure is contemplated. Open primary realignment in the absence of bladder neck injury or rectal injury has no place in the treatment of posterior urethral injuries because of its higher morbidity.

Table 11: Results of immediate realignment in complete urethral disruption (68,70,72,74,77-91)

Series	Ref.no.	No. of patients	Follow-up months (range)	Erectile dysfunction	Incontinence	Restricture rate
Gibson (1974)	77	35†	n/a	12 (34%)	1 (3%)	26 (74.3%)

**Stricture that requires internal urethrotomy, or open urethroplasty, or more than one dilatation;*
[†]5 patients with partial rupture;
[‡]children;
[§]some partial ruptures included.

This type of summary of the literature suggests that immediate realignment is associated with an impotence rate of approximately 35%, an incontinence rate of 5%, and a restricture rate of 60%.

5.3.2.4 Immediate open urethroplasty

Immediate open urethroplasty of posterior injuries is not indicated because of poor visualisation and the inability to assess accurately the degree of urethral disruption during the acute phase, characterised by extensive swelling and ecchymosis. The difficulty in identifying structures and planes hampers adequate mobilisation and subsequent surgical apposition (24). Incontinence and impotence rates are higher than with the other techniques described in these guidelines (impotence 56%, incontinence 21%, restricture 49%) (6,29,48,62,65,93,94).

However, in posterior urethral injuries associated with concomitant bladder neck or rectal injuries, immediate open exploration, repair and urethral realignment over a catheter is advisable (29,40,64-66). In children, similar results have been reported with delayed repair and immediate open urethroplasty (63).

5.3.2.5 Delayed primary urethroplasty

Delayed primary urethroplasty is mainly indicated in female urethral disruption, although no large series exists. It requires placement of a suprapubic tube at the time of initial injury, with repair undertaken when the patient is stable, usually within 7 days. Fewer than 50 cases have been reported, and most of these are individual case reports only (12).

Delayed primary repair tries to preserve as much urethral length as possible, and to avoid the urethra becoming embedded in dense scar tissue with consequent incontinence. Surgical exploration should be attempted via the retropubic route for proximal injuries, and the vaginal route for distal injuries (29).

5.3.2.6 Delayed urethroplasty

Delayed urethroplasty is the procedure of choice and the gold standard for the treatment of posterior urethral distraction defects.

Most posterior urethral distraction defects are short, and these can generally be resolved by a perineal approach anastomotic repair, provided that they are not associated with extensive haematoma-fibrosis and the bladder neck mechanism is occlusive and competent. After division of the bulbar urethra at the distal point of obliteration, mobilisation of a normal bulbar urethra to the base of the penis generally achieves 4-5 cm of elastic lengthening. This is usually sufficient to achieve a tension-free 2 cm spatulated overlap anastomosis, after bridging a gap of 2.0-2.5 cm without rerouting (24).

This technique has the advantage that associated injuries, damaged skin and tissues, and pelvic haematoma have resolved by the time it is performed. The only problem with this approach would be the length of time that the patient must have a suprapubic catheter in place before definitive treatment.

When the prostatobulbar gap is longer than 2-3 cm as a result of a high dislocation of the prostate, or when the available elongation of the mobilised urethra has been foreshortened by damage caused by a previous surgical procedure, additional procedures may be required. The following manoeuvres are carried out sequentially to gain sufficient anterior urethral mobility to bridge up to 8 cm of separation, and are referred to as the 'progressive perineal approach' (95):

- midline separation of the proximal corporal bodies;
- inferior pubectomy;
- supracorporal urethral rerouting.

In addition to its use as an initial therapy for posterior urethral distraction injuries, the progressive perineal approach can also be applied successfully to salvage procedures following failed repair.

There is a number of circumstances that might preclude successful perineal anastomotic repair as either initial or salvage therapy. These circumstances probably represent fewer than 5% of cases and are shown in Table 12 (96,97).

Table 12: Circumstances that might preclude successful perineal anastomotic repair as either initial or salvage therapy (96,97)

Circumstance	Alternative procedure
Distraction defects longer than 7-8 cm	A tubed interposition flap of penile or peri-neoscrotal skin can be used for reconstruction. This is seldom required and most patients that require the use of flap urethroplasties have previous failed repairs of posterior urethral rupture (see section 4.3.2.7).
Fistulae	These might require a combined abdominoperineal approach to secure adequate closure.
Synchronous anterior urethral stricture	The presence of anterior urethral stricture may compromise the blood supply to the bulbar urethra following division of the bulbar arteries, and these patients should be treated cautiously.
Urinary incontinence	The distal urethral sphincter mechanism could be defunctionalised by urethral distraction, so urinary continence may be maintained primarily by the proximal bladder neck sphincter. Concomitant bladder neck injury might increase incontinence, and could require an abdominoperineal procedure to allow simultaneous bladder neck and urethral reconstruction. The most common cause of bladder neck incompetence is the circumferential tethering of the uninjured bladder neck by scarring. In such cases, it is usually possible to restore functional competence of the bladder neck by mobilising it meticulously. This can be accomplished by removal of the dense haematoma-fibrosis anchoring the bladder neck to the pubis, anteriorly and laterally. Secondary rescarring is prevented by placement of a local omental flap (44, 98).

The results of various techniques are reviewed by Koraitim (66) in a personal series of 100 patients combined with a review of 771 patients from published reports. Immediate and early realignment (n = 326) was associated with rates of 53% for stricture, 5% for incontinence, and 36% for impotence. Of the patients successfully managed with immediate realignment, 42% needed subsequent instrumentation to attempt stabilisation of stricture. Urethroplasty was ultimately necessary in 33%.

Primary suturing (n = 37) was associated with rates of 49% for stricture, 21% for incontinence, and 56% for impotence. In comparison, inserting a suprapubic catheter before delayed repair (n = 508) was associated with rates of 97% for stricture, 4% for incontinence, and 19% for impotence.

The restricture rate after delayed anastomotic urethroplasty was less than 10% (28,38,43,51,55,99-102), and the risk of impotence caused by delayed urethroplasty was about 5% (37,51,55,56,65,103-105).

The gold standard remains delayed urethral repair at a minimum of 3 months after trauma, using a one-stage perineal approach.

The results obtained in children are similar to those in adults. The higher incidence of abdominal surgery simply reflects the greater propensity to damage of the bladder neck in children (105-106).

5.3.2.7 Reconstruction of failed repair of posterior urethral rupture

Restenosis after delayed urethral repair mostly occurs within 6 months. If the anastomosis has a normal calibre at 6 months, then it is extremely unlikely that the patient will develop further stricturing (38).

The principles of salvage repair are similar to those of the initial procedure. Progressive perineal anastomotic repair alone can be successful in 85% of salvage urethroplasties. If an anastomotic repair cannot be performed, a one-stage substitution urethroplasty using a pedicle island of penile skin might be possible

and could be more desirable than the final alternative, a two-stage scrotourethral inlay procedure or mesh split-thickness skin graft urethroplasty (63,107,108).

The main indications for a combined abdominoperineal surgical approach are:

- the presence of fistulous tracts to the bladder base, abdominal wall or rectum;
- peri-urethral epithelialised cavities;
- an ability to achieve the lithotomy position (97).

Restenosis to a luminal calibre of 12 French Foley catheter or smaller is required before a reduction in the urinary flow is perceived as abnormal (109). A wide calibre stricture may be observed or gently dilated. Optical urethrotomy is an alternative, particularly for a short, narrow stricture.

5.3.2.8 Delayed endoscopic optical incision

The principles of the procedure were described by Sachse in 1974 (109). A curved metal sound is passed through the suprapubic cystostomy into the blind-ended proximal urethra. The direct vision urethrotome is inserted into the urethra, and cuts are made towards the sound.

Blandy described a modification of this procedure: suprapubic passage of a cystoscope for transillumination of the thin perineal membrane and transurethral 'cutting-to-the-light' with an electrode (110). Today, the cut-to-the-light technique is sometimes carried out using C-arm fluoroscopy for stereotactic guidance. The urethral catheter is left in place for between 1 and 3 weeks, and the suprapubic drainage for an additional 2 weeks to confirm consistent voiding (111).

The results of several small series have been reported and are summarised in Table 13.

Table 13: Results of optical urethrotomy for traumatically obliterated pelvic urethra (82,112-116,118-123)

**Laser urethrotomy*

The procedure is only indicated if the urethral defect is short, the bladder neck is competent and there is minimal displacement of the prostate and proximal bulbous urethra (116). Although immediate restoration of urethral continuity is commonly possible, failure is common. Urethral dilatation, optical urethrotomy, and transurethral resection of stricture will be needed in about 80% of patients. Most repeat urethrotomies are performed in the first year of follow-up.

It should be noted that after failure of the initial urethrotomy, alternative treatments should be

considered, as repeat urethrotomy achieves only temporary improvement (124). Urethral false passage and rectal perforation have been reported (112,116,119). Stents are not currently recommended for patients with strictures following pelvic trauma, as fibrotic tissue tends to grow though into the lumen of the stent (43,125-127).

5.4 Recommendations for treatment: algorithms

The optimal management of patients with prostatomembranous disruptions should not be thought of as delayed repair versus other types of treatment modalities. Each patient should be assessed and managed according to the initial clinical circumstances. It is impractical to suggest that all patients be managed by one single method because of the variability of each case and the severity of associated injuries. The intervention should be guided by the clinical circumstances. The following algorithms are suggested for the treatment of urethral injuries in males and females (Figures 5-7).

Figure 5: Management of posterior urethral injuries in men

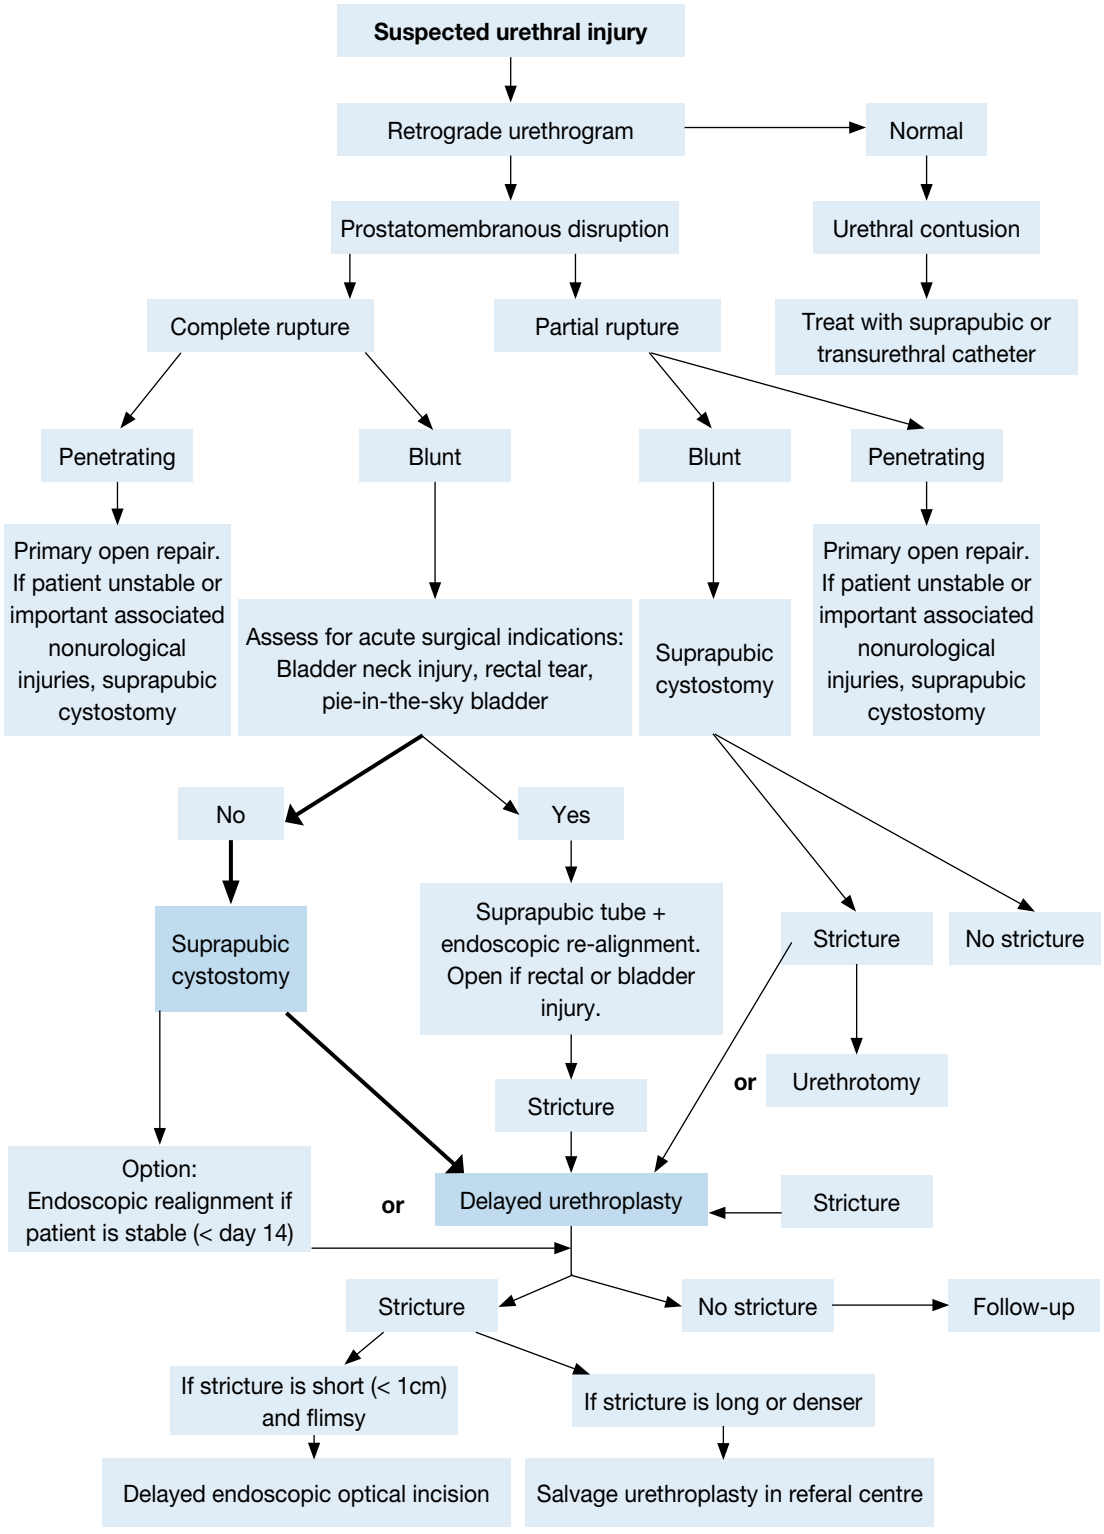

Figure 6: Management of anterior urethral injuries in men

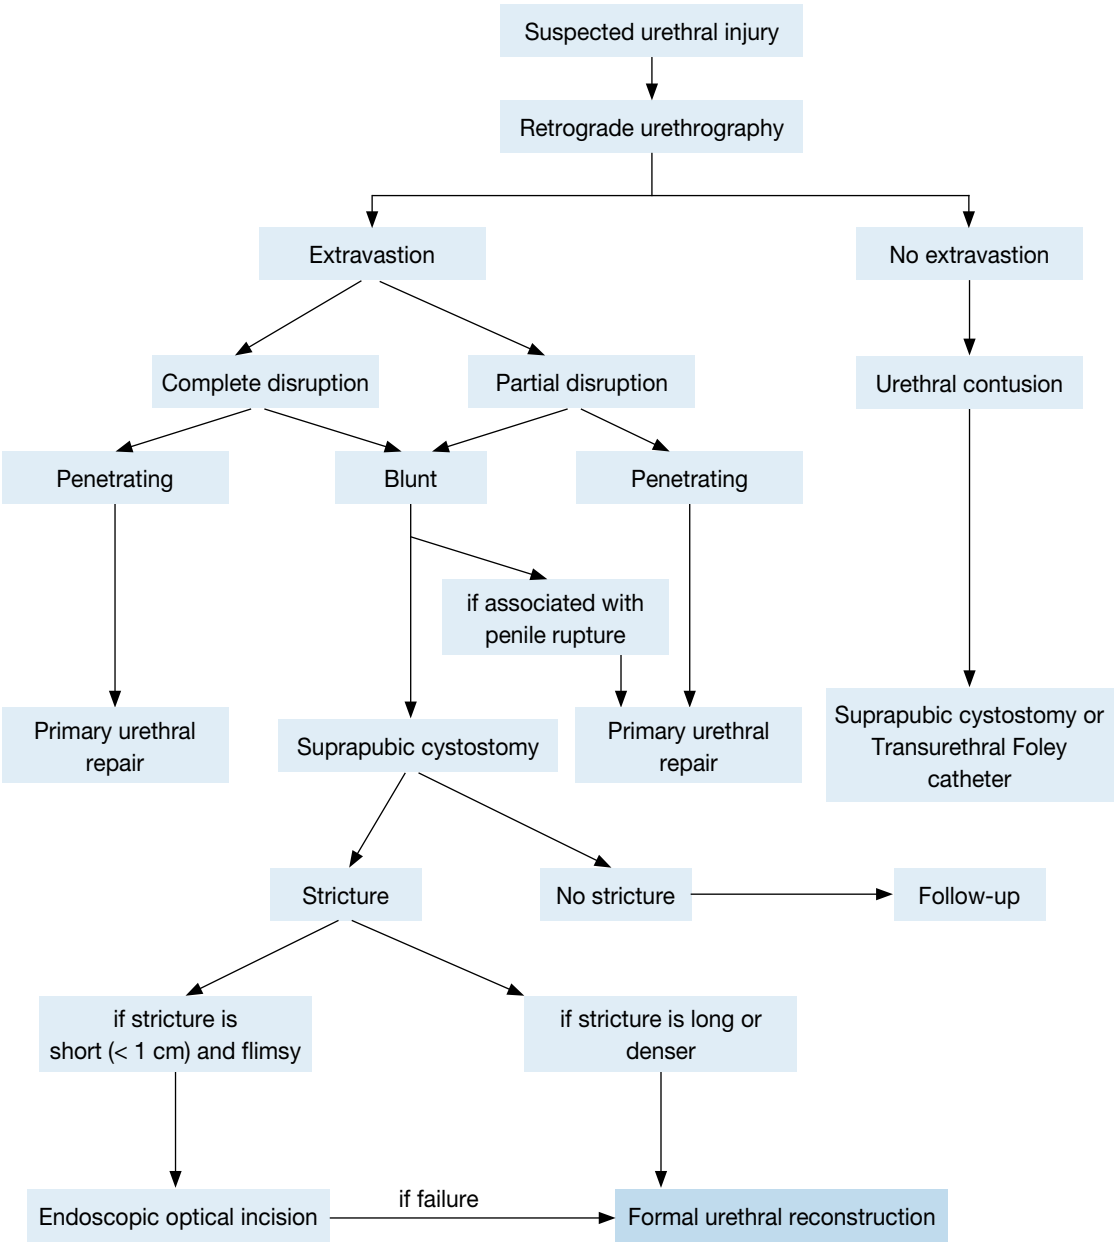

Figure 7: Management of urethral injuries in women

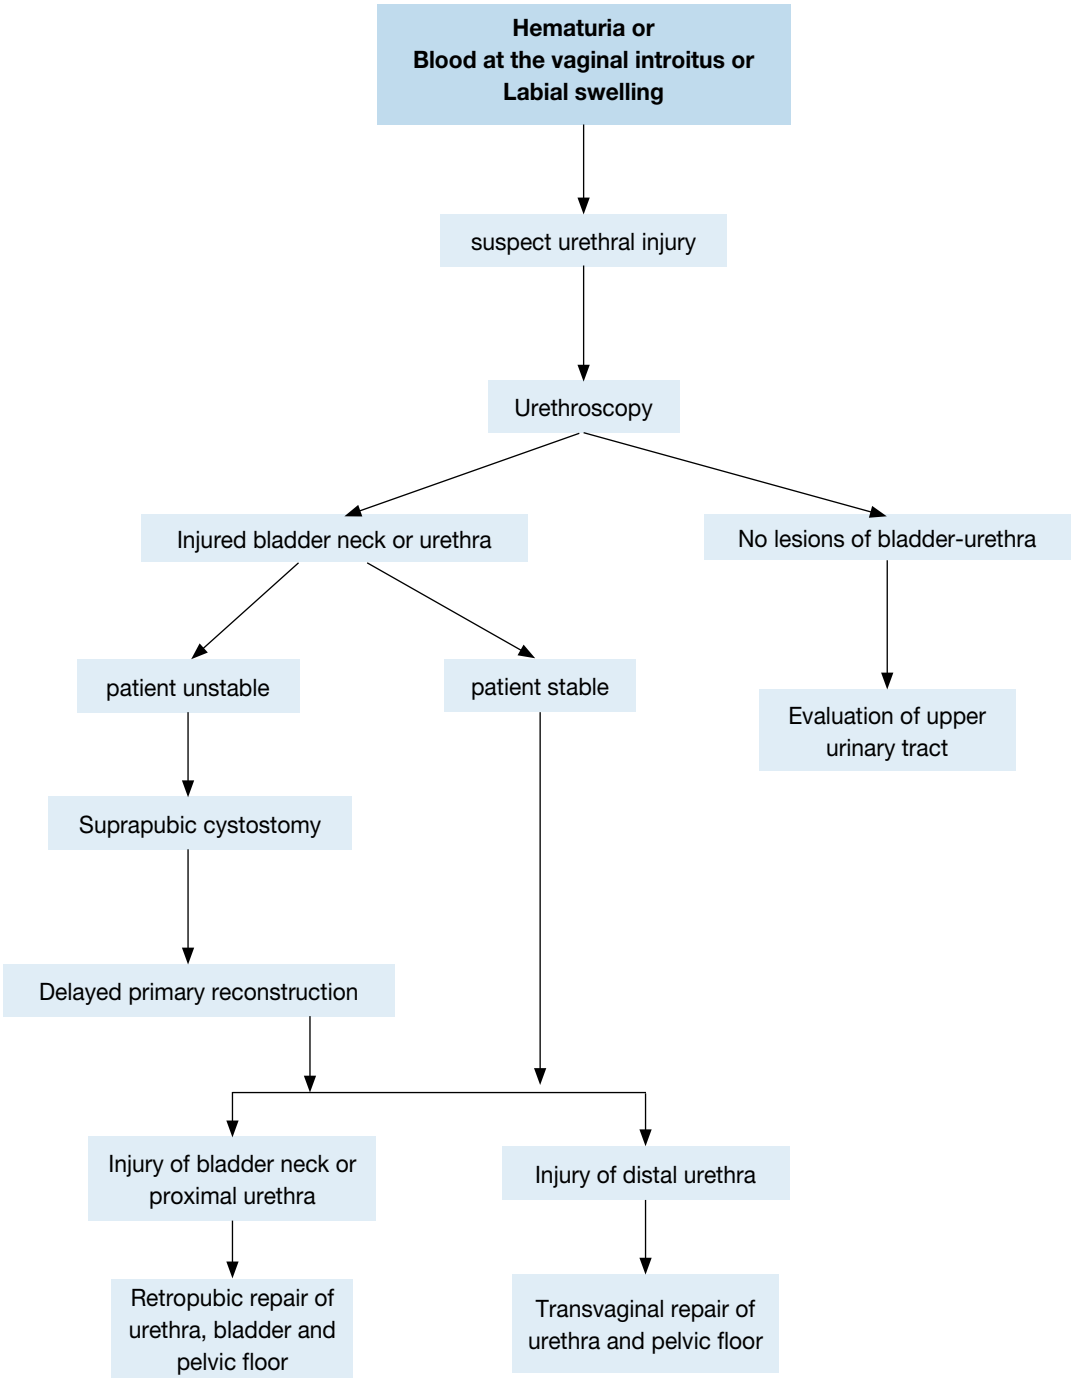

5.5 Iatrogenic urethral trauma

5.5.1 ***Introduction***

The most common form of iatrogenic urethral trauma is that caused by instruments. Most of the relevant urethral lesions caused by iatrogenic trauma are strictures. These strictures are of variable location and severity. They often require different management strategies (128,129).

5.5.2 ***Iatrogenic urethral trauma caused by catheterisation***

The majority of iatrogenic lesions are the result of improper or prolonged catheterisation. They are surprisingly common and account for 32% of urethral strictures. Of these, 52% affect the bulbar and/or prostatic urethra (129) (LE: 3).

Improper insertion of a urethral catheter is a preventable cause of urethral trauma in male patients (130) (LE: 4). The incidence of this type of urethral injury, especially weighed against the total number of urethral catheterisations performed in the same period of time, is difficult to evaluate, and there have been no statistical

data published on this matter so far. However, the risk to an individual patient of a urethral injury caused by improper catheterisation during a hospital stay has been estimated to be 3.2:1000 (129).

Prolonged catheterisation contributes to stricture formation (129). The anterior urethra is primarily affected. The bladder neck is rarely affected (131) (LE: 1b). Iatrogenic urethral injuries can be prevented by the implementation of educational programmes for medical practitioners that are designed to decrease the exposure of patients to catheter-related risk factors (such as prolonged catheterisation and improper catheterisation) (132) (LE: 2b).

*5.5.3 **Iatrogenic urethral trauma caused by transurethral surgery***

Transurethral procedures, especially transurethral resection of the prostate (TURP), are the second most common cause of iatrogenic urethral lesions. Electrical dispersion generated by unipolar electric current and direct urethral injury related to the diameter of the instruments used are factors (133) (LE: 1b). Risk factors include:

- large prostate volume;
- the presence of prostate cancer;
- inexperienced surgeon.

Another cause of stricture formation following transurethral procedures is the form of post-operative urinary drainage used. Urethral catheterisation following transurethral procedures such as TURP, and general post-operative urinary drainage with silicone Foley catheters, both result in a higher incidence of stricture development (134) (LE: 1b).

*5.5.4 **Iatrogenic urethral trauma related to surgical prostate cancer treatment***

A major source of iatrogenic urethral trauma is the treatment of prostate cancer. Urethral stricture after prostate cancer treatment can occur anywhere from the bladder neck to the meatus. The rate of bladder neck contracture after radical prostatectomy lies between 0.5% and 32%, varying according to the definition of stricture and individual practice (135,136) (LE: 2a).

The incidence of urethral stricture after multiple forms of prostate cancer therapy is determined from the CaPSURE database, a registry of men with biopsy-proven prostate cancer. The incidence varies from 1.1-8.4%, depending on the form of cancer treatment. The risk is highest after radical prostatectomy or brachytherapy plus external beam radiotherapy. Stricture formation after prostatectomy occurred within the first 24 months, whereas onset was delayed after radiation therapy. In a multivariate analysis, the type of primary treatment, age and obesity were found to be significant predictors for stricture development (135) (LE: 2b).

New surgical methods, such as robot-assisted prostatectomy can also cause iatrogenic trauma. In a recent study, bladder neck contracture was found in 2% of these patients. This correlates to the stricture rate found after conventional radical prostatectomy (137) (LE: 2b).

*5.5.5 **Iatrogenic urethral trauma related to radiotherapy for prostate cancer treatment***

Prostate brachytherapy (BT), external beam radiotherapy (EBRT), or a combination of the two are options for selected patients as the primary treatment for prostate cancer. Any of these options can cause urinary fistulas, with an incidence of 0.3-3% for patients after BT, and 0.0-0.6% of those treated with EBRT. Most fistulas will involve the rectum (138,139) (LE: 3).

*5.5.6 **Iatrogenic urethral trauma related to major abdominal surgery***

Iatrogenic injuries to the urethra can occur after abdominal and pelvic procedures. Pre-procedure bladder catheterisation must be performed to prevent or to reveal these complications (140) (LE: 2).

*5.5.7 **Symptoms of iatrogenic urethral injury***

The symptoms of urethral injury caused by improper catheterisation or use of instruments are:

- penile and/or perineal pain (100%);
- urethral bleeding (86%) (4) (LE: 2b).

Failure accurately to diagnose and treat urethral injuries may lead to significant long-term sequelae (141).

*5.5.8 **Diagnosis***

The diagnostic investigation of iatrogenic urethral trauma does not differ from that of other urethral injuries.

*5.5.9 **Treatment***

Temporary urethral stenting with an indwelling catheter is a good conventional therapeutic option for treating

acute false passage (142). The placement of a urethral catheter may be impossible, and endoscopic assistance or even placement of a suprapubic tube might be necessary (143) (LE: 3).

Iatrogenic prostatic urethral strictures after radical prostatectomy can be successfully treated by endoscopic management, either by incision or resection. Failure rates can be high, and repeat therapy might be necessary. The alternative is an indwelling catheter, urethral dilatation or open procedures. Open procedures might be required to salvage recurrent cases, but have increased morbidity (144) (LE: 2b).

Conservative treatment in patients with urethral lesions caused by radiotherapy is often ineffective. Major surgery or lifelong suprapubic diversion might ultimately be necessary (138,139) (LE: 3).

Table 14 details the most common causes of stricture, and Figures 8-10 show flow diagrams for the treatment of stricture after urethral injury due to improper insertion of a catheter, radical prostatectomy, and major abdominal surgery or radiotherapy, respectively.

Table 14 Aetiology of stricture

Causes of stricture
Improper catheterisation
Transurethral surgery
Prostate cancer surgery
Prostate cancer radiotherapy
Abdominal and pelvic surgery

5.5.10 Recommendations for treatment: algorithms

Figure 8: Flow diagram of treatment for iatrogenic urethral injury caused by improper insertion of a catheter

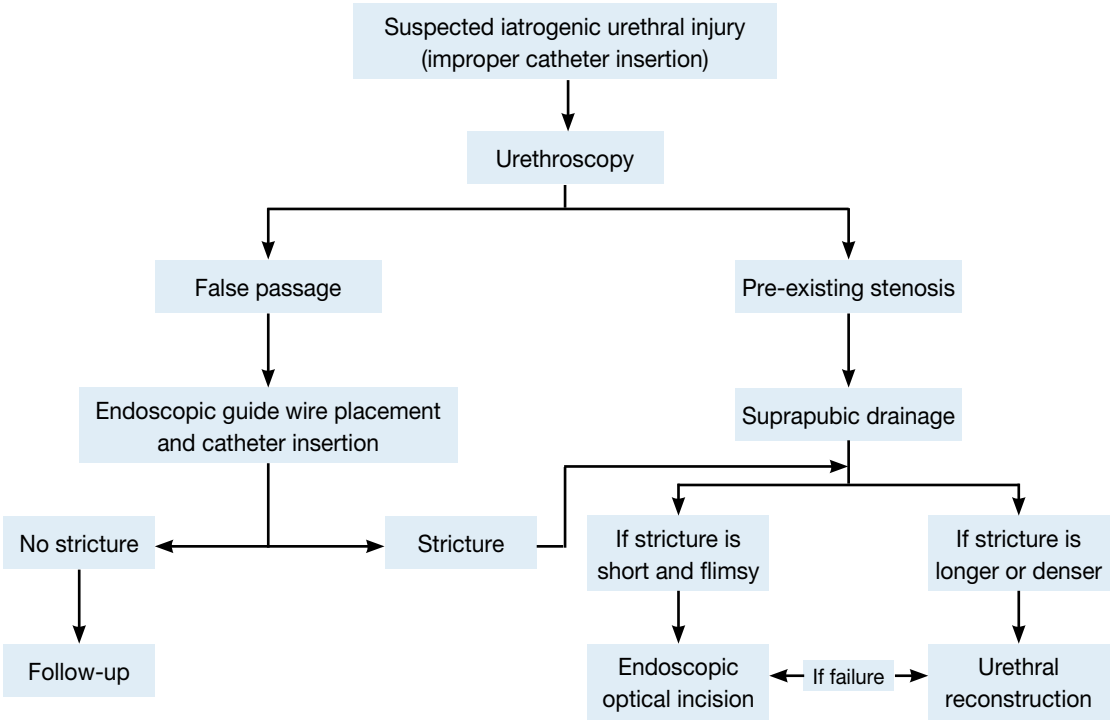

Figure 9: Flow diagram of treatment for stricture after radical prostatectomy

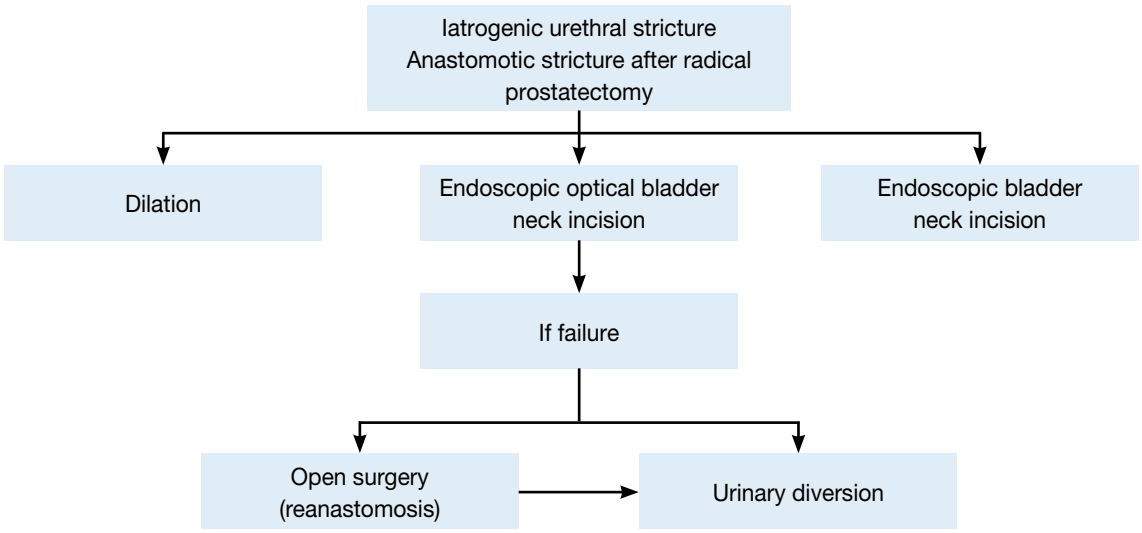

Figure 10: Flow diagram for treatment for stricture after major abdominal surgery or radiotherapy

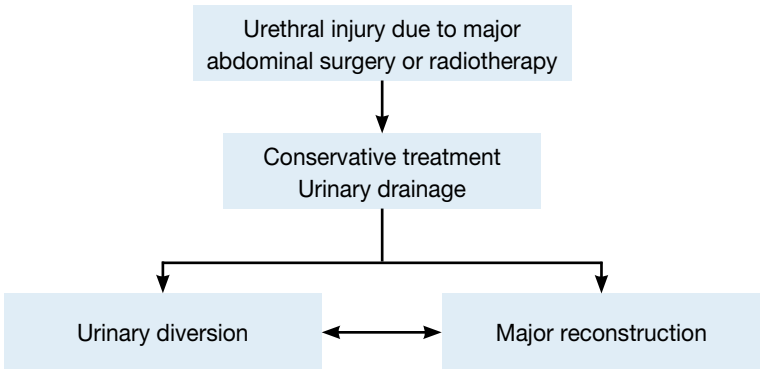

5.5.11 ***Recommendations***

	GR
Avoid traumatic catheterisation.	A
Keep the length of time an indwelling catheter is present to a minimum.	B
Major abdominal and pelvic surgery should be undertaken with a catheter inserted.	B

6. GENITAL TRAUMA

6.1 Background

Traumatic injuries to the genitourinary tract are seen in 2-10% of patients admitted to hospitals (1-5). Of these injuries, between one-third and two-thirds of cases are associated with injuries to the external genitalia (1). The

incidence of genital trauma is higher in men than in women, not only because of anatomical differences but also due to increased exposure to violence, the performance of aggressive sports, and a higher incidence of motor vehicle accidents. In addition, an increase in domestic violence has led to an increase in gunshot and stab wounds over the last several years (6-9). Approximately 35% of all gunshot wounds are affiliated with genital injuries (10).

Genitourinary trauma is seen in all age groups, most frequently in males between 15-40 years. However, 5% of patients are less than 10 years old (10). Genitourinary trauma is commonly caused by blunt injuries (80%) but the risk of associated injuries to neighbouring organs (bladder, urethra, vagina, rectum, bowel) after blunt trauma is higher in females than in males.

Penetrating external genital trauma is seen in about 20% with 40-60% of all penetrating genitourinary lesions involving the external genitalia (11-13).

In men, blunt genital trauma frequently occurs unilaterally. Only 1% present as bilateral scrotal or testicular injuries (10). Penetrating scrotal injuries affect both testes in 30% of cases (10,14). In both genders, penetrating genital injuries occur with other associated injuries in 70% of patients.

The accurate diagnosis and treatment of patients with penetrating injuries are of utmost importance.

However, it is essential that physicians and nurses treating trauma patients are aware of an increased risk of hepatitis B and/or C infection in this cohort (7). Recently, a 38% infection rate with hepatitis B and/or C was reported in males with penetrating gunshot or stab wounds to the external genitalia (7). This was significantly higher compared to normal population, and exposes emergency staff to an increased risk.

6.2 Pathophysiology

Proper management of genital trauma requires information about the accident, involved persons, animals, vehicles, and weapons order to estimate the injury and potential risk of associated lesions.

6.2.1 ***Blunt trauma***

In males, a direct blow to the erect penis may cause penile fracture. Usually the penis slips out of the vagina and strikes against the symphysis pubis or perineum. This most frequently (60%) occurs during consensual intercourse (15). Penile fracture is caused by rupture of the cavernosal tunica albuginea, and may be associated with subcutaneous haematoma, and lesions of the corpus spongiosum or urethra in 10-22% (16,17).

Due to the thickness of the tunica albuginea in the flaccid state (approximately 2 mm), blunt trauma to the flaccid penis does not usually cause tearing of the tunica. In these cases, only subcutaneous haematoma with intact tunica albuginea may be seen.

Blunt trauma to the scrotum can cause testicular dislocation, testicular rupture and/or subcutaneous scrotal haematoma. Traumatic dislocation of the testicle occurs rarely. It is most common in victims of motor vehicle accidents or auto-pedestrian accidents (18-21). Bilateral dislocation of the testes has been reported in up to 25% of cases (21). It can be classified as:

1. Subcutaneous dislocation with epifascial displacement of the testis;
2. Internal dislocation; in these cases, the testis is positioned in the superficial external inguinal ring, inguinal canal or abdominal cavity.

Testicular rupture is found in approximately 50% of cases of direct blunt scrotal trauma (22). It may occur under intense, traumatic compression of the testis against the inferior pubic ramus or symphysis, resulting in a rupture of the tunica albuginea of the testis. Wasko and Goldstein estimated that a force of approximately 50 kg is necessary to cause testicular rupture (23).

In females, blunt trauma to the vulva is rarely reported. The incidence of traumatic vulvar haematomas after vaginal deliveries has been reported as 1 in 310 deliveries (24). The frequency in non-obstetric vulvar haematomas is even lower, with only individual cases reported (25). Although blunt trauma to the female external genitals is rarely reported, the presence of vulvar haematoma is closely related to an increased risk of associated vaginal, pelvic or abdominal injuries. Goldman *et al*. reported that blunt injuries of the vulva and vagina were associated with pelvic trauma in 30%, after consensual intercourse in 25%, sexual assault in 20%, and other blunt trauma in 15% (26).

6.2.2 ***Penetrating trauma***

Penetrating trauma to the external genitalia is frequently associated with complex injuries of other organs. In children, penetrating injuries are most frequently seen after straddle-type falls or laceration of genital skin due to falls on sharp objects (10, 27).

Increasing civilian violence has led to a rising incidence of stab and/or gunshot injuries associated with injuries of the genitourinary tract. The extent of injuries associated with guns is related to the calibre and velocity of the missile (8). Handguns or pistols range from 0.22 to 0.45 calibre and produce bullet velocities of

200-300 meters/second (m/s). In addition, “magnum” handguns have larger gunpowder loads, and transmit 20-60% more energy than standard handguns due to the higher velocity of the missile. Injuries by rifles cause even more extensive lesions. Rifles have a calibre ranging from 0.17 to 0.460, with bullet velocities up to 1000 m/s.

Missiles with a velocity of approximately 200-300 m/s are considered “low velocity”. These bullets only induce a ‘permanent cavity’. The energy transmitted to the tissue along the projectile path is much less than in high-velocity missiles, so that tissue destruction in low-velocity guns is less extensive (8). High-velocity missiles (velocity of 800-1000 m/s) have an explosive effect with high-energy transmission to the tissue causing a ‘temporary cavity’ in addition to the permanent cavity. Due to the high-energy released, gaseous tissue vaporisation induces extensive damage often associated with life-threatening injuries.

Gunshot wounds are classified as penetrating, perforating or avulsive. Penetrating injuries are caused by low-velocity missiles, with bullets often retained in the tissue and a small, ragged entry wound. Perforating gunshot wounds are frequently seen in low to high-velocity missiles. In these cases, the missile passes through the tissue with a small entry wound, but larger, exit one. Serious injuries are associated with avulsive gunshot wounds caused by high-velocity missiles, with a small entry wound comparable to the calibre but a large tissue defect at the exit wound.

In any penetrating trauma, tetanus vaccination is mandatory and should be given using active (tetanus toxoid booster) and passive immunisation (250 IE human tetanus immunoglobulin) if the patient’s last immunisation was given more than 5 years ago (28). For current recommendations for tetanus vaccination, see information from the Robert Koch Institute, Germany (http://www.rki.de/cln_116/nn_504558/DE/Content/Infekt/Impfen/ImpfungenAZ/Tetanus/Tetanus_ImpfenA-Z_ges.html [Articles in German]).

Although animal bites are common, bites injuring the external genital are rare. Wounds are usually minor, but have a risk of wound infection. The most common bacterial infection by a dog bite is *Pasturella Multicida*, which accounts for up to 50% of infections (28). Other commonly involved organisms are *Escherichia coli, Streptococcus viridans, Staphylococcus aureus, Eikenella corrodens, Capnocytophaga canimorsus, Veillonella parvula, Bacteroides* and *Fusobacterium spp*. (28-30).

The first choice of antibiotics is penicillin-amoxiclavulanic acid followed by doxycycline, cephalosporine or erythromycine for 10-14 days (31–33). After any animal bite, one has to consider the possibility of rabies infection. In cases where rabies is locally present, vaccination must be given to prevent life-threatening infection (34). Besides vaccination, local wound management is an essential part of post-exposure rabies prophylaxis. If rabies infection is suspected, vaccination should be considered in relation to the animal involved, specific nature of the wound and attack (provoked/unprovoked) and the appearance of the animal (aggressive, foam at the mouth). In high risk patients, vaccination with human rabies immunoglobulin and human diploid cell vaccine is recommended (34,35).

Genital bites from humans can rarely occur, but can also become infected. Wound infections in these cases may include *Streptococci, Staphylococcus aureus, Haemophilus spp., Bacteroides spp*. and other anaerobes. Transmission of viruses (e.g. hepatitis B, hepatitis C, human immunodeficiency virus [HIV]) following human bites is much less common but should be considered especially in risk groups. Since transmission of viral diseases may occur, risk assessment should be made and, if appropriate, hepatitis B vaccine/immunoglobulin and/or HIV post-exposure prophylaxis offered. For further details see Guidelines for the Management of Human Bite Injuries (36).

Wound management should include cleaning with warm running water or disinfectants. Debridement should be conservative, due to the regenerative capacity of genital skin (36). Antibiotic therapy may be considered only in cases with infected wounds using amoxiclavulanic acid as first line therapy, or, alternatively clindamycin.

6.3 Risk factors

There are certain sports with an increased risk for genital trauma. Off-road bicycling and motorbike riding, especially on bikes with a dominant petrol tank, accidents from in-line hockey skating and rugby footballers have been associated with blunt testicular trauma (37-40). Any kind of full contact sports, without the use of necessary protective aids, may be associated with genital trauma.

Besides these risk groups, self-mutilation of the external genitalia have also been reported in psychotic patients and transsexuals (29).

6.4 Diagnosis

Investigating genital trauma requires information concerning the accident and a thorough history and physical examination, if possible. Trauma to external genitalia at any age may be due to abusive assault. In these cases, the extraordinary emotional situation of the patient must be considered and the privacy of the patient respected. In suspicious cases, a sexual assault forensic exam is necessary. Swabs or vaginal smears should be taken for detection of spermatozoa (27) and local legal protocols followed closely. A thorough history and

examination (in some cases under anaesthesia), photodocumentation, and identification of forensic material may be important. Genital injury is seen frequently (42%) after sexual abuse, and must be considered when such injuries present at any age (41). In a recent report, only 38% of the forensic samples tested positive for an ejaculate and/or sperm. This may be due to delayed presentation or lack of vaginal/anal ejaculation (42-43).

In patients with gunshot wounds to the genitals several pieces of information will be useful: close or far range, calibre and type of weapon. Get a urinalysis. The presence or macro- and or microhaematuria requires a retrograde urethrogram in males (see above Chapter 4, Urethral trauma). In females, flexible or rigid cystoscopy has been recommended to exclude urethral and bladder injury (26,44). In women with genital injuries and blood at the vaginal introitus, further gynaecologic investigation to exclude vaginal injuries (44). The potential for significant injury should never be discounted in those patients who also may have blood in the vaginal vault from menstruation. Complete vaginal inspection with specula is mandatory. Depending on the nature of the injury, this may require sedation or general anaesthesia to be completed comfortably.

6.4.1 ***Blunt penile trauma***

6.4.1.1 Penile fracture

Penile fracture is associated with a sudden cracking or popping sound, pain and immediate detumescence. Local swelling of the penile shaft develops quickly, due to enlarging haematoma. Bleeding may spread along the fascial layers of the penile shaft and extend to the lower abdominal wall if Buck's fascia is also ruptured. The rupture of the tunica may be palpable if the hematoma is not too large. Physical exam and history usually confirm the diagnosis, but in rare cases imaging may be required.

Cavernosography or MRI (45-47) can identify lacerations of the tunica albuginea in unclear cases (48). In case of tunical laceration, surgical correction with suturing of the ruptured area is indicated.

6.4.2 ***Blunt testicular trauma***

Testicular rupture is associated with immediate pain, nausea, vomiting, and sometimes fainting. The hemiscrotum is tender, swollen, and eccymotic. The testis itself may be difficult to palpate. High-resolution, real-time ultrasonography with a high resolution probe (minimum 7.5MHz or higher) should be performed to determine intra- and/or extratesticular haematoma, testicular contusion, or rupture (49-57). In children, scrotal ultrasonography must be performed with a 10-12MHz probe.

The literature is contradictory as to the real usefulness of US over exam alone. Some studies report convincing results with accuracy of 94% (29,49,54,55). Others reported poor specificity (78%) and sensitivity (28%) for differentiation of testicular rupture or haematocele, and accuracy as low as 56% (52).

Colour Doppler-duplex ultrasonography may provide useful information when used to evaluate testicular perfusion. In case of inconclusive scrotal sonography, testicular CT or MRI may be helpful (58). However, these techniques did not specifically increase the detection of testicular rupture. It may be most prudent to surgically explore these equivocal patients. If imaging studies cannot definitively exclude testicular rupture, surgical exploration is indicated.

6.4.3 ***Blunt female trauma***

In females with blunt trauma to the external genitalia, imaging studies of the pelvis with US, CT, or MRI should be performed since additional injuries and extensive intrapelvic haematoma are frequently found (27,44).

6.4.4 ***Penetrating trauma***

In penetrating trauma of the external genital in men, urethrography should be performed in all patients (irrespective of urinalysis). Associated pelvic or abdominal trauma may also require an abdominal CT. CT cystography should be performed in pelvic injuries associate with microhaematuria. In females, the use of diagnostic laparoscopy for identification of intraperitoneal injuries has been reported prior to explorative laparotomy (27). This approach is only reasonable in haemodynamic stable patients, in whom CT cannot exclude presence of associated bowel injuries or significant intra-abdominal bleeding.

6.5 Treatment

6.5.1 ***Penile trauma***

6.5.1.1 Blunt trauma

Subcutaneous haematoma, without associated rupture of the cavernosal tunica albuginea does not require surgical intervention. In these cases, nonsteroidal analgesics and ice-packs are recommended (13).

Benign penile injuries can be distinguished from penile fracture, because fracture is always associated with rapid post-traumatic detumescence. In penile fracture, surgical intervention with closure of the tunica albuginea is recommended. Closure can be obtained by using either absorbable or non-absorbable sutures, with good long-term outcome and protection of potency. Post-operative complications were reported in 9%, including superficial wound infection and impotence in 1.3% (15,59). Conservative management of penile

fracture is not recommended. It increases complications such as penile abscess, missed urethral disruption, penile curvature, and persistent haematoma requiring delayed surgical intervention (59). Late complications after conservative management were fibrosis and angulations in 35% and impotence in up to 62% (15,59).

6.5.1.2 Penetrating trauma

In penetrating penile trauma, surgical exploration and conservative debridement of necrotic tissue is recommended in most severe injuries. Non-operative management is recommended in small superficial injuries with intact Buck's fascia (13). Even in extended injuries of the penis, primary alignment of the disrupted tissues may allow for acceptable healing because of the robust penile blood supply (29). In extended loss of penile shaft skin, split-thickness grafts can be placed, either acutely or after the wound bed has been prepared by several days of wet/dry dressing changes and infection is under control. McAninch *et al*. recommended the use of a skin graft thickness of at least 0.015 inch in order to reduce the risk of contraction (29).

6.5.2 ***Testicular trauma***

6.5.2.1 Blunt trauma

Blunt trauma to the scrotum can cause significant haematocele even without testicular rupture. Conservative management is recommended in haematoceles smaller than three times the size of the contralateral testis (6).

In large haematoceles, non-operative management often fails, and often requires delayed surgery (> 3 days). These patients suffer from a higher rate of orchiectomy than acutely-operated patients, even in non-ruptured testis (10,22,29,60,61).

Early surgical intervention resulted in > 90% preservation of the testis whereas delayed surgery necessitates orchiectomy in 45-55% (22). Additionally, non-operative management is associated with prolonged hospital stays. Large hematocoles should be treated surgically, irrespective of testicle contusion or rupture. At the very least, the blood-clot should be evacuated from the tunica vaginalis sac to relieve disability and hasten recovery. Patients initially treated nonoperatively may need delayed surgery if they develop infection or undue pain.

In testicular rupture, surgical exploration with excision of necrotic testicular tubules and closure of the tunica albuginea is indicated. This results in a high rate of testicular preservation and normal endocrine function. Traumatic dislocation of the testis is treated by manual replacement and secondary orchidopexy. If primary manual reposition cannot be performed, immediate orchidopexy is indicated.

6.5.2.2 Penetrating trauma

Penetrating injuries to the scrotum require surgical exploration with conservative debridement of non-viable tissue. Depending on the extent of the injury, primary reconstruction of testis and scrotum can be performed in most cases. In complete disruption of the spermatic cord, realignment without vaso-vasostomy may be considered if surgically feasible (62). Staged secondary microsurgical vaso-vasostomy can be performed after rehabilitation, although there are only a few cases reported (62). If there is extensive destruction of the tunica albuginea, mobilisation of a free tunica vaginalis flap can be performed for testicular closure. If the patient is unstable or reconstruction cannot be achieved, orchiectomy is indicated.

Prophylactic antibiotics are recommended by experts after scrotal penetrating trauma, although data to support this approach is lacking. Tetanus prophylaxis is mandatory. Postoperative complications were reported in 8% of patients who underwent testicular repair after penetrating trauma (13).

Extended laceration of scrotal skin requires surgical intervention for skin closure. Due to the elasticity of the scrotum, most defects can be primarily closed, even if the lacerated skin is only minimally attached to scrotum (29). Local wound management with extensive initial wound debridement and washout is important for scrotal convalescence.

6.5.3 ***Vulvar injuries***

Blunt trauma to the vulva is rare and commonly present as a large haematoma. However, in contrast to men, blunt vulvar or perineal trauma may be associated with voiding problems. Bladder catheterisation will usually be required. Vulvar haematomas usually do not require surgical intervention, although they can cause significant blood loss, even requiring red blood cell transfusions. Data are scarce (25-27,44), but in haemodynamically stable women, non-steroidal anti-inflammatory medication and cold packs are used. In massive vulvar haematoma or haemodynamically unstable patients, surgical intervention, lavage and drainage is indicated (63).

Antibiotics are recommended by experts after major vulvar trauma, but data supporting this approach are lacking. It is important to emphasise that vulvar haematoma and/or blood at the vaginal introitus are an indication for vaginal exploration under sedation or general anaesthesia in order to identify possible associated vaginal and/or rectal injuries (44). In case of vulvar laceration, suturing after conservative debridement is indicated. If there are associated injuries to the vagina, these can be repaired immediately by primary suturing.

Additional injuries to the bladder, rectum or bowel may require laparotomy for closure. The rectal injuries may also require colostomy.

7. MASS CASUALTY EVENTS, TRIAGE AND DAMAGE CONTROL

7.1 Definition

A mass casualty event is one in which the number of injured people is significantly higher than the number of healthcare providers available (1). A mass casualty disaster does not therefore necessarily involve a large number of victims, but is related to the disproportion between the number of victims and the size of the medical team available (2,3). There is little published data on how best to handle these events.

7.2 Causes of mass casualty events

Potential mass casualty events include:

- the collapse of buildings or bridges;
- earthquakes;
- floods;
- tsunamis;
- train collisions;
- aircraft catastrophes;
- civilian terrorism.

Most mass injury caused by civilian terrorism is caused by explosions. The combined effects of blast, shrapnel, bomb projectiles, and burns result in multiple penetrating injuries involving several body systems and unpredictable degrees of damage.

7.3 Mechanisms of explosive injury

The mechanism of injury in explosions is divided into three phases:

- **Primary blast injury:** this is caused by the powerful shock wave that spreads from the site of the explosion. The most commonly injured organs are those containing air (lungs and ears), but any tissue can be damaged by the pressure wave passing through the body. Urogenital injuries as a direct result of primary blast have not been described in survivors of blast injuries.
- **Secondary blast injury:** this is produced by the debris and projectiles set in motion by the explosion. Penetrating injuries to the urogenital system, as to any organ, have been described.
- **Tertiary injury:** this occurs when the victim displaced by the blast wave hits a fixed object. An acceleration-deceleration mechanism produces severe injuries to organs, large blood vessels, and bones. Blunt renal, ureteral, and bladder injuries are induced by this mechanism.

The patterns and severity of injury after explosions differ according to the location of the event. Explosions in confined spaces (e.g. buildings or buses) are more devastating than those that occur in open spaces because of amplification of the blast wave by reflection, and structural collapse, which can cause further injury.

7.4 Triage

Triage after mass casualty events is difficult, controversial, and full of difficult ethical and moral questions. Disaster triage requires one to differentiate the few critically injured that can be saved by immediate intervention from the many with non-life-threatening injuries for whom treatment can be delayed.

Triage divides patients into four groups (4,5):

1. Patients with life-threatening injuries that require immediate intervention, presenting with **A**irway compromise, **B**reathing failure and/or **C**irculatory compromise from ongoing external haemorrhage.
2. Patients with severe but non-life-threatening injuries, in whom treatment can be acceptably delayed: major fractures, vascular injuries of the limbs and large soft tissue wounds.
3. ‘Walking wounded’ with minimal injuries.
4. Patients who are so severely injured that treatment would require allocation of resources and time that would deny other, more salvageable patients, timely care. These patients are given minimal or no treatment, and re-evaluated when resources become available. There is no absolute definition for this

group because triage is individualised according to the number and severity of casualties related to the available resources.

Triage contradicts the everyday principles of care, in which the goal is maximal and optimal care for every individual patient. Triage is necessary in mass casualty scenarios because of the need to provide effective treatment to the maximum number of salvageable patients within the limited resources.

7.4.1 ***Primary triage***

Primary triage begins when trained medical teams arrive at the event. It is concerned with the initial stabilisation and rapid evacuation of the prioritised victims to the nearest hospital.

7.4.2 ***Secondary triage***

Secondary triage begins at the medical facility that is receiving the mass casualties. The most experienced trauma surgeon who is not taking part in surgical or resuscitation procedures performs triage.

7.4.3 ***Re-triage***

Re-triage is performed frequently. After all the victims have undergone triage, the senior surgeon repeats triage and reclassifies patients as necessary.

Repeat triage is important. It avoids under-triage, which results in serious injury being missed, or over-triage, which results in some patients being assigned for immediate care when in fact they do not have critical injuries.

The surgeon in charge is responsible for directing specialty surgical consultants, including urologists, and assigning them responsibility for specific patients as dictated by the specific injuries.

7.5 Principles of 'damage control'

Damage control is a prioritised three-phase approach to patients with major injuries (6). The first phase consists of rapid control of haemorrhage, wound contamination, and faecal spillage using simple measures and temporary abdominal closure. The second phase is resuscitation in the intensive care unit (ICU), with the goal of restoring normal temperature, coagulation, perfusion, and oxygenation of tissues. Then, in the third stage, definitive surgery and abdominal wall closure is performed in stable patients.

Damage control is a life-saving strategy for patients with multiple injuries that has been adopted by trauma surgeons as a result of the observation that such patients often die from hypothermia, coagulopathy, and acidosis-induced physiological insults (7-9). In unstable patients, extensive and time-consuming reconstructive procedures could further destabilise the patient beyond recovery.

Identifying those critically injured patients who are candidates for damage control is difficult. The most senior trauma surgeon should make the decisions, in co-operation with other specialist surgeons.

Damage control principles have also been successfully adopted in the context of civilian mass casualty events, military field surgery, and initial treatment in rural areas with long-range transfers (9,10).

7.6 Urological aspects of 'damage control'

In events involving mass casualties, the principles of triage and damage control are the same. Damage control can theoretically lower the mortality rates by allowing a limited number of qualified personnel to treat more patients.

Urologists are frequently consulted in patients with multiple injuries, and should be familiar with the damage control approach. Damage control is well suited to urological trauma, and should result in more efficient interaction with the trauma team, improved patient survival and lower morbidity.

In fact, because urological surgery is often elective, management of urological trauma has traditionally consisted of temporary measures followed by definitive surgery later on, which meshes well with modern damage control principles (8). It is important to be aware of damage control opportunities, and to maximise the quality of care with creative improvisation.

7.6.1 ***The urological consultation in the emergency room during mass casualty events***

7.6.1.1 Responsibility and primary overall assessment

After primary assessment and triage by the surgeon in charge, a urological consultation might be required for patients triaged to groups 2 (severe but not immediately life-threatening injuries) and 3 ('walking wounded' with mild injuries). The urologist might even become primarily responsible for these patients if they are stable and have few other injuries.

It is important to remember that under-triage can happen during a mass casualty event. A complete re-assessment of the patient assigned must therefore be performed, paying attention to the whole body so as to detect previously unnoticed injuries. This assessment should be quick but comprehensive. Conduct a

rapid ABCDE survey (**A**irway, **B**reathing, **C**irculation, **D**isability or neurological status, **E**xposure) as dictated by advanced trauma life support (ATLS) principles (3). Urological care should begin only after the patient is cleared for the presence of other injuries.

7.6.1.2 Imaging

Evaluation of patients with penetrating and blunt abdominal or pelvic trauma usually includes imaging procedures such as contrast CT scans or retrograde cystourethrography (11,12). However, when mass casualty protocols are instituted, decisions on care must be made with a minimum of imaging procedures. In those situations, create a unidirectional flow of patients in order to avoid the bottleneck that usually occurs in imaging departments. The 'normal' pattern of sending patients for imaging and then returning them to the accident and emergency department for re-evaluation may not be feasible.

7.6.1.3 Primary management

Following initial primary evaluation, there are several possible scenarios:

1. Haemodynamically unstable patients with suspected intra-abdominal bleeding are transferred urgently to the operating theatre without any pre-operative imaging.
2. Stable patients with suspected renal injuries (penetrating trauma to the upper abdomen/flanks/lower chest, blunt abdominal trauma, and gross haematuria) should have delayed imaging once the protocols of mass casualties are cancelled, or when resources become available. These patients should be transferred to surgical wards and re-evaluated by the urologist as soon as possible.
3. Patients with suspected bladder or urethral injuries (pelvic fractures, high riding prostate on rectal examination, blood at the urethral meatus and/or inability to void) need to undergo imaging of the lower urinary tract, but this is not urgent as these injures are not considered life-threatening (13).
4. In cases of suspected urethral injuries, the 'minimal acceptable treatment' will be one gentle trial of catheterising the bladder or insertion of a suprapubic cystostomy, followed by transfer of the patient to the surgical ward for later evaluation (14).
5. Bladder injuries following blunt or penetrating trauma are usually associated with other severe injuries (15) and thus require a prioritising surgical approach. The first priority in this scenario is the treatment of the associated life-threatening injuries. Bladder drainage is a sufficient first measure, but should be followed by delayed evaluation aiming to obtain accurate diagnosis and to distinguish between intraperitoneal and extraperitoneal bladder rupture.
6. Blunt injuries of the external genitalia are often isolated and can be managed conservatively. On the other hand, penetrating injuries of the genitalia are often associated with injuries of adjacent abdominal organs and haemodynamic instability (7). In mass casualty scenarios, external genital injuries should be operated on only if they have resulted in major haemorrhage. Surgery can be performed in the operating theatre or in a well-equipped shock room in the accident and emergency department. Compression dressings, or clamping/ligation of bleeding vessels are highly efficient manoeuvres that require a minimum of time. When severe haemorrhage is not present, any further diagnostic steps can be postponed. The patient can be transferred to the surgical ward for later re-evaluation followed by delayed reconstruction.

Urological consultations during a mass casualty scenario should be performed according to the following principles:

1. Rule out under-triage by the surgeon in charge, and perform a rapid primary survey of every patient.
2. Avoid unnecessary imaging procedures such as CT scans and retrograde urethrography. These procedures should be performed later, after re-evaluation of the patient, and after mass casualty protocols have been suspended.
3. Treat unstable patients who are to have surgery using damage control principles.
4. Stable patients with suspected renal injuries should be transferred to the surgical ward without imaging procedures. Re-evaluate if there is any change in their haemodynamic status, or when possible as dictated by the constraints of the mass casualty event. Patients managed in this delayed fashion should be treated according to traditional trauma management protocols.
5. 'Minimal acceptable' procedures should be performed in order to transfer patients to the surgical wards, e.g. suprapubic drainage of the bladder when bladder or urethral injuries are suspected, clamping and ligation of bleeding vessels from wounds to the external genitalia, etc.

7.6.2 ***The urological consultation in the operating room during mass casualty events***

During emergency laparotomy, urologists are usually present in the operating theatre along with the general surgeons.

During mass casualty events, the principle of 'minimum acceptable intervention' for the 'maximum

salvageable outcome' applies. Procedures should be directed at the rapid control of active bleeding, and management of urinary extravasation by simple diversion measures. Complex and time-consuming reconstructive procedures should be delayed whenever possible.

7.6.2.1 Renal trauma

The ultimate goal of all renal exploration in the setting of major traumatic renal injury is to control life-threatening bleeding and to preserve the maximal amount of viable renal parenchyma (16).

Renal reconstruction might be too time-consuming in the context of an unstable, multiply injured patient, or in the scenario of mass casualties in which the operating theatre should not be occupied by time-consuming reconstructive procedures (17).

Whenever major active haemorrhage of renal origin can be ruled out, it is best not to explore the injured kidney, even if a secondary delayed laparotomy will eventually be needed (18).

In unstable patients, packing the renal fossa with laparotomy pads and transferring the patient to the surgical ICU is best. Later, a planned second-look laparotomy is better than time-consuming reconstruction (19). Alternatively, especially in briskly bleeding patients, speedy nephrectomy may be required.

Haemostatic techniques, many of which were developed for hepatic surgery and splenic trauma, can be used to control renal parenchymal bleeding (20):

- Mattress sutures through the parenchyma (renorrhaphy), similar to the sutures used in extensive hepatorrhaphy (7).
- Packing with dry folded laparotomy pads as described for peri-hepatic tamponade (7).
- Fibrin hemostatic agents, may be used to control bleeding.
- Absorbable mesh kidney bags maintain renal parenchymal fragments in contact with each other and ensure lasting haemostasis (21).
- Urinary extravasation may be ignored during the acute phase; acutely, urine leak will be drained by intraoperatively placed drains; defer ureteral stents or percutaneous nephrostomies.
- The abdomen is temporarily closed with towel clips or other measures.

Following urgent primary exploration, patients should be carefully monitored in an ICU. When they are sufficiently stable, begin radiological assessment of their injuries and plan their definitive operative management accordingly.

Delayed imaging is obtained by CT scan. If the extent of renal injury has not been clearly defined at the initial laparotomy (by choosing not to explore the retroperitoneal haematoma), a CT scan performed before the second laparotomy can help in decision-making. CT allows the existence and function of the contralateral kidney to be documented, the kidney injury to be graded according to traditional protocols, and a clinical plan to be created, which will then determine the selection of operative or non-operative management of the renal trauma, and whether nephrectomy or reconstruction is to be attempted.

In patients who are haemodynamically unstable after the initial acute damage control laparotomy, or in patients with deteriorating haemodynamic parameters (indicating ongoing or delayed bleeding), the management options are angiographic embolisation of the bleeding kidney or re-operation. This decision should be made according to several factors:

- The general status of the patient.
- The presence of associated injuries that have been treated according to damage control principles (bowel injuries, packed liver, or splenic injuries) and that need re-operation irrespective of the renal injury.
- The availability of angiography.

7.6.2.2 Ureteral injuries

Although excellent results can be achieved with acute ureteral reconstruction, the surgery is time-consuming and might not be appropriate in the mass casualty setting.

During mass casualty events, diagnostic procedures such as the intraoperative injection of indigo carmine, intraoperative IVP or retrograde ueretropyelography that are intended to evaluate ureteral injuries should be discouraged.

If a ureteral injury is suspected but not clearly identified, a drain may be left in place. If urine leaks, a nephrostomy tube can be placed post-operatively.

If a partial ureteral tear is identified (less than half circumference) and the ureter looks viable, a double J-stent may be inserted over a guide wire through the tear, and the tear quickly closed with interrupted absorbable stitches.

When complete ureteral injuries are identified, definitive repair should not be performed. Dissection of the

ureteral stumps should be avoided as it interferes with the blood supply. Instead:

- place a single J or 8 French feeding tube into the ureter;
- tie the distal end of the ureter over the tube;
- exteriorise it through a small stab incision;
- tie it to the skin.

The distal ureteral stump does not need to be ligated, and any unnecessary manipulation should be avoided.

Tying off the injured ureteral segment and inserting a percutaneous nephrostomy post-operatively (22,23) is a viable alternative, but is not the procedure of choice.

In rare, selected cases, nephrectomy is required to treat ureteral injury, but only in cases of severe associated injuries of the ipsilateral kidney (24).

Ureteral injuries are rarely life-threatening and should be addressed only after other injuries have been attended to. In an unstable patient, temporary measures to control urine spillage should be performed, for example:

- tying off of the injured ureteral segment and post-operative insertion of percutaneous nephrostomy (15,19);
- placement of a single J or feeding tube into the ureter, tying the distal end of the ureter over the tube and exteriorising it (15,19,23).

Intraoperative placement of a nephrostomy tube is time-consuming and should be avoided (15,19).

7.6.2.3 Bladder injury

Bladder injuries should be classified, when time and resources allow, as extraperitoneal or intraperitoneal. Extraperitoneal injuries can usually be managed with bladder drainage alone. Intraperitoneal injuries require surgical exploration and layered closure of the bladder wall (13). The degree to which penetrating bladder injury can be treated non-surgically is not known. However, non-surgical management of iatrogenic bladder injuries has been reported, and could be effective after penetrating injury (11,19).

7.6.2.3.1 Auxiliary damage control measures

Examples of auxiliary damage control measures that could be applicable include:

- the placement of externalised ureteral stents can provide external urinary drainage in extensive bladder rupture (19);
- packing or arteriography and selective embolisation can be applied in cases of bladder haemorrhage in patients who are unsuitable for urgent pelvic exploration (13,19);
- the placement of a pelvic suction drain for urinary evacuation (19).

7.6.2.4 Urethral injury

Urethral injury of any kind is never life-threatening per se, but the associated injuries might cause haemodynamic instability. The patient is usually seen by the urologist during an operation performed because of the other injuries. In this situation, no matter whether the urethral tear is posterior or anterior, partial or complete, drainage through a suprapubic or urethral catheter should be obtained without prior imaging.

7.6.2.5 Injury of the external genitalia

Traumatic injuries of the external genitalia are much more common in men than in women, probably because of the anatomical differences (11,25). Blunt injuries of the genitalia are usually isolated, and can be managed conservatively. Penetrating injuries of the genitalia are often associated with injuries of adjacent abdominal organs and related haemodynamic instability (12). In mass casualty events, both types of injury should be managed by watchful waiting. Urethral or testicular imaging and surgical exploration should be deferred.

7.6.2.5.1 Temporary damage control measures

Temporary damage control measure that might be applicable include:

- compression dressing of the penis;
- packing of penetrating testicular injuries;
- tampons for vulvar lacerations.

7.7 Summary

- Damage control surgery has become the standard approach in the management of unstable patients, and is especially useful in a mass trauma event.
- Medical teams should be well prepared ahead of time to deal with mass casualty events.
- All surgical sub-specialists involved in trauma management should be very familiar with the principles of triage and damage control.

8. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

AAST	American Association for the Surgery of Trauma
ATLS	advanced trauma life support
BT	Transperineal, interstitial, permanent prostate brachytherapy
BUN	blood urea nitrogen
CT	computed tomography
DMSA	dimercaptosuccinic acid
EBRT	External beam radiotherapy
ePTFE	polytetrafluoroethylene
GR	grade of recommendation
HIV	human immunodeficiency virus
hpf	high-power field
ICU	intensive care unit
IVP	intravenous pyelography/pyelogram
IVU	intravenous urography
KUB	kidney-ureter-bladder
LE	level of evidence
MRI	magnetic resonance imaging
m/s	metres per second
PCNL	percutaneous nephrolithotomy
rbc/hpf	red blood cells per high-power field
TOT	transobturator tape
TURP	Transurethral resection of the prostate
TVT	tension-free vaginal tape
US	Ultrasonography

Conflict of interest

All members of the Urological Trauma Guidelines working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on Pain Management

1. INTRODUCTION

1.1 The Guideline

The European Association of Urology (EAU) Guidelines Working Group for Pain Management have prepared this guidelines document to assist medical professionals in appraising the evidence-based management of pain in urological practice. These guidelines include general advice on pain assessment, with a focus on treatment strategies relating to common medical conditions and painful procedures. No attempts have been made to exhaustingly cover the topic of pain.

The multidisciplinary panel of experts responsible for this document include three urologists, two radiotherapists and two anaesthesiologists.

*1.1.1 **Methodology***

The recommendations provided in the current guidelines are based on systematic literature search using Medline, the Cochrane Central Register of Controlled Trials, and reference lists in publications and review articles.

It has to be emphasised that the current guidelines contain information for the treatment of an individual patient according to a standardised general approach.

1.2 Publication history

The Pain Management Guidelines were first published in 2003, with a partial update in 2007, followed by a full text update in 2009. In 2010 two new topics were added, Section 5.6 “Peri-operative pain management in children” and Chapter 6 “Non-traumatic acute flank pain”. The quick reference guide was completely reworked. In the 2011 print all chapters were abridged. The current 2012 edition contains partial updates based on the available literature and two new topics were added, Section 3.4 “Denusomab” and Section 3.5 “Palliative care”. A quick reference document presenting the main findings of the General Pain Management guidelines is also available. All texts can be viewed and downloaded for personal use at the EAU website: http://www.uroweb.org/guidelines/online-guidelines/.

1.3 Level of evidence and grade of guideline recommendations*

References used in the text have been assessed according to their level of scientific evidence (Table 1) and guideline recommendations have been graded (Table 2) according to the Oxford Centre for Evidence-based Medicine Levels of Evidence (1). The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence (LE)*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

**Modified from Sackett et al. (1)*

It should be noted that when recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of randomised controlled trials (RCTs) may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Alternatively, absence of high level evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful for the reader. The quality of the underlying scientific evidence -

although a very important factor - has to be balanced against benefits and burdens, values and preferences and cost when a grade is assigned (2-4).
The EAU Guidelines Office do not perform cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever this data is available, the expert panels will include the information.

Table 2: Grade of recommendation (GR)*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett et al. (1)*

2. BACKGROUND

2.1 Definition of pain

Pain is the most common symptom of any illness, and is defined by the International Association for the Study of Pain (IASP) as 'an unpleasant sensory and emotional experience associated with either actual or potential tissue damage, or described in terms of such damage' (1).

The alerting function of pain evokes protective responses, and is intended to keep tissue damage to a minimum. The capacity to experience pain has a protective role. If tissue damage is unavoidable, a cascade of changes occurs in the peripheral and central nervous system responsible for the perception of pain (2).

Acute pain - usually occurring in response to an identifiable noxious event with stimulation of the nociceptive system - has a time-limited course during which treatment, if necessary, is aimed at correcting the underlying pathological process. In contrast, maladaptive (pathological) pain offers no biological advantage because it is uncoupled from a noxious stimulus or tissue healing, and is usually persistent or recurrent. It may occur in response to damage to the nervous system. It is known as neuropathic pain, and is pain as a disease (3-5).

2.2 What is suffering?

Pain is a complex experience entailing physiological, sensory, affective, cognitive, and behavioural components. An individual's perception of the intensity of pain relates to the interactions of physical, psychological, cultural and spiritual factors (6).

Pain and suffering are closely identified, but are nevertheless distinct. Patients can experience severe pain without suffering (e.g. during childbirth), and suffering can include physical pain, but it is by no means limited to it. Patient distress also results from factors other than pain that add to suffering, such as anxiety, depression, nightmares, change in body perception, and changes in professional and social function.

The differences between pain and suffering are most pronounced in cancer pain patients. Cancer is one of the medical conditions patients fear most, because of the expectation that it will end in death, and that that death will be while in excruciating pain (7,8).

2.3 Nociception and innervation

Structure of the peripheral neural apparatus

Sensory information from the skin is transmitted to the central nervous system (dorsal horn of the spinal cord) via three different types of primary sensory neurones: Aβ-, Aδ-, and C-fibres.

These primary afferent neurones are responsible for transducing mechanical, chemical, and thermal information into electrical activity. Although all three classes can transmit non-nociceptive information, under physiological circumstances only C-fibres (dull pain) and Aδ-fibres (sharp pain) are capable of transmitting nociceptive information from the periphery to the dorsal horn of the spinal cord. Thus, under normal circumstances, Aβ-fibres are responsive only to non-noxious mechanical stimuli, including touch, vibration and pressure (9-12). Nociceptive information for the viscera reaches the central nervous system along the sympathetic chains and pelvic parasympathetic chain. However, the density of visceral afferents is low compared with the skin, which can explain the poor localisation of noxious stimuli in the viscera (responsible for the diffuse nature of visceral pain) (13).

2.4 Neuropathic pain

Definition of neuropathic pain

Neuropathic pain is defined by the IASP as 'pain initiated or caused by a primary lesion or dysfunction of the nervous system' (2). While this definition has been useful in distinguishing some characteristics of neuropathic and nociceptive types of pain, a more precise definition has been developed (14): pain arising as a direct consequence of a lesion or disease affecting the somatosensory system. Where possible, neuropathic pain should be divided into peripheral or central neuropathic pain based on the anatomic location of the lesion or disease.

Both negative and positive sensory symptoms may be present. Positive signs include pain, paraesthesia, dysaesthesia, hyperalgesia, and allodynia. Negative signs involve sensory deficits (hypoaesthesia and hypoalgesia), weakness, and reflex changes. Clinically, patients may complain of spontaneous ongoing pain (stimulus-independent pain) that is burning, with intermittent shooting or electric shock-like (lancinating) sensations, and/or have pain hypersensitivity evoked in response to stimuli (stimulus-evoked pain) such as hyperalgesia and allodynia (15,16).

Mechanisms of neuropathic pain

A change in function, chemistry, and the structure of neurones (neural plasticity) leads to the production of the altered sensitivity characteristics of neuropathic pain. Peripheral sensitisation acts on the nociceptors, and central sensitisation takes place at various levels ranging from the dorsal horn to the brain. In addition, abnormal interactions between the sympathetic and sensory pathways contribute to mechanisms mediating neuropathic pain (17,18).

2.5 Innervation of the urogenital system

The differences between the mechanisms of nociception in the skin and viscera have been emphasised by studies of the response properties of visceral afferents from the urinary tract (19-21). (see also EAU Guidelines "Chronic Pelvic Pain", Chapter 2)

Ureter

The only sensation that can be evoked from the ureter is pain, whereas other organs such as the bladder can give rise to several sensations ranging from mild fullness to pain.

Ureteric afferents are thinly myelinated or unmyelinated, and respond to direct probing of a limited area of tissue. Two populations of afferents have been distinguished by Cervero and Jänig (22). The first responds to contractions of the ureter and is also excited by low levels of distension. The second group does not respond to peristaltic contractions of the ureter, but it is excited by distension with a wide range of thresholds (22).

Activation of muscarinic and adrenergic receptors increases the amplitude of urteral contractions. The sympathetic nerves modulate contraction by α-adrenoceptors and relaxation by α-adrenoceptors. The purinergic system is important in sensory/motor functions. Important non-adrenergic non-cholinergic transmitters are ATP, nitric oxid (NO) and serotonin, as well as the prostataglandins F2, E1 and E2 (23). Understanding ureteral function and physiology is the basis for developing new drugs, for example, in renal colic (23).

Urinary bladder

Two distinct groups of afferent fibres capable of signalling noxious stimuli have been identified in the urinary bladder. Most visceral afferents from the urinary bladder are unmyelinated fibres, although a population of

myelinated A-fibres is also present (18). The majority of visceral primary afferents from the bladder, urethra and reproductive and other pelvic organs encode for both noxious and non-noxious stimuli (19-21).

Graded distension of the healthy urinary bladder in humans initially gives rise to a sensation of fullness and eventually pain as volume increases and intravesical pressure exceeds 25-35 mmHg (19-21). In the inflamed bladder, the sensations during bladder emptying become unpleasant and painful. Nearly all afferents are small, myelinated or unmyelinated, and travel with sympathetic (hypogastric) or parasympathetic (pelvic) nerves.

Male reproductive organs
The sensory innervation of the testes (dog model) shows that more than 95% of the fibres of the superior spermatic nerve are unmyelinated, with the great majority having polymodal properties (i.e., responding to mechanical, chemical and thermal stimuli) (24). Myelinated and unmyelinated afferent fibres form a homogeneous group with polymodal receptors in testes and/or epididymis. Prostaglandins do not excite but sensitise the afferents to other stimuli (25).

2.6 Pain evaluation and measurement

*2.6.1 **Pain evaluation***

Health professionals should ask about pain, and the patient's self-report should be the primary source of assessment. Clinicians should assess pain with easily administered rating scales, and should document the efficacy of pain relief at regular intervals after starting or changing treatment.

Systematic evaluation of pain involves the following steps.

- Evaluate its severity.
- Take a detailed history of the pain, including an assessment of its intensity and character.
- Evaluate the psychological state of the patient, including an assessment of mood and coping responses.
- Perform a physical examination, emphasising the neurological examination.
- Perform an appropriate diagnostic work-up to determine the cause of the pain, which may include tumour markers.
- Perform radiological studies, scans, etc.
- Re-evaluate therapy.

The initial evaluation of pain should include a description of the pain using the PQRST characteristics:

P Palliative or provocative factors: 'What makes it less intense?'
Q Quality: 'What is it like?'
R Radiation: 'Does it spread anywhere else?'
S Severity: 'How severe is it?'
T Temporal factors: 'Is it there all the time, or does it come and go?'

Pain in patients with cancer is a complex phenomenon. Not all pains will be of malignant origin, they will often have more than one pain problem, and each pain must be individually assessed and evaluated. A key principle is constantly to re-evaluate pain and the effect and side-effects of analgesic therapy.

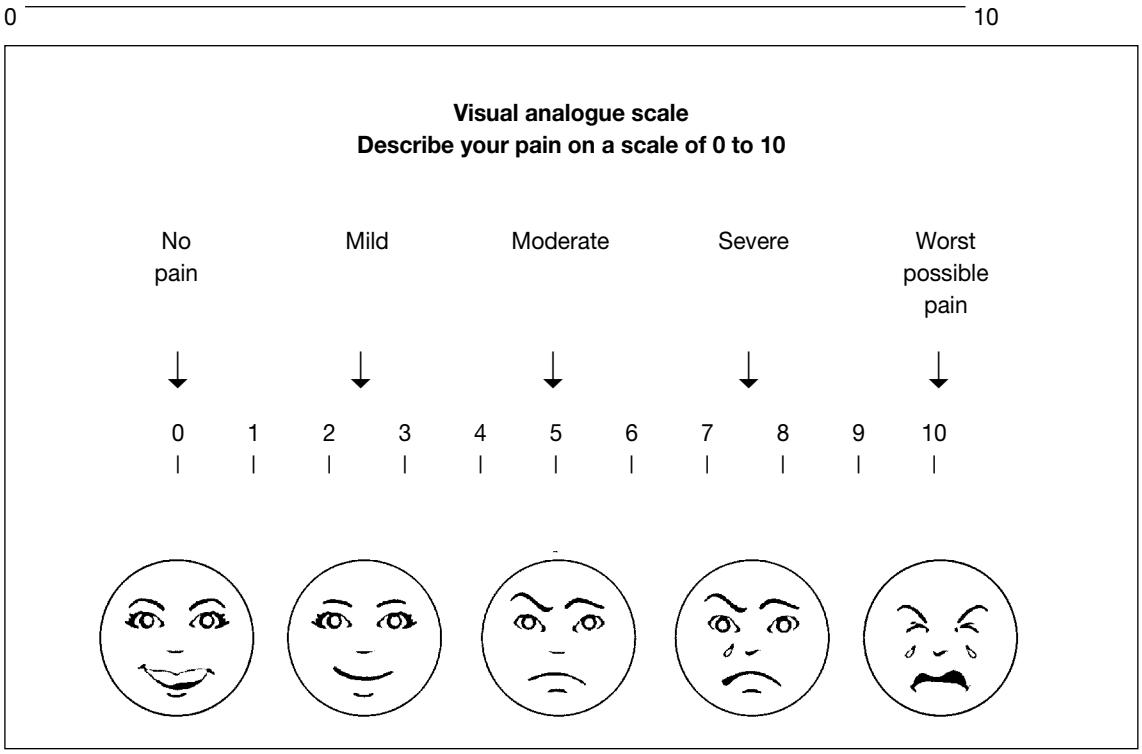
Pain in cancer patients could be caused by the cancer itself, be due to secondary muscular spasm, be secondary to cancer treatments, or have no relation to the cancer, e.g. arthritis.

In general, cancer pain consists of two broad diagnostic types: nociceptive and neuropathic pain. When evaluating pain, it is useful to try to determine whether the pain is one of these types or a mixture of the two. Nociceptive pain includes bone pain and soft tissue pain. Typically it is described as a dull, aching pain. This type of pain will be largely sensitive to non-steroidal anti-inflammatory drugs (NSAIDs) and opioids. Neuropathic pain results from damage to the peripheral or central nervous system. It is usually described as a burning or sharp, shooting pain. Neuropathic pain is usually not particularly responsive to NSAIDs or opioids. Adjuvant analgesics such as anti-depressants and anti-convulsants should be used in the first instance.

*2.6.2 **Assessing pain intensity and quality of life (QoL)***

There are several rating scales available to assess pain. Rating pain using a visual analogue scale (VAS, Figure 1) or collection of VAS scales (such as the brief pain inventory) is an essential part of pain assessment. Its ease of use and analysis has resulted in its widespread adoption. It is, however, limited for the assessment of chronic pain.

Figure 1: Visual analogue scale



To study the effects of both physical and non-physical influences on patient well-being, an instrument must assess more dimensions than the intensity of pain or other physical symptoms. Several validated questionnaires to assess various QoL dimensions are available, including the Medical Outcomes Short-Form Health Survey Questionnaire 36 (SF-36), and the European Organisation for Research and Treatment of Cancer Quality of Life Core Questionnaire (EORTC QLQ-C30) (26-30).

3. CANCER PAIN MANAGEMENT (GENERAL)

3.1 Classification of cancer pain

The physical causes of pain are either nociceptive or neuropathic. In cancer patients, nociceptive pain tends to be caused by invasion of the bone, soft tissues or viscera (e.g. bowel, bladder), and neuropathic pain by nerve

compression or infiltration.

Urogenital neoplasms frequently metastasise to bone (e.g. spine, pelvis, skull). Bone metastases are associated with pathological fractures, hypercalcaemia and neurological deficits, leading to substantial impairment of QoL. The release of algogenic substances in the tissue, microfractures and periosteal tension are the main mechanism for pain sensation (1).

Pain caused by bone metastasis is nociceptive, but can become neuropathic if the tumour invades or compresses a nerve, neural plexus or spinal cord. One-third of patients with tumour-related pain are affected by neuropathic pain components (2). Nociceptive pain is well localised. Initially it occurs on physical movement, but later might also occur at rest.

Neuropathic pain frequently has a constant 'burning' character. The efficacy of opioids may be diminished in neuropathic pain, making co-analgesia necessary (3). Patients with severe neuropathic pain are a special challenge. Psychological changes frequently occur, and specific therapeutic intervention may be necessary (4).

The World Health Organization (WHO) recommends a stepwise scheme for the treatment of cancer pain syndromes and neoplastic bone pain. Bisphosphonates and calcitonin are helpful for stabilising bone metabolism. Epidural and intrathecal opioids are sometimes useful in managing metastatic bone pain. Selected patients with neuropathic pain sometimes benefit from nerve destruction by intrathecal or epidural phenol (5).

3.2 General principles of cancer pain management

The four goals of care are:

- prolonging survival
- optimising comfort
- optimising function
- relieving pain.

Pain leads to a vicious cycle of sleeplessness, worry, despair, isolation, hopelessness, depression, and escalation of pain. The following hierarchy of general treatment principles is useful in guiding the selection of pain management choices.

1. Individualised treatment for each patient.
2. Causal therapy to be preferred over symptomatic therapy.
3. Local therapy to be preferred over systemic therapy.
4. Systemic therapy with increasing invasiveness (the WHO ladder).
5. Conformance with palliative guidelines.
6. Both psychological counselling and physical therapy from the very beginning.

The fundamental principle is the individualisation of therapy. Repeated evaluations allow the selection and administration of therapy to be individualised in order to achieve and maintain a favourable balance between pain relief and adverse effects.

The next steps in the hierarchy, especially points 2-4, necessitate a continuing risk-to-benefit assessment between therapeutic outcome versus tolerability and willingness to accept adverse effects.

The more invasive the therapy, the more difficult the decisions become. This is particularly true with palliative medicine, where the prospects of healing are limited and there is the problem of working against time.

If local therapy is not feasible or cannot be well tolerated, then symptomatic measures are appropriate, although local therapy is to be preferred over systemic treatment. In simple cases, measures such as drainage and stenting can make analgesic medication redundant, e.g. gastric probe, ureteral

stent, percutaneous nephrostomy, bladder catheter. Patients with recurrent subileus caused by peritoneal carcinomatosis are immediately relieved of their pain when they are given an artificial anus.

The indication is in direct relation to the severity of the disease and the operation, especially if the aim is palliative, although such cases are sometimes in particular need of invasive measures, not only to relieve pain in the terminal phase, but also to improve the general QoL, despite the potential for surgery to have a negative impact on patients' wellbeing. Examples include evisceration to prevent cloaca in cervical carcinoma, or implanting a prosthetic hip due to a pathological fracture originating in metastasised bladder or kidney cancer.

When dose escalation of a systemically administered opioid proves unsatisfactory, the following gradual strategy can be considered (LE: 4):

- Switch to another opioid.
- Intervene with an appropriate primary therapy or other non-invasive analgesic approach.
- Pursue psychological, rehabilitative and neurostimulatory techniques (e.g. transcutaneous electrical nerve stimulation).
- Use invasive analgesic techniques after careful evaluation of the likelihood and duration of the analgesic benefit, the immediate risks, and the morbidity of the procedure (epidural infusion).
- Use neurodestructive procedures (chemical or surgical neurolysis, coeliac plexus blockade).
- Some patients with advanced cancer where comfort is the overriding goal can elect to be deeply sedated.

The importance of physiotherapy and psychological counselling cannot be emphasised too strongly.

3.3 Non-pharmacological therapies

3.3.1 ***Surgery***

Surgery may have a role in the relief of symptoms caused by specific problems, such as obstruction of a hollow viscus, unstable bony structures and compression of neural tissues or draining of symptomatic ascites (1-3). The potential benefits must be weighed against the risks of surgery, the anticipated length of hospitalisation and convalescence, and the predicted duration of benefit. Radical surgery to excise locally advanced disease in patients with no evidence of metastatic spread may be palliative, and potentially increase the survival of some patients (4) (LE: 2b).

4. Temple WJ, Ketcham AS. Sacral resection for control of pelvic tumours. Am J Surg 1992 Apr;163(4):370-4. http://www.ncbi.nlm.nih.gov/pubmed/1373043

3.3.2 ***Radionuclides***

3.3.2.1 Clinical background

Bone metastases are the most frequent source of pain during the evolution of cancers (1). Approximately 30% of patients with osseous metastases have pain that requires analgesia, interfering with QoL, causing anxiety, isolation, immobility, depression, and sleeplessness (1).
In single lesions, bone stability and pain reduction can be achieved by external beam radiotherapy (LE: 1b) (GR: A). About 80-90% of patients will experience durable pain relief, but many will develop further multiple painful metastases (1).

3.3.2.2 Radiopharmaceuticals: physical characteristics

- Strontium-89 chloride (^{89}Sr) emits a beta particle with a maximum energy of 1.46 MeV, a mean energy of 0.58 MeV, an average soft-tissue range of 2.4 mm and 0.01% abundant gamma emission with a 0.91 MeV photopeak. The physical half-life is 50.5 days (2,3).
- Samarium-153 lexidronam (^{153}Sm) emits a beta particle with a maximum energy of 0.81 MeV, a mean energy of 0.23 MeV, an average soft-tissue range of 0.6 mm and 28% abundant 0.103 MeV gamma emission with a 0.103 MeV photopeak. The physical half-life is 1.9 days (4).

- Renium-186 etidronate (^{186}Re) emits a beta particle with a maximum energy of 1.07 MeV, a mean energy of 0.349 MeV, an average soft-tissue range of 1.1 mm and a 9% abundant gamma emission with a 0.137 MeV photopeak. The physical half-life is 3.7 days (5).
- Therapy in this context means the intravenous administration of ^{89}Sr or ^{153}Sm (^{153}Sm ethylenediaminetetramethylenephosphonate [EDTMP]).

The most important radiopharmaceuticals are ^{89}Sr, ^{153}Sm and, to a lesser extent, ^{186}Re. There is no clear difference in treatment response between them (2), but, because of the differences in half-life, there is a difference in onset and duration of response, and in toxicity. For ^{153}Sm and ^{186}Re, the onset of response is rapid but duration is shorter (6,7). Note that ^{186}Re is no longer used in many European countries.

3.3.2.3 Indications and contraindications

^{89}Sr and ^{153}Sm are indicated for the treatment of bone pain resulting from skeletal metastases involving more than one site and associated with an osteoblastic response on bone scan but without spinal cord compression (1,8-15) (LE: 2, GR: B).

^{89}Sr and ^{153}Sm have no place in the management of acute or chronic spinal cord compression or in treating pathological fracture (1,8,11) (LE: 2, GR: B).

Some 60-80% of patients presenting with osteoblastic metastases benefit from ^{89}Sr and/or ^{153}Sm (1) (LE: 2). The choice between the two depends solely on practical considerations. ^{89}Sr and/or ^{153}Sm should be administered by a slow (^{89}Sr) or bolus (^{153}Sm) injection using an intravenous (iv) catheter. The recommended doses are 148 MBq (^{89}Sr) (16) and 37 MBq/kg (^{153}Sm) (1,16) (LE: 2).

About 10% of patients experience a temporary increase in bone pain (pain flare) (3,6,7,17), generally 2-4 days after ^{153}Sm, and 1-2 weeks after ^{89}Sr (acute side-effect) (1,4,8,11,12,15,18). Pain flare is associated with a good clinical response (LE: 2) (3,6,7,17), and sometimes requires a transient increase in analgesia. Pain reduction is unlikely to occur within the first week, and can occur as late as 1 month after injection. Analgesics should therefore be continued until bone pain improves (GR: B). Late side-effects include temporary myelosuppression (platelets, white blood cells). Recovery occurs 4-6 weeks later depending on bone marrow reserve. There is generally no significant effect on haemoglobin.

The patient can pose a radiation exposure risk for 2-4 days after ^{153}Sm, and 7-10 days after ^{89}Sr (4,8,11,13-15,18-23) (LE: 2). Information about radioprotection should be provided (GR: B).
If the pain responds to the initial treatment, administration of ^{153}Sm can be repeated at intervals of 8-12 weeks in the presence of recurrent pain (1,2,23) (LE: 2, GR: B). The response rate for second and subsequent treatments may be lower than for the first (1,8,12,23) (LE: 2).

3.3.2.4 Contraindications

Absolute contraindications:

- During or within 4 weeks of myelotoxic chemotherapy (all compounds except cisplatin), or within 12 weeks of hemibody external radiation therapy. The delay between these treatments and metabolic radiotherapy is necessary to avoid severe haematopoietic toxicity. However, treatment can be safely combined with limited local field external beam radiotherapy (LE: 3, GR: C).
- Known hypersensitivity to EDTMP or similar phosphonate compounds for ^{153}Sm (1).
- Glomerular filtration rate (GFR) < 30 mL/min (1,2).
- Pregnancy; continued breastfeeding (2).

Relative contraindications:

- Not recommended for women of child-bearing age (negative pregnancy test and contraception mandatory).
- In acute or chronic severe renal failure (GFR 30-60 mL/min), the dose administered should be adapted: if the GFR is > 60 mL/min, reduce the normal dosage by 25%; if the GFR is 30-60 mL/min, reduce the normal dosage by 50% (LE: 4). GFR should be measured if creatinine is > 20 mg/L.
- With a single painful lesion: external limited field radiotherapy should be performed (16,24) (LE: 1b).

Caution:

Caution must be used in the following circumstances.

- Risk of fracture.
- Nerve or spinal cord compression that requires other treatments in an emergency: external radiotherapy or surgery, or a combination of the two.
- Urinary incontinence: special recommendations including catheterisation before administration of the radionuclide. The catheter should remain in place for 4 days (^{89}Sr), 3 days (^{186}Re), and 24 hours (^{153}Sm), respectively (2) (GR: A).

- Compromised bone marrow reserve.
- White blood cell count of < 2500/µL (LE: 4) (preferably > 3500/µL according to European Association of Nuclear Medicine guidelines) (2).
- Platelets < 80,000/µL (LE: 4) (preferably > 100,000/µL according to the European Association of Nuclear Medicine guidelines) (2).
- Haemoglobin < 90 g/L (2).

3.3.3 ***Radiotherapy for metastatic bone pain***

3.3.3.1 Clinical background

Radiotherapy alleviates metastatic bone pain in the majority of patients (1) (LE: 1a). Pain relief is obtained in 50-80% of patients, with complete pain relief at the treated site in up to 30% of patients (1,2) (LE: 1a). The onset of pain relief varies from a few days to 4 weeks (1) (LE: 2b). Re-irradiation should therefore not be considered sooner than 4-6 weeks after the initial radiotherapy. The median duration of pain relief reported by most studies is 3-6 months (1) (LE: 1a).

3.3.3.2 Mechanism of pain relief by radiotherapy

Tumour shrinkage and inhibition of the release of chemical pain mediators are the main mechanisms by which radiotherapy relieves pain. Tumour shrinkage is unlikely to account for early pain relief, which is hypothesised to involve early-reacting and sensitive cells, as well as the molecules that they produce. Obvious candidates are the inflammatory cells present in the bone metastasis microenvironment. Reduction of these cells by ionising radiation inhibits the release of chemical pain mediators, and is probably responsible for the rapid reaction seen in some patients. Another possible mechanism for the analgesic action of ionising irradiation includes its direct effect on osteoclast activity (3) (LE: 3).

3.3.3.3 Imaging

The detection of bone metastases is usually based on 99m technetium bone scintigraphy, which lacks diagnostic specificity (11) (LE: 3), but the addition of single photon emission computed tomography (SPECT) to planar acquisition has been reported to improve its diagnostic accuracy (12-14) (LE: 2b). Regions of increased uptake need further investigation. Plain films have a false-negative rate of 10-17% (LE: 3). At least 50% erosion must be present for a change to be seen on plain films (15) (LE: 3). The combination of bone scintigraphy and plain films results in specificity of 64% and sensitivity of 63% (16) (LE: 3).

Because of the complex anatomy of the vertebrae, computed tomography (CT) is more useful than conventional radiography for evaluating the location of lesions and analysing bone destruction and condensation (17). When combined with myelography, excellent information about the bony anatomy and an accurate view of the compressed neural elements is provided (18-19) (LE: 3). However, CT myelography is invasive and time-intensive, and so, particularly when spinal cord compression is suspected, magnetic resonance imaging (MRI) is currently the gold standard for detection and therapeutic management (20-24) (LE: 2b), with sensitivity of 93% (25) (LE: 3) and specificity of 96% (25) (LE: 3).

3.3.3.4 Radiotherapy scheme

Single-fraction radiotherapy is as effective as multifraction radiotherapy in relieving metastatic bone pain (1, 4-8) (LE: 1a). However, the rates of retreatment and pathological fractures are higher after single-fraction radiotherapy (1,9) (LE: 1a).

Single-fraction radiotherapy is the treatment of choice for alleviating bone pain because of its greater convenience for patients (LE: 1a), as well as faster patient turnover for the radiotherapy unit (10) and lower costs (5,11) (LE: 3). The recommended dose is 8 Gy (LE: 1a) (1,4-8,12,13). Pain relief can be achieved in a significant number of patients with lower doses (LE: 1b), but some studies have indicated that 4 Gy is less effective than 8 Gy (1) (LE: 1b). A dose of 6 Gy gives similar results to 8 Gy but has been insufficiently studied (1) (LE: 1b). A dose of 8 Gy in combination with zoledronic acid is associated with a longer period without skeletal events, compared to 6 Gy with zoledronic acid (14).These lower doses should be borne in mind if a third retreatment is necessary, or if there is concern about radiation tolerance (1) (LE: 2b).

In cases of oligometastases (< 5), a case can be made for aggressive therapy, such as radiosurgery or high-dose radiotherapy to improve survival (LE: 3).

3.3.3.5 Spinal cord compression

Metastatic epidural spinal cord compression (MSCC) is a common, severe complication of malignancy. The most common symptom is back pain (83-95%), and weakness is present in 35-75%. The level of neurological function at the start of treatment determines the functional outcome (15). A delay in treatment, surgery or external radiotherapy is the most common cause of an unfavourable outcome. Magnetic resonance imaging is the best tool for diagnosing MSCC (16).

Corticosteroids reduce oedema and might have an oncolytic effect on certain tumours, such as lymphoma, breast cancer and leukaemia. However, the extent of the benefit obtained from corticosteroids and the optimal dosage are unclear. High-dose corticosteroids carry a significant risk of adverse affects. One randomised controlled trial of patients with carcinomatous MSCC has compared radiotherapy with or without dexamethasone, and showed significantly better functional outcome when dexamethasone was added (17) (LE: 1b).

Radiotherapy is generally the treatment of choice. Surgery is reserved for a selected group of patients who meet the criteria listed below.

To date, there is no standard radiotherapy regimen for MSCC. In general, a multifraction regimen (10 × 3 Gy) is preferable in these patients because it allows for a higher dose and thus greater reduction in tumour size. For patients whose chances of survival are estimated to be poor, a short course of radiotherapy is advised (e.g., 1 × 8 Gy (18) or 2 × 8 Gy (19) (LE: 1b). A small randomised trial, including patients with MSCC and a short life-expectancy (≤ 6 months), has compared a short-course (2 × 8 Gy) with a split-course (5 × 3 Gy followed by 3 × 5 Gy) radiotherapy regimen, and has concluded that there were no significant differences in functional outcome or toxicity (19).

Several uncontrolled surgical trials (20-22) and one meta-analysis (23) have indicated that direct decompressive surgery is superior to radiotherapy alone with regard to regaining ambulatory and sphincter function, and obtaining pain relief (LE: 1a). However, the decision to pursue surgery must be tempered by awareness of the attendant significant morbidity and mortality risks. Careful patient selection is of utmost importance; the criteria are shown in Table 3 (LE: 3).

Table 3: Criteria for selecting patients for primary therapy for spinal cord compression

Absolute criteria	**Surgery**	**Radiotherapy**
Operability	Medically operable	Medically inoperable
Duration of paraplegia	< 48 h	≥ 48 h
Life expectancy	> 3 months	< 3 months
Radiosensitivity		Highly sensitive
Relative criteria		
Diagnosis of primary tumour	Unknown	Known
Bone fragments with compression	Present	Absent
Number of foci of compression	1 focus	> 1 foci

A randomised prospective trial has demonstrated that patients treated with a combination of surgery followed by radiotherapy can remain ambulatory longer, and those who are not ambulatory at presentation have a better chance of regaining ambulatory function than those treated with radiotherapy alone (24) (LE: 1b).

3.3.3.6 Pathological fractures

In patients with impending pathological fractures (e.g., femoral lesion with an axial cortical involvement > 30 mm), a prophylactic orthopaedic procedure should be considered (25).

3.3.3.7 Side effects

Side effects are related to the total dose, fractionation size, and the localisation of the metastases. Acute grade 2-4 toxicity is more frequent after multifraction radiotherapy regimens. The incidence of late toxicity is low (9).

The side effects are mostly transient, lasting a few days and include:

1) pain flare (within 24 h and due to oedema). Pain flare is common after palliative radiotherapy for bone metastases, and patients should be counselled accordingly and given breakthrough opioids. Patients receiving single-fraction radiotherapy may be at higher risk than those receiving multifraction radiotherapy (26). A small phase II study has shown that 8 mg dexamethasone is effective for prophylaxis of radiotherapy-induced pain flare after palliative radiotherapy for bone metastases (LE: 3) (27).
2) symptoms depend on the treatment field and location and can include:
   - nausea (especially with larger fields)
   - diarrhoea
   - irritation of the throat and oesophagus.

3.3.4 ***Psychological and adjunctive therapy***

3.3.4.1 Psychological therapies

The perception of pain and the suffering it causes derive from a combination of physical, emotional, spiritual, and social constructs. Psychological assessment and support are an integral and beneficial part of treating pain in cancer patients (1,2). There is evidence that highly emotional cancer patients, as detected through their own narratives, experience less pain than their less emotional counterparts (3).

Depression is the most prevalent psychiatric diagnosis in patients with cancer. Although there is no proof that psychotherapy is useful in non-cancer patients with depression, patients with incurable cancer can take advantage of this type of treatment (4). In this setting, structured psychotherapy seems to be more effective than antidepressant medication (5). Interestingly, effective psychological management results in a reduction in depressive complaints, inflammatory markers, pain, and fatigue in cancer patients (6).

Cognitive behavioural therapy (CBT), such as relaxation and distraction, can provide pain relief (7-9). As expected, protocols tailored to individual patient characteristics can result in higher satisfaction in terms of pain relief, mood improvement and general well-being. The possibility of delivering CBT by home visits, telephone, or through the internet seems promising (10-12). Virtual consultation and automated symptom monitoring for cancer patients with depression can exceed all expectations (13). It has also been suggested that CBT is particularly helpful for younger cancer patients (14).

Families can be exposed to poor functioning during palliative care and bereavement. Family-focused grief therapy based on communication, cohesiveness, conflict resolution, and shared grief is effective in protecting family members against the drama of disease and death (15). Other psychological interventions targeted to minimise caregiver emotional distress have not been effective (16).

3.3.4.2 Adjunctive therapy

A number of therapeutic strategies have been proposed as non-pharmacological adjunctives to medical and surgical procedures. To date, there is no conclusive evidence on the effect of reflexology and massage therapy (1-3). Nevertheless, certain manipulations (e.g., sciatic nerve press) seem to be effective for immediate pain relief in many oncological conditions (4). The notion that acupuncture may be effective for cancer patients is not methodologically supported by the currently available data (5). However, modest although significant improvements in depression and pain scales have been confirmed by well-conducted studies on acupuncture (6). Evidence from robust studies is still lacking on the effect of traditional Chinese medicine and complementary alternative medicine (7,8). Physical exercise (short walks) can positively affect the pain experience of prostate cancer patients (9). Similarly, moderate exercise positively affects cancer-related sleep disturbance (10).

Transcutaneous electrical nerve stimulation might mitigate hyperalgesia in cancer patients. Unfortunately, reliable studies in this field are lacking (11).

Listening to music - an otherwise harmless activity - slightly reduces distress, pain intensity and opioid requirements in cancer patients (12,13).

3.4 Pharmacotherapy

The successful treatment of cancer pain depends on the clinician's ability to assess the presenting problems, identify and evaluate pain syndromes, and formulate a plan for comprehensive continuing care. This requires familiarity with a range of therapeutic options and responsiveness to the changing needs of the patient. The treatment of pain must be part of the broader therapeutic agenda, in which tumour control, symptom palliation (physical and psychological), and functional rehabilitation are addressed concurrently.

3.4.1 ***Antibiotics***

Antibiotics may be analgesic when the source of the pain involves infection (e.g. pyonephrosis, abscess, osteitis pubis). In some cases, infection may be occult and confirmed only by the symptomatic relief provided by empirical treatment with these drugs (1) (LE: 2b).

3.4.2 ***Chemotherapy***

A successful effect on pain is generally related to tumour response. There is a strong clinical impression that tumour shrinkage is generally associated with relief of pain, although there are some reports of analgesic value even in the absence of significant tumour shrinkage (1) (LE: 1a).

3.4.3 ***Bisphosphonates***

Bisphosphonates are pyrophosphate analogues.

3.4.3.1 Mechanisms of action

- Inhibition of bone resorption: beginning 24-48 hours after administration, the target cells are the osteoclasts. There are three different mechanisms of inhibition of bone resorption corresponding to the three generations of bisphosphonates. There are four distinct effects on osteoclasts:
  - reduction of osteoclastic activity;
  - inhibition of osteoclast adhesion;
  - decrease in number of osteoclasts;

- induction of osteoclast apoptosis.
- Inhibition of crystallisation and mineralisation: clinically not relevant.
- Promotion of osteoblastic bone formation and production of osteoclast resorption inhibitor.
- Anti-angiogenic effect and effect on tumour cells.

3.4.3.2 Effects and side-effects

The main effects are:

- decrease of the risk of skeleton-related events, e.g. hormone-refractory prostate cancer with bone metastasis (1) (LE: 1b, GR: A);
- pain response in 60-85% of patients (1-3) (LE: 1b, GR: A).

The main side-effects are:

- flu-like symptoms (20-40%), bone pain, fever, fatigue, arthralgia and myalgia (all < 10%);
- hypocalcaemia (caution: rapid infusion - older patients with vitamin D deficiency);
- acute renal failure (rapid infusion); always check renal function (GFR);
- osteonecrosis of the jaw bones (only after iv therapy);
- gastrointestinal symptoms can occur after oral administration (2-10%).

Some remarks (all grade B recommendations):

- Recognise and treat dehydration before administration of bisphosphonates.
- Reduce the dose in the event of impaired renal function when using zoledronate (4) (LE: 2).
- Avoid simultaneous administration of aminoglycosides (5).
- Perform clinical examination of the patient's mouth and jaws; avoid oral/dental surgery during administration of iv bisphosphonates (6-10) (LE: 2).

3.4.3.3 Denosumab

Histological findings and analysis of bone turnover markers support the view that bone metatases from prostate cancer are characterised by an excess osteoclastic activity inducing bone destruction. This results in an increased risk of skeletal-related events (SREs), such as pathologic fractures, spinal cord compression, pain requiring radiotherapy or surgery, and hypercalcemia. To maintain skeletal integrity and prevent skeletal complications treatment with bisphosphonates are often initiated.

The receptor activator of NF-kB ligand (RANKL), mediates the formation, function, and survival of osteoclasts.

It is hypothesised that through RANKL, tumor cells induce osteoclast activation, which then mediates bone resorption and releases growth factors, resulting in a cycle of bone destruction and tumor proliferation. Denosumab is a fully human monoclonal antibody that specifically binds and neutralises RANKL, inhibiting osteoclastogenesis and decreasing osteoclastmediated bone destruction (11). Improvement in bone metastases free survival (4.2 months) and increased time to first bone metastasis (3.7 months) has been reported with denosumab in a phase III randomised placebo controled trial (12).

Another recently published phase 3 study, randomised men with castration-resistant prostate cancer and no previous exposure to iv bisphosphonate between 120 mg subcutaneous denosumab plus iv placebo, or 4 mg iv zoledronic acid plus subcutaneous placebo, every 4 weeks until the primary analysis cutoff date. Denosumab significantly delayed the time to first onstudy skeletal-related event by 18% compared with zoledronic acid, with a between-group difference of 3-6 months (13). Occurrences of adverse events and serious adverse events were similar between groups. More events of hypocalcaemia occurred in the denosumab group (121 [13%]) than in the zoledronic acid group (55 [6%]; p<0·0001). Osteonecrosis of the jaw was infrequent in both groups. The authors concluded that denosumab was better than zoledronic acid for prevention of skeletal-related events, and potentially represents a novel treatment option in men with bone metastases from castration-resistant prostate cancer (13). However, data on QoL are lacking.

A small randomised phase II trial evaluated the effect of denosumab after iv bispfhosphonates (14). However, actually there are insufficient data to support a routine switch from iv bisphosphonates to denosumab.

*3.4.4 **Systemic analgesic pharmacotherapy - the analgesic ladder***

Analgesic pharmacotherapy is the mainstay of cancer pain management (1-3). Although concurrent use of other interventions is valuable in many patients, and essential in some, analgesic drugs are needed in almost every case. Based on clinical convention, analgesic drugs can be separated into three groups:

- non-opioid analgesics
- opioid analgesics
- adjuvant analgesics.

Emphasising that pain intensity should be the prime consideration (LE: 1a), the WHO has proposed a three-step approach to analgesic selection for cancer pain (1,3). Known as the analgesic ladder, when combined with appropriate dosing guidelines it can provide adequate relief in 70-90% of patients (4,5).

- **Step 1: non-opioid analgesic** Patients with mild to moderate cancer-related pain should be treated with a non-opioid analgesic.
- **Step 2: non-opioid analgesic + weak opioid** Patients who present with moderate to severe pain or who fail to achieve adequate relief after a trial of a non-opioid analgesia should be treated with a weak opioid (e.g. codeine or tramadol), typically by using a combination product containing a non-opioid (e.g. aspirin or paracetamol) and an opioid (e.g. codeine, tramadol or propoxyphene).
- **Step 3: non-opioid analgesic + strong opioid** Patients who present with severe pain or who fail to achieve adequate relief with step 2 drugs, should receive a strong opioid (e.g. morphine, fentanyl, oxycodone, methadon, buprenorphine, or hydromorphone).

3.4.4.1 Non-opioid analgesics

- Non-opioid analgesics are aspirin, paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs).
- Can be useful alone for mild to moderate pain (step 1 of the analgesic ladder).
- May be combined with opioids.
- Have a ceiling effect of analgesic efficacy.
- No tolerance or physical dependence.
- Inhibit the enzyme cyclo-oxygenase and block the synthesis of prostaglandins.
- Involvement of central mechanisms is also likely in paracetamol analgesia (6).
- Potential adverse effects (7): bleeding diathesis due to inhibition of platelet aggregation, gastroduodenopathy (including peptic ulcer disease) and renal impairment are the most common; less common adverse effects include confusion, precipitation of cardiac failure and exacerbation of hypertension. Particular caution must be used in elderly patients and those with blood-clotting disorders, predisposition to peptic ulceration, impaired renal function and concurrent corticosteroid therapy.
- Non-acetylated salicylates (choline magnesium trisalicylate and salsalate) are preferred in patients who have a predilection to bleeding; these drugs have less effect on platelet aggregation and no effect on bleeding time at the usual clinical doses.
- Rarely, paracetamol produces gastrointestinal toxicity, but with no adverse effect on platelet function. Hepatic toxicity is possible, however, and patients with chronic alcoholism and liver disease can develop severe hepatotoxicity at the usual therapeutic doses (8).

3.4.4.2 Opioid analgesics

Cancer pain of moderate or severe intensity should generally be treated with a systemically administered opioid analgesic (9). Classification is based on interaction with the various receptor subtypes:

- Agonist: most commonly used in clinical pain management, no ceiling effect.
- Agonist-antagonist (pentazocine, nalbuphine and butorphanol): ceiling effect for analgesia.

By convention, the relative potency of each of the commonly used opioids is based on a comparison with 10 mg of parenteral morphine. Equi-analgesic dose information provides guidelines for dose selection when the drug or route of administration is changed (10).

A trial of systemic opioid therapy should be administered to all cancer patients with moderate or severe pain (10-13). Patients who present with severe pain should be treated with a strong opioid from the outset. Patients with moderate pain are commonly treated with a combination drug containing paracetamol or aspirin plus codeine, tramadol, or propoxyphene, the dose of which can be increased until the maximum dose of the non-opioid co-analgesia is attained (e.g. 4000 mg paracetamol).

Factors to consider when selecting an opioid include:

- pain intensity
- patient age
- response to previous trials of opioid therapy
- co-existing disease
- influence of underlying illness, characteristics of the opioid and concurrent medications.

Routes of administration

Opioids should be administered by the least invasive and safest route that can provide adequate analgesia. In a survey of patients with advanced cancer, more than half required two or more routes of administration prior to death, and almost a quarter required three or more.

Non-invasive routes

- **Oral** routes are the preferred approach in routine practice. Alternative routes are necessary for patients who have impaired swallowing, gastrointestinal dysfunction, require a very rapid onset of analgesia, or cannot tolerate the oral route.
- **Rectal** suppositories containing oxycodone, hydromorphone, oxycodone and morphine in combination are available, and controlled-release morphine tablets can also be administered per rectum. The potency of rectally administered opioids is believed to approximate to oral dosing (14).
- **Transdermal** routes: fentanyl and buprenorphine have been demonstrated to be effective in postoperative and cancer pain (15). The fentanyl transdermal therapeutic system dosing interval is usually 72 h, but some patients require a 48 h schedule. There is some interindividual variability in fentanyl bioavailability by this route, which, combined with large differences in elimination pharmacokinetics, necessitates dose titration in most cases (16). The efficacy of transdermal fentanyl

is equal to morphine. The incidence of side-effects such as sedation and constipation are lower than for morphine (17,18) (LE: 1b).

- Transdermal patches able to deliver 12,25,50,75 and 100 mg/h are available. Multiple patches can be used simultaneously for patients who require higher doses. Current limitations of the transdermal delivery system include costs, and the need for an alternative short-acting opioid for breakthrough pain.
- Recently, buprenorphine has become available for transdermal administration. A high affinity partial μ-opioid agonist, it is in clinical use for the treatment of acute and chronic pain (19). Its analgesic effect is comparable with that of other opioids, and it shows no relevant analgesic ceiling effect throughout the therapeutic dose range (20). Unlike full μ-opioid agonists, buprenorphine's physiological and subjective effects, including respiratory depression and euphoria, reach a plateau at higher doses. This ceiling may limit the abuse potential, and might result in a wider safety margin (21).

- **Sublingual** absorption of any opioid is potentially clinically beneficial, but bioavailability is very poor with drugs that are not highly lipophilic, so the chances of an adequate response are low (22). Sublingual buprenorphine, a relatively lipophilic partial agonist, can provide adequate relief for mild to moderate cancer pain. Overall, this route has limited value due to the lack of formulations, poor absorption of most drugs, and the inability to deliver high doses or prevent swallowing of the dose. An oral transmucosal formulation of fentanyl (incorporated into a sugar base) is useful for the rapid relief of breakthrough pain (23,24). Fentanyl delivered by this means is more effective than oral morphine at relieving pain (LE: 2).

Recommendation	GR
Oral transmucosal administration of fentanyl should be used to provide rapid relief of breakthrough pain. The starting dose is 400 μg, or 200 μg in the elderly and those with a history of opioid sensitivity or underlying pulmonary disease.	B

Invasive routes

For patients undergoing a trial of systemic drug administration, a parenteral route must be considered when the oral route is not available. Repeated parenteral bolus injections, which can be administered iv, intramuscularly (im) or subcutaneously (sc), may be useful in some patients, but are often compromised by the occurrence of prominent bolus effects (toxicity at peak concentration and/or pain breakthrough at the trough). Repeated im injections are common, but are painful and offer no pharmacokinetic benefit; their use is not recommended (25).

- **Intravenous bolus** administration provides the most rapid onset and shortest duration of action. Time to peak effect correlates with the lipid solubility of the opioid, and ranges from 2-5 minutes for methadone, to 10-15 minutes for morphine (26). This approach is appropriate in two settings:
  - To provide parenteral opioids, usually transiently, to patients who already have venous access and are unable to tolerate oral opioids.
  - To treat very severe pain, for which iv doses can be repeated at an interval as brief as that determined by the time to peak effect until adequate relief is achieved.
- **Continuous parenteral infusions** is mainly used in patients who are unable to swallow, absorb opioids or otherwise tolerate the oral route, but is also employed in patients whose high opioid requirement renders oral treatment impractical (27). Long-term infusions can be administered iv or sc.
  - Ambulatory patients can easily receive a continuous sc infusion using a 27-gauge butterfly needle, which can be left in place for up to a week. A recent study demonstrated that the bioavailability of hydromorphone by this route is 78% (28), and clinical experience suggests that dosing can be identical to that for continuous iv infusion. A range of pumps is available to provide patient-controlled rescue doses (supplemental doses offered on an as-needed basis to treat pain that breaks through the regular schedule) as an adjunct to continuous basal infusion.
  - Opioids suitable for continuous sc infusion must be soluble, well absorbed and non-irritant. Extensive experience has been reported with hydromorphone, oxycodone and morphine (29). Methadone appears to be relatively irritating and is not preferred (30). To maintain the comfort of an infusion site, the sc infusion rate should not exceed 5 cc/h.
  - The infraclavicular and anterior chest sites provide the greatest freedom of movement for patients, but other sites can be used. A single infusion site can usually be maintained for 5-7 days.

Changing the route of administration

Switching between oral and parenteral routes should be guided by a knowledge of relative potency to avoid subsequent over- or underdosing. In calculating the equi-analgesic dose, the potencies of the iv, sc and im routes are considered equivalent. Perform changes slowly in steps, e.g. gradually reducing the parenteral dose and increasing the oral dose over a 2-3 day period (LE: 3).

Dosing

- **Around-the-clock dosing** Patients with continuous or frequent pain generally benefit from scheduled around-the-clock dosing, which provides continuous relief by preventing recurrence of the pain. This approach should be used only in patients with no previous opioid exposure. Patients should also be provided with a rescue dose. This combination offers gradual, safe and rational dose escalation that is applicable to all routes of opioid administration.
- **Controlled-release drug formulations** These preparations of oral opioids can lessen the inconvenience of around-the-clock administration of drugs with a short duration of action. Numerous studies have demonstrated the safety and efficacy of these preparations in cancer patients with pain (31,32).
- **As-needed (prn) dosing** This strategy is beneficial if rapid dose escalation is necessary or when beginning therapy with opioids with a long half-life (e.g. methadone or levorphanol). As-needed dosing may also be appropriate for patients who have rapidly decreasing analgesic requirements, or intermittent pains separated by pain-free intervals.
- **Patient-controlled analgesia (PCA)** This is a technique of parenteral drug administration in which the patient controls an infusion device that delivers a bolus of analgesic drug on demand according to parameters set by the physician. Long-term PCA in cancer patients is most commonly sc using an ambulatory infusion device. PCA is usually added to a basal infusion rate and acts, in effect, as a rescue dose.

Adverse effects and their management

- **Tolerance** There is great variation in the opioid dose required to manage pain (400-2000 mg of im morphine per 24 hours) (33). The induction of true analgesic tolerance that could compromise the utility of treatment can only be said to occur if a patient manifests the need for increasing opioid doses in the absence of other factors (e.g. progressive disease) that would be capable of explaining the increase in pain. Extensive clinical experience suggests that most patients who require dose escalation to manage increasing pain do have demonstrable disease progression (34). This suggests that true pharmacological tolerance to the analgesic effects of opioids is not a common clinical problem, and has two important implications:
  - Concern about tolerance should not impede the use of opioids early in the course of the disease.
  - Worsening pain in patients receiving a stable dose of opioids should not be attributed to tolerance, but be assessed as evidence of disease progression or, less commonly, increasing psychological distress.
- **Adverse drug interactions** There is potential for cumulative side-effects and serious toxicity to arise from combinations of drugs. The sedative effect of an opioid may add to that of other centrally acting drugs, such as anxiolytics, neuroleptics and antidepressants. Likewise, constipation produced by opioids is probably worsened by anticholinergic drugs.
- **Respiratory depression** This is the most serious adverse effect of opioid therapy, which can impair all phases of respiratory activity (rate, minute volume and tidal exchange). Clinically significant respiratory depression is always accompanied by other signs of central nervous system depression, including sedation and mental clouding. Repeated administration of opioid drugs appears to produce a rapid tolerance to their respiratory depressant effects, however, so these drugs can be used in the management of chronic cancer pain without significant risk of respiratory depression. When this does occur in patients on chronic opioid therapy, administration of the specific opioid antagonist naloxone usually improves ventilation.
- **Sedation** Tolerance to this effect usually develops within a period of days to weeks. Patients should be warned about it, to reduce anxiety and discourage activities that could be dangerous if sedation occurs (e.g. driving). Some patients have a persistent problem with sedation, particularly if other sedating drugs are also being taken or if there is co-morbidity such as dementia, metabolic encephalopathy or brain metastases.
- **Confusion and delirium** Confusion is a greatly feared effect of opioid drugs, and mild cognitive impairment is common (35). However, similar to sedation, pure opioid-induced encephalopathy appears to be transient in most patients, persisting from days to 1-2 weeks. Although persistent

confusion attributable to opioids alone does occur, it is usually related to the combined effect of the opioid and other factors, including electrolyte disorders, neoplastic involvement of the central nervous system, sepsis, vital organ failure and hypoxaemia (36). A stepwise approach to management often culminates in a trial of a neuroleptic drug. Haloperidol in low doses (0.5-1.0 mg orally or 0.25-0.5 mg iv or im) is most commonly recommended because of its efficacy and low incidence of cardiovascular and anticholinergic effects.

- **Constipation** This is the most common adverse effect of chronic opioid therapy (37-39), and laxative medication should be prescribed prophylactically. There are no controlled comparisons of the performance of the various laxatives in opioid-induced constipation. Combination therapy is frequently used, particularly co-administration of a softening agent (e.g. docusate) and a cathartic (e.g. senna, bisocodyl or phenolphthalein). The doses should be increased as necessary, and an osmotic laxative (e.g. magnesium sulphate) should be added if required. Chronic lactulose therapy is an alternative that some patients prefer, and the occasional patient is managed with intermittent colonic lavage using an oral bowel preparation.
- **Nausea and vomiting** Opioids may produce nausea and vomiting via both central and peripheral mechanisms. These drugs stimulate the medullary chemoreceptor trigger zone, increase vestibular sensitivity, and affect the gastrointestinal tract (increased gastric antral tone, diminished motility, delayed gastric emptying). The incidence of nausea and vomiting in ambulatory patients is estimated to be 10-40%, and 15-40%, respectively (40), with the effects greatest at the start of therapy. Metoclopramide is the most reasonable initial treatment. Tolerance typically develops within weeks. Routine prophylactic administration of an anti-emetic is not necessary. Serotonin antagonists (e.g. ondansetron) are not likely to be effective with opioid-induced symptoms as they do not eliminate apomorphine-induced vomiting and motion sickness, which appear to be appropriate models for opioid effects. Clinical trials are needed to confirm this.
- **Addiction and dependence** Confusion about physical dependence and addiction augments the fear of opioids and contributes substantially to the undertreatment of pain (41). Patients with chronic cancer pain have a so-called therapeutic dependence on their analgesic pharmacotherapy, which may or may not be associated with the development of physical dependence, but is seldom associated with addiction. The medical use of opioids is rarely associated with the development of addiction (42). There are no prospective studies in patients with chronic cancer pain, but extensive clinical experience affirms the low risk of addiction in this population (LE: 3). Healthcare providers, patients and families often require vigorous and repeated reassurance that the risk of addiction is small.

Adjuvant analgesics

Defined as a drug that has a primary indication other than pain but is analgesic in some conditions, these drugs may be combined with primary analgesics on any of the three steps of the analgesic ladder to improve the outcome for patients who cannot otherwise attain an acceptable balance between relief and side-effects. In the management of cancer pain, adjuvant analgesics are conventionally categorised as follows.

- **Corticosteroids** Widely used as adjuvant analgesics (43,44), this group has been demonstrated to have analgesic effects, to improve QoL significantly (45), and to have beneficial effects on appetite, nausea, mood and malaise in patients with cancer (46). The mechanism of analgesia may involve anti-oedemic and anti-inflammatory effects, plus a direct influence on the electrical activity in damaged nerves. (i.e. reduction of neuropathic pain). Patients with advanced cancer who experience pain and other symptoms may respond favourably to a relatively small dose of corticosteroids (e.g. dexamethasone 1-2 mg twice daily) (LE: 2a).
- **Benzodiazepines** These drugs have a small analgesic effect (47), and must be balanced by the potential for side-effects, including sedation and confusion. Benzodiazepines are generally used only if another indication exists, such as anxiety or insomnia (LE: 2b).

3.4.5 ***Treatment of neuropathic pain***

Numerous options are available for relieving neuropathic pain, including opioids, which give patients significant pain reduction with greater satisfaction than antidepressants (1,2). However, the potential complications of opioids mean that they are not always a satisfactory option (3). Beside opioids, effective therapies for managing neuropathic pain include antidepressants, anticonvulsants, topical treatments (lidocaine patch, capsaicin), N-methyl-D-aspartate (NMDA) receptor antagonists, baclofen, local anaesthetics, and clonidine (4,5).

3.4.5.1 Antidepressants

There is clear evidence for the effectiveness of antidepressants in the treatment of neuropathic pain (5), which work primarily via interaction with pathways running through the spinal cord from serotoninergic and noradrenergic structures in the brain stem and mid-brain.

Tricyclic antidepressants (TCAs) such as amitriptyline, nortriptyline (metabolite of amitriptyline), imipramine, and desipramine (metabolite of imipramine) are often the first drugs selected to alleviate neuropathic pain (6,7) (LE: 1a). The mechanism of action is predominantly by blocking the reuptake of norepinephrine and serotonin (dual acting), together with a blockade of neuronal membrane ion channels (reducing neuronal influx of Ca2+ or Na+), and interaction with adenosine and NMDA receptors. However, treatment with these analgesics may be compromised (and outweighed) by their side-effects. TCAs must be used cautiously in patients with a history of cardiovascular disorders, glaucoma, and urine retention. In addition, combination therapy with monoamine-oxidase inhibitors could result in the development of serotonin syndrome.

Duloxetine enhances both serotonin and norepinephrine function in descending modulatory pathways. It has weak affinity for the dopamine transporter and insignificant affinity for several neurotransmitters, including muscarinic, histamine, glutamate, and gamma-aminobutyric acid (GABA) receptors. Duloxetine has demonstrated a significant pain-relieving effect with a generally favourable side-effect profile in painful diabetic neuropathy (7) (LE: 1b).

Selective serotonin reuptake inhibitors (SSRIs) - sertraline, paroxetine, fluoxetine and citalopram - selectively inhibit the reuptake of serotonin. These antidepressants have a more favourable side-effect profile than TCAs, but their effectiveness in neuropathic pain is disputed in the literature (second-line pharmacological treatment).

Recommendations	GR
Amitriptyline and nortriptyline are the first line treatment for neuropathic pain; nortriptyline has fewer side-effects.	A
TCAs must be used cautiously in patients with a history of cardiovascular disorders, glaucoma, and urine retention.	
Duloxetine is the first-line treatment for neuropathic pain due to diabetic polyneuropathy.	A
Duloxetine may be tried as an analgesic in other neuropathic pain syndromes.	GCP

GCP = good clinical practice.

3.4.5.2 Anticonvulsant medication

The rationale for the use of anti-epileptic drugs in treating neuropathic pain is the reduction of neuronal hyperexcitability, one of the key processes in the development and maintenance of neuropathic pain (8). Different anticonvulsants have demonstrated pain relief by a blockade of neuronal membrane ion channels (reducing neuronal influx of Ca2+ or Na+), and effects on neurotransmitters (enhancement of GABA, inhibition of glutamate release) and/or neuromodulation systems (blocking the NMDA receptor) (9,10). Carbamazepine and phenytoin were initially used for the treatment of trigeminus neuralgia. Although both drugs reduce neuropathic pain, their attendant side-effects and complicated pharmacokinetic profile limit their use.

Despite the introduction of newer anticonvulsants with better side-effect profiles, carbamazepine remains the drug of choice for treating trigeminus neuralgia (11) (LE: 1a). However, oxcarbazepine (10-keto analogue of carbamazepine), a new anticonvulsant with a similar mechanism of action to that of carbamazepine but with a better side-effect profile, may replace carbamazepine for this (12).

Gabapentin and pregabalin are first-line treatments for neuropathic pain (reducing elements of central sensitisation), especially in post-zoster neuralgia and diabetic polyneuropathy (13-15) (LE: 1a). The combination of gabapentin with opioids seems to display synergistic effects in relieving neuropathic pain (16,17). Gabapentin has a favourable safety profile with minimal concern for drug interactions and no interference with hepatic enzymes. However, renal failure results in higher gabapentin concentrations and a longer elimination half-life, making dose adjustments necessary. Pregabalin (3-isobutyl GABA) is a structural analogue of gabapentin, but shows greater analgesic activity in rodent models of neuropathic pain than did gabapentin (18). Recent studies confirm the effectiveness of pregabalin in peripheral (including post-herpetic neuralgia and diabetic polyneuropathy) and central neuropathic pain (19).

Recommendation	GR
Gabapentin and pregabalin are first line treatments for neuropathic pain, especially if tricyclic antidepressants are contraindicated.	A

3.4.5.3 Topical analgesics

Neuropathic pain syndromes are typically associated with touch-evoked allodynia and hyperalgesia that impair patients' QoL. As well as treatment with anticonvulsants and antidepressants, a topical drug can be effective in treating ongoing pain and allodynia, supporting the idea that peripheral actions are of key importance in the initiation and maintenance of neuropathic pain.

Topical treatments for neuropathic pain include the 5% lidocaine patch, and capsaicin. The 5% lidocaine patch, a targeted peripheral analgesic, is effective in the treatment of post-herpetic neuralgia and a variety of other focal peripheral neuropathies (20,21) (first-line pharmacological treatment; LE: 1b). Once a day, up to three patches are applied to the painful skin, covering as much of the affected area as possible.

Capsaicin causes pain due to release of substance P from the nociceptive terminals, initiating nociceptive firing. An analgesic response follows because prolonged exposure to capsaicin desensitises the nociceptive terminals and elevates the pain threshold. Capsaicin (third-line pharmacological treatment) reduces pain in a variety of neuropathic pain conditions (including post-herpetic neuralgia, diabetic neuropathy and painful polyneuropathy). It is applied in a 0.075% concentration (22) (LE: 3).

Recommendations	GR
Topical lidocaine 5% should be used as an adjuvant in patients suffering from post-herpetic neuralgia.	A
Transdermal capsaicin may be used as an adjuvant in patients with neuropathic pain.	C

3.4.5.4 NMDA receptor antagonists

Within the dorsal horn, ionotropic glutamate receptors (NMDA, ⟨-amino-3-hydroxyl-5-methyl-4-

isoxazolepropionate [AMPA], kainate) and metabotropic glutamate receptors are all involved in neuropathic pain (23). However, the actions of excitatory amino acids (glutamate) on the NMDA receptor is considered a pivotal event in the phenomenon of wind-up and neuronal hyperexcitability (enhancement and prolongation of sensory transmission) that eventually leads to allodynia, and primary and secondary hyperalgesia.

Subanaesthetic doses of ketamine, and its active enantiomer S(+)-ketamine, given parenterally, neuraxially, nasally, transdermally or orally, alleviate pain post-operatively and in a variety of neuropathic pain syndromes, including central pain (24) (LE: 2b). However, ketamine may result in unwanted changes in mood, conscious perception, and intellectual performance, as well as psychomimetic side-effects (including visual and auditory hallucinations, dissociation and nightmares), limiting its use for neuropathic pain (25). It must therefore be reserved as a third-line option for when other standard analgesic treatments are exhausted (26,27).

Low dose systemic ketamine's primary role (bolus 0,25 mg/kg followed by a continuous administration between 0.1 - 0.4 mg/kg/h) is as an anti-hyperalgesic, anti-allodynic, or tolerance-protective compound in patients with severe acute pain, chronic or neuropathic pain, opioid tolerance, or those at risk for developing chronic post surgical pain (following laparotomy, thoractomy, breast surgery, and nephrectomy) (28,29).

In the acute setting ketamine is effective as a rescue analgesic (0.25 mg/kg, iv) for acute pain that is not, or poorly, responsive to opioids (30).

Despite improved and prolonged analgesia following caudal administration of ketamine in paediatric anaesthesia, there remains a controversy in the preclinical (animal) and clinical literature as to the safety and justifiability of this compound for neuraxial administration. In a case report as well as in an animal study, severe histological abnormalities indicating neurotoxicity were observed following neuraxial administration of ketamine (31,32).

Recommendation	**GR**
Ketamine is effective as an analgesic in neuropathic pain, but may be responsible for severe life-threatening side-effects and should be reserved for specialised pain clinics and as a last resort (third-line treatment).	B

3.4.5.5 Other drug treatments

Baclofen, a muscle relaxant, is analgesic due to its agonistic effect on the inhibitory GABAB receptors. Baclofen is efficacious in patients with trigeminal neuralgia, but not in those with other neuropathic pain conditions (33). However, this analgesic also has antispasticity properties and may induce analgesia by relieving muscle spasms, a frequent accompaniment of acute neuropathic pain. Baclofen can be considered a second-line agent for trigeminus neuralgia, or a third-line agent in neuropathic pain syndromes (LE: 3).

Clonidine, an α2-adrenoreceptor agonist, is available as a patch for transdermal administration and has been used in neuropathic pain states. When used topically, it seems to enhance the release of endogenous encephalin-like substances, but its use in the treatment of neuropathic pain is focused on intrathecal or epidural administration in combination with opioids and/or local anaesthetics. This delivery improves pain control because of a possible supra-additive effect during neuropathic pain treatment (34) (LE: 2b).

Summary: treatment of neuropathic pain

- **First-line agent:**
  - nortirptylinepregabalin, gabapentin;
  - duloxetine (first-line treatment in diabetic polyneuropathy only);
  - lidocaine 5% patch (first-line treatment in post-herpetic neuralgia only).
- **Second-line agent:**
  - opioids/tramadol (first-line treatment in patients with neuropathic cancer pain only).
- **Third-line agent:**
  - baclofen;
  - transdermal capsaicin 0.075%;
  - ketamine (an anaesthetic).

3.4.5.6 Invasive analgesic techniques

Studies suggest that 10-30% of patients with cancer pain do not achieve a satisfactory balance between relief and side-effects using systemic pharmacotherapy alone without unacceptable drug toxicity (35,36). Anaesthetic and neurosurgical techniques may reduce the need for systemically administered opioids, while achieving relief.

Peripheral nerve catheterisation in the management of cancer pain

Tumour infiltration or compression of a peripheral nerve or plexus can result in severe neuropathic pain resistant to pharmacological treatment. In these patients invasive analgesic techniques may be emphasised (37,38).

Recommendation	GR
Reversible regional anaesthetic techniques must be considered for the management of neuropathic pain.	GCP

GCP = good clinical practice.

Neurolytic blocks to control visceral cancer pain

Visceral cancer pain is mainly treated with NSAIDs and opioids, but neurolytic blockade can be used to optimise palliative treatment for cancer in the viscera.

Different neurolytic blockades have been described (39,40). A coeliac plexus block is indicated to treat pain secondary to malignancies of the retroperitoneum or upper abdomen (distal part of the stomach, pancreas, liver, gall bladder) (41) (LE: 1b). A superior hypogastric plexus block has proven utility for pelvic pain (rectum, vaginal fundus, bladder, prostate, testes, seminal vesicles, uterus and ovaries) due to a neoplasm that is refractory to pharmacological treatment (LE: 3) (42-44).

Neuraxial administration of opioids

The delivery of low-dose opioids near the sites of action in the spinal cord may decrease supraspinally mediated adverse effects. Compared with neuroablative therapies, spinal opioids have the advantage of preserving sensation, strength and sympathetic function (45,46). Contraindications include bleeding diathesis, profound leucopenia and sepsis. A temporary trial of spinal opioid therapy should be performed to assess the potential benefits of this approach before implantation of a permanent catheter.

The addition of a low concentration of a local anaesthetic, such as 0.125-0.25% (levo)bupivacaine, to an epidural/intrathecal opioid increases the analgesic effect without increasing toxicity (47,48). The potential morbidity of these procedures requires well-trained clinicians and long-term monitoring (LE: 2).

Recommendation	GR
Continuous intrathecal or epidural administration of morphine may be considered in patients with inadequate pain relief despite escalating doses with sequential strong opioids, or the development of side-effects (nausea, vomiting, constipation, drowsiness, sedation) limiting further dose increase.	B

Chemical rhizotomy

Chemical rhizotomy, produced by the instillation of a neurolytic solution into the epidural or intrathecal space, can be an effective method of pain control for patients with otherwise refractory localised pain syndromes (49,50). The technique is most commonly used in chest-wall pain due to tumour invasion of somatic and neural structures. Other indications include refractory upper limb, lower limb, pelvic or perineal pain (lower end block).

Because of the significant risk of increased disability through weakness, sphincter incompetence and loss of positional sense, chemical rhizotomy of lumbosacral nerve roots is best reserved for patients with limited function and pre-existing urinary diversion. Adverse effects can be related to the injection technique (spinal headache, mechanical neural damage, infection and arachnoiditis) or to the destruction of nonnociceptive nerve fibres (51) (LE: 4).

Recommendation	GR
Lower end block may be considered in patients with intractable perineal pain (bladder, rectum) that has responded insufficiently to more conservative therapy. This technique may only be performed in patients with loss of sphincter function (rectum and/or bladder).	C

Cordotomy

During cordotomy, the anterolateral spinothalamic tract is sectioned to produce contralateral loss of pain and temperature sensitivity. The patient with severe unilateral pain arising in the torso or lower extremity is most likely to benefit from this procedure. The percutaneous technique is generally preferred. Significant pain relief is achieved in more than 90% of patients during the period immediately following cordotomy (52). Of surviving patients, 50% have recurrent pain after 1 year. Repeated cordotomy can sometimes be effective. The neurological complications of cordotomy include paresis, ataxia and bladder dysfunction (53) (LE: 3).

3.5 Quality of life

It seems beyond question that systematic assessment and objective pain evaluation can be of help for pain control in cancer patients (1-3). There is also proof of the strong relationship between pain, anxiety and depression, and health-related QoL in cancer patients (4,5). Anxiety is a common symptom in patients near the end of life. There is currently insufficient evidence on the role of drugs for treatment of anxiety associated with terminal illness, and it is therefore not possible to draw any conclusions about the effectiveness of

pharmacotherapy in this setting (6).

Cancer-related fatigue (CRF) is a significant problem. It can occur because of the side effects of treatment or the disease itself, and can have a significant impact on a person's ability to function. The causes of fatigue are not fully understood and so it is difficult to treat it appropriately. Trials of erythropoietin and darbopoetin (for anaemic patients on chemotherapy) and psychostimulants (amphetamines) provide evidence for improvement in CRF at a clinically meaningful level. There are no data to support the use of paroxetine or progestational steroids for the treatment of CRF. Methylphenidate is an obvious candidate for a large CRF study (7).

The proportion of people surviving and living with cancer is growing, which has led to increased awareness of the importance of QoL, including sexual function, to people with cancer. Sexual dysfunction is a potential long-term complication of cancer treatment. Following treatment for prostate cancer, there is evidence that transurethral alprostadil and vacuum constriction devices reduce sexual dysfunction, although negative effects are common. Vaginal lubricating creams are also effective, as are PDE5 inhibitors for sexual dysfunction secondary to prostate cancer treatment (8). Psychological **interventions** focused on **sexual dysfunction following cancer** can be considered as moderately effective (9).

Chronic constipation can be a serious problem for cancer patients taking opioids. In this setting, lactulose seems more effective than polyethylene glycol (10).

Palliative care / physical-psychological support / quality of life
Palliative care includes pain management as well as functional, psychosocial and spiritual support. Medical, psychological, physical, social, hospicial, and pastoral interdisciplinary services could be helpful at the end of life (11). Patients facing advance stages of prostate cancer frequently experience 'total pain', a mix of physical, psychological, spiritual and social suffering (12). Information about the illness and the process of care has been proved to reduce distress (13,14). Treatment should include both psychological and somatic symptoms (12). Moderate exercise seems to provide a certain benefit in the treatment of fatigue (15,16). Family caregivers and support groups are crucial components of the patient support system (11). Members of prostate cancer self-help groups provide each other with various types of help, usually nonprofessional and nonmaterial, for a particular shared, usually burdensome, characteristic (14). The help may take the form of providing and evaluating relevant information, relating personal experiences, listening to and accepting others' experiences, providing sympathetic understanding and establishing social networks. A supporting self-help group may also work to inform the public or engage in advocacy. All efforts aimed the improvement of the QoL (14).

3.6 Conclusions

The goal of analgesic therapy in cancer patients is to optimise analgesia with the minimum of side-effects. Current techniques can provide adequate relief for the large majority of patients. Most will need ongoing analgesic therapy, and requirements often change as the disease progresses. Patients with refractory pain should have access to specialists in pain management or palliative medicine who can provide an integrated multidisciplinary approach.

4. PAIN MANAGEMENT IN UROLOGICAL CANCERS

4.1 Pain management in prostate cancer patients

*4.1.1 **Clinical presentation***

Pain in both early and advanced prostate cancer (PCa) can be caused directly by the cancer (77%), be related to the treatment (19%), or be unrelated to either (3%) (1). Management must focus on symptomatic patients with locally advanced disease or metastases.

The overall incidence of chronic pain in PCa patients is about 30-50%, but as patients enter the terminal phase this rises to 90% (2). Pain may be directly attributable to tumour infiltration of and growth in three main areas: bone, nerve or a hollow viscus.

*4.1.2 **Pain due to local impairment***

4.1.2.1 Invasion of soft tissue or a hollow viscus

Pain caused by invasion of a hollow viscus is treated with surgery or minimally invasive procedures (e.g. catheter, stent or nephrostomy tube).

4.1.2.2 Bladder outlet obstruction

Continuous growth of the prostate can lead to an outlet obstruction. Lower urinary tract symptoms (LUTS) can occur, especially stranguria and an inability to void. Acute pain requires prompt relief. The best method is to insert a suprapubic catheter and treat the tumour according to the stage (3). If the outlet obstruction persists

transurethral palliative resection (TURP) is an option if no curative therapy can be offered.

4.1.2.3 Ureteric obstruction

Ureteric obstruction is most frequently caused by tumour compression or infiltration within the true pelvis (4-7). Less commonly, obstruction can be more proximal, associated with retroperitoneal metastases. In most cases, obstruction is primarily asymmetrical. Untreated progressive ureteric obstruction results in bilateral hydronephrosis and subsequent renal failure. It is good practice to drain symptomatic hydronephrosis at once, and to drain only one kidney (the less dilated and better appearing kidney or the one with the better function if known) in asymptomatic patients. A nephrostomy tube is superior to a double-J stent for drainage because the subsequent routine endoscopic replacement of the stent could be increasingly difficult in a continuously growing prostate gland, and a nephrostomy tube can be changed without anaesthesia.

4.1.2.4 Lymphoedema

Patients with a huge prostate mass and/or lymph node metastases in the pelvis frequently get lymphoedema of the legs. Physiatric techniques such as wraps, pressure stockings and pneumatic pumps can improve function and relieve pain and heaviness.

4.1.2.5 Ileus

Local obstruction of the rectum is a common occurrence in advanced PCa, and can lead to abdominal pain caused by obstructive ileus. Rarely, peritoneal involvement can also result in ileus. Surgery and/or rectal stenting must be performed for mechanical obstruction. Paralytic ileus due to tumour infiltration of a nerve plexus or secondary to analgesics may require laxatives for opioid-induced constipation to improve motility and reduce pain.

4.1.3 ***Pain due to metastases***

4.1.3.1 Bone metastases

- Bone metastases are the most common cause of chronic pain in patients with PCa (8,9) as a result of:
  - endosteal or periosteal nociceptor activation (mechanical distortion or release of chemical mediators)
  - tumour growth into adjacent soft tissues or nerves and
  - other complex mechanisms (9).
- Widespread bony metastases frequently cause multifocal pain. Patients with multiple bony metastases typically report pain in only a few sites.
- More than 25% of patients with bony metastases are pain-free (10).
- The factors that convert a painless lesion into a painful one are unknown.

The choice of treatment will depend on the site, histology and stage of the tumour, and on the patient's physical and emotional condition. Although tumour-cell specific therapies are being developed, most commonly used techniques damage normal tissues, with consequent side-effects. The pros and cons of the therapeutic options should be considered in each case, those with fewest side-effects being administered first. The options are:

- hormone therapy;
- radiotherapy;
- orthopaedic surgery;
- radioisotopes;
- bisphosphonates;
- calcitonin;
- chemotherapy;
- systemic analgesic pharmacotherapy (the analgesic ladder).

Other pain management tools such as nerve blocks are rarely used.

Hormone therapy

Huggins and Hodges (11) first noted the effect of exogenous oestrogen administration on prostatic carcinoma. Hormone changes may cause complex endocrine effects, such as pituitary inhibition of luteinising hormone (LH), follicle-stimulating hormone (FSH) and prolactin, as well as changes in endogenous corticosteroid hormone production (12). A variety of additive or ablative hormone manipulations have been employed, including oestrogen, anti-androgen (cyproterone, flutamide), oestrogen-mustine complex (estramustine), progestogens, aminoglutethimide, gonadotrophin-releasing hormone (GnRH) analogues, orchidectomy, adrenalectomy and hypophysectomy. Corticosteroids are also used for the palliation of pain, particularly that due to bone deposits.

Side-effects

Hormone therapy is generally much better tolerated than chemotherapy. It can cause a temporary exacerbation of pain (pain flare), which is generally predictive of a subsequent response (13). The side-effects are:

- GnRH analogues and orchidectomy:
  - loss of body hair
  - testicular atrophy
  - gynaecomastia
  - loss of libido
  - impotence
  - increased cardiovascular mortality rate in long term administration
  - psychological morbidity.
- anti-androgens:
  - gynaecomastia (more often if used alone than when used in combination with GnRH analogues)
  - hepatic impairment
  - less sexual dysfunction than with GnRH analogues.
- cyproterone acetate:
  - fewer side-effects than oestrogens
  - lower incidence of cardiovascular complications than with oestrogens.
- oestrogens:
  - loss of body hair
  - testicular atrophy
  - gynaecomastia
  - loss of libido
  - impotence.
- Long-term administration results in higher mortality from cardiac and cerebrovascular disease as compared to GnRH analogues.
- adrenalectomy:
  - major operative procedure.
- hypophysectomy:
  - small but significant mortality rate
  - hormone replacement is subsequently required for life.

Efficacy

In a collected series of protocols, pain relief has been estimated at between 35% (14) and 70% (15). The differences may be due to the selection of patients and problems in pain measurement. Well-differentiated prostatic carcinoma is more likely to respond to hormones than are poorly differentiated tumours. Manipulations that include replacement corticosteroid therapy or have additional corticoid effects seem to give higher response rates. Corticosteroids are also used for the palliation of pain, particularly in bone metastases.

Problems

To date, most patients with adenocarcinoma of the prostate present in early tumour stages and undergo radical surgery or radiotherapy. In cases of disease progression and symptoms, hormone therapy can be indicated with patients remaining asymptomatic for years. Pain is associated with a hormone-resistant tumour in progression, which necessitates alternative therapeutical options.

Radiotherapy

- The role of radiotherapy in the management of pain due to bone metastases is unquestionable.
- Radiotherapy techniques vary widely, from a large dose given as a single treatment to as many as 20 smaller treatments given over 4 weeks.
- Dose-time factors: the biological effect of the radiation depends not only on the total dose delivered, but also on the number of separate treatments and the total time over which the irradiation therapy is administered.
- Palliative doses are smaller than maximum tolerance doses.
- Bear in mind that radiological evidence of a deposit may considerably underestimate the extent of disease.

In metastatic adenocarcinoma of the prostate, radiotherapy is associated with palliation of pain from bony metastases and improved QoL. Radiation therapy is effective at treating painful sites, and might also be effective at reducing the propensity for adjuvantly treated disease to become symptomatic in most patients

(16). This effect does not appear to be significantly influenced by dose-time relationships or histology. The proportion of patients achieving complete pain relief approaches 80% (17) (see also Section 3.3.3).

Orthopaedic surgery
If more than 50% of the thickness of the cortex of a long bone is eroded by metastasis, prophylactic fixation rather than radiotherapy alone should be considered. Internal fixation should be followed by postoperative radiotherapy because there is a real danger of continued tumour growth and further structural weakness (18,19). Radiotherapy should not be withheld for fear of inhibiting bone healing and regrowth. There is good evidence that palliative doses of radiotherapy are associated with recalcification (20).

Radioisotopes
Widespread axial skeletal involvement in PCa has been successfully treated with systemically administered bone-seeking radioisotopes (see also Section 3.3.2). Commonly used radionuclides are strontium-89 chloride (^{89}Sr) and samarium-153-ethylenediaminetetramethylene phosphonic acid (^{153}Sm-EDTMP). The addition of ^{89}Sr as a single injection of 10.8 mCi (399.6 MBq) is an effective adjuvant therapy to local field radiotherapy, reducing disease progression, the requirement for further radiotherapy and analgesic support (16), and improving QoL. Some evidence suggests that radioisotopes could give complete relief from pain over 1-6 months, with no increase in analgesia, although adverse effects, specifically leucocytopenia and thrombocytopenia, have been experienced (21).

Bisphosphonates
Bisphosphonates are routine supportive care for patients with bone metastases, and in a meta-analysis of 8 randomised studies some improvement in pain control due to bone metastases could be demonstrated (22). Bisphosphonates act by inhibiting osteoclast activities. Recent studies showed no statistically significant difference between the bisphosphonate and control groups in terms of PCa death, disease progression, and radiological and PSA response, but they should be considered for treating refractory bone pain and preventing skeletal events in those with metastatic PCa (22).

Zoledronic acid is effective for treating the complications of bone metastasis. Its efficacy and safety have been established in three pivotal trials involving more than 3000 patients (23). Although they appear osteoblastic on radiographic imaging, most bone metastases are characterised by excess osteoclast volume and activity. Pathological osteoclast activation is associated with increased risk of skeletal complications. Zoledronic acid, a potent inhibitor of osteoclast activity, differentiation and survival, decreases the risk of skeletal complications in men with androgen-independent PCa and bone metastases. Other bisphosphonates, including pamidronate and clodronate, seem to be less effective (24).

Zoledronic acid administration for one year to patients with hormone-sensitive PCa and bone metastases who were on androgen-deprivation therapy was safe and prevented bone loss, as shown by significant increases in bone mineral density and sustained suppression of biochemical markers of bone turnover (25). Zoledronic acid (4 mg intravenously over 15 minutes every 3-4 weeks) decreased the frequency of skeleton-related events, delayed the time to the first occurance, and reduced pain (23). Visual analogue scale improvement is positively correlated with a decrease of C-telopeptide and bone phosphatase alkaline ($p < 0.05$) serum levels (26). Studies are needed to determine the optimal timing, schedule and duration of treatment in men with bone metastases, as well as other potential roles for bisphosphonates, e.g. prevention of bone metastases (see Section 3.4.3).

Calcitonin
Current evidence does not support the use of calcitonin to control pain arising from bone metastases (27).

Chemotherapy
In about 80% of men with metastatic PCa, primary androgen ablation leads to symptomatic improvement and a reduction in the serum levels of PSA. The disease eventually becomes refractory to hormone treatment, and systemic chemotherapy should be reserved for this patient group. Recent data have shown encouraging signs in overall survival, palliation of symptoms and improvements in QoL (28), particularly with docetaxel.

Trials using single-agent chemotherapy in advanced disease have shown poor results, but newer studies suggest multiagent chemotherapies may be more effective. A randomised trial showed that mitoxantrone plus low-dose prednisone relieved pain and improved QoL more frequently than did prednisolone alone.
Other studies have confirmed the symptomatic effect of this regimen, but none found improved survival.

A PSA-response rate and a reduction of pain were also reported with other combined chemotherapies (Table 4). Individualised therapy was necessary as side-effects were common and no regimen showed a survival benefit.

A major proportion of the morbidity and mortality related can be traced to the burden of bone metastases (29). Any effective hormone therapy or chemotherapy is generally suited to relieve metastatic pain, or to limit, at least. Over the last decade, several new agents for mCRPC targeting different mechanisms of progression have been applied successfully: docetaxel, cabazitaxel, sipuleucel-T, denosumab, and abiraterone acetate (30). Docetaxel is the standard first-line chemotherapeutic agent (31). Despite a survival benefit the prognosis remains limited. Second-line therapeutic options are limited. Results from recently completed trials show a statistically and clinically significant improvement in pain relief and overall survival with cabazitaxel compared with mitoxantrone. Cabazitaxel has been shown to be well tolerated and has been approved as second-line chemotherapy for mCRPC (31,32). In 2010 two further randomized trials were published which demonstrate a survival benefit in the second-line setting: sipuleucel-T (immunotherapy) and abiraterone acetate versus placebo (20). The identification of intracellular androgen synthesis by prostate cancer cells has led to the development of third generation drugs for the therapy of mCRPC. Inhibitors of androgen synthesis and more potent androgen receptor antagonists will relief pain and improve palliation. A significant reduction of tumor-associated pain and a survival advantage of 4.6 months compared to placebo following docetaxel-based chemotherapy has already been shown for abiraterone (phase III study) (32) (LE: 1b, GR: A).

Table 4: PSA-response rates to selected combined chemotherapy regimens

Chemotherapy agent	Plus	Response rate (%)
Ketoconazole	+ doxorubicin	55
Vinblastine	+ estramustine	54-61
Estramustine	+ etoposide	39-58
Mitoxantrone	+ prednisone	33
Paclitaxel	+ estramustine	53

In 2005, two studies demonstrated that docetaxel-based regimens have a very good symptomatic effect that is significantly better than that of the mitoxantrone-based approach (Table 5) (25,26). Additionally, for the first time, a significant survival benefit was shown for the docetaxel group (18.9 versus 16.5 months).

Table 5: Docetaxel-based chemotherapy versus mitoxantrone-based regimens

Chemotherapy	Plus	Frequency	Response rate (29)	
agent			Pain (%)	Quality of life (%)
Docetaxel	+ prednisone	Every 3 weeks	35	22
Docetaxel	+ prednisone	Weekly	31	23
Mitoxantrone	+ prednisone	Every 3 weeks	22	13

Although most of these regimens are associated with side-effects such as fatigue, mild myelosuppression and gastrointestinal irritation, they are generally well tolerated by most patients (33). The docetaxel-based regimens are now the standard of care for patients with advanced hormone-refractory PCa. Soft-tissue lesions could be influenced to a greater extent than bony metastases. Pain management by chemotherapy could be effective, although it is much more cost-intensive than the administration of opioids, and the survival advantage is limited.

4.1.4 Systemic analgesic pharmacotherapy (the analgesic ladder)

If the treatments described above provide insufficient pain relief, systemic analgesic pharmacotherapy should be administered (see Section 3.4.4). In most cases, the drug selection scheme proposed by the World Health Organization (WHO), the analgesic ladder, is recommended.

Short-term studies have shown that NSAIDs alone are effective in managing cancer pain, with side-effects similar to those with placebo. In about 50% of studies, increasing the dose of NSAIDs increased efficacy but not the incidence of side-effects. No large clinical difference has been demonstrated between combining an NSAID with an opioid versus either medication alone (34).

Tramadol extended-release tablets and dihydrocodeine extended-release tablets were effective for the management of chronic tumour pain associated with PCa with bone metastasis on step 2 of the WHO ladder, with the tramadol giving slightly better pain management and fewer side-effects, particularly constipation (35). The treatment of constipation in palliative care is based on experimental evidence, and uncertainty persists about its optimum management in this group of patients (36).

Oral morphine is an effective analgesic for cancer pain, with qualitative evidence showing that it compares well with other opioids. Morphine is the gold standard for moderate to severe cancer-related pain. Alternatives such as hydromorphone are now available, but no clinically significant difference has been shown compared to and other strong opioids such as morphine (37). Patients with inadequate pain control and intolerable opioid related toxicity/adverse effects may have to switch to an alternative opioid for symptomatic relief, although the evidence to support opioid switching is largely anecdotal, observational or from uncontrolled studies (38).

Breakthrough pain is a common and debilitating problem for patients with cancer. Evidence suggests that oral transmucosal fentanyl citrate is effective for breakthrough pain (39), giving more rapid relief than morphine (40).

4.1.5 ***Spinal cord compression***

Spinal cord compression can occur due to the collapse of a vertebral body or to pressure from an extradural tumour within the spinal canal. Prodromal pain is a feature in 96% of these patients. The overall incidence in PCa patients is less than 10% (42). Thoracic cord compression is the most common area (70%), and the incidence of multiple extradural sites can be as high as 18% (43). Definitive treatment with surgery (anterior decompression with spinal stabilisation) or radiotherapy should be considered. The symptom of local back pain sometimes disappears, despite an increase in motor deficits, because of the evolving sensory component of the paraplegia.

Corticosteroids (typically dexamethasone 16 mg daily) are of only temporary use in cord oedema. There is evidence that decompressive surgery benefits ambulant patients with poor prognostic factors for radiotherapy, and non-ambulant patients with a single area of compression, paraplegia of < 48 hours' duration, nonradiosensitive tumours and predicted survival of > 3 months. There is a significant risk of serious adverse effects from high-dose corticosteroids (44).

4.1.6 ***Hepatic invasion***

Hepatic invasion by secondary tumour is a common cause of severe hypochondrial pain, often radiating to the back and shoulder blade. The mechanism may be the stretching of nerve endings in the liver capsule, diaphragmatic irritation, or haemorrhage into a necrotic area of tumour. Liver pain can often be controlled by conventional titration of appropriate analgesics or with corticosteroids.
Whole-liver palliative radiotherapy can also be useful in carefully selected patients with refractory pain, giving far fewer side-effects than the alternatives of intra-arterial chemotherapy or hepatic artery embolisation. Hepatic irradiation can improve abdominal pain with little toxicity in more than half of patients (45). Doses should not exceed 30 Gy in 15 daily fractions or its equivalent if radiation hepatitis is to be avoided.

4.1.7 ***Pain due to cancer treatment***

4.1.7.1 Acute pain associated with hormonal therapy

Luteinising hormone-releasing hormone (LHRH) tumour flare in PCa

Initiation of LHRH therapy for PCa produces a transient symptom flare in 5-25% of patients (46,47), presumably caused by an initial stimulation of LH release before suppression is achieved (47,48). The syndrome typically presents as an exacerbation of bone pain or urinary retention. Spinal cord compression and sudden death have also been reported (46). Symptom flare is usually observed within the first week of therapy, and lasts 1-3 weeks. Co-administration of an androgen antagonist at the start of LHRH agonist therapy can prevent this (49).

4.1.7.2 Chronic pain associated with hormonal therapy

Gynaecomastia

Chronic gynaecomastia and breast tenderness are common complications of anti-androgen therapies for PCa, the incidence varying between drugs. Frequently associated with diethylstilboestrol (50), it is less common with flutamide and cyproterone (51-53), and uncommon in patients receiving LHRH agonist therapy (54). In elderly patients, it must be distinguished from primary breast cancer or secondary cancer in the breast (54).

4.1.8 ***Conclusions***

Radio-, chemo- and hormone therapy are all valuable options for relieving cancer pain. The side-effects of

inappropriate anticancer treatments can be very distressing, and so the disadvantages of treatments must be balanced against the palliative benefits. In many patients, the best approach to pain relief is through interdisciplinary co-operation.

Surgery, radio-, chemo- and hormone therapy are mainly used as antitumour treatment in the relief of pain. The rational use of any of these treatments demands knowledge not only of tumour biology, but also of the mechanisms of action of these specific oncological techniques. The therapeutic aim should be clearly understood prior to starting treatment.

Radical treatment should be given if the disease is potentially curable, but the intent should be symptomatic or palliative if the tumour is advanced or widely disseminated (55). The importance of early intervention needs to be emphasised, and education is crucial: patients must be aware of the early signs and symptoms of metastatic disease, which does not necessarily involve pain.

*4.1.9 **Recommendations at a glance (stage M1) (56-61)***

ANTICANCER TREATMENT		
Recommendation	**LE**	**GR**
Hormonal therapy (orchiectomy, LHRH analogues, diethylstilboestrol equivalent)	1a	A
Total androgen blockade: flare prevention, second-line	2b	B
Intermittent androgen suppression experimental	3	B
Monotherapy with anti-androgen is an option	2	B
First-line treatment controls disease for 12-18 months, second-line individualised	1b	A
Supportive care		
Low-dose glucocorticoids	1b	A
Chemotherapy		
Mitoxantrone plus prednisolone	1b	B
Estramustine + vinblastine or etoposide or paclitaxel	2b	B
Docetaxel	1b	A
PAIN MANAGEMENT		
Recommendation	**LE**	**GR**
Pain assessment (localisation, type, severity, overall distress)		B
Pain due to painful or unstable bony metastases (single lesions)		
External beam irradiation	1b	A
Pain due to painful bony metastases (widespread)		
Radioisotopes (^{89}Sr or ^{153}Sm-EDTMP)	2	B
Pain due to painful metastases (many spots)		
Bisphosphonates	1b	A
Systemic pain management		
WHO analgesic ladder step 1: NSAID or paracetamol	1a	A
Opioid administration		
Dose titration	2	B
Access to breakthrough analgesia	1b	A
Tricyclic antidepressant and/or anticonvulsant in case of neuropathic pain	1a	A

4.2 Pain management in transitional cell carcinoma patients

*4.2.1 **Clinical presentation***

In more developed countries, urothelial cancer is the 5th most common cancer in men and the 13th in women (1). Transitional cell carcinoma (TCC) is the most frequent cancer of the bladder and upper urinary tract. It arises much more frequently in the bladder than in the collecting system (calices, renal pelvis and ureter).

From the perspective of pain, there are no differences between TCC and other histotypes of urothelial malignant tumour. In bladder carcinoma, pain can be present at an early stage as a burning pain (dysuria),

together with irritative symptoms (urgency and frequency), or late in advanced disease due to obstruction of the upper urinary tract, or local invasion of neighbouring tissues causing pelvic or metastatic organ invasion.

TCC of the renal collecting system represents 5-10% of all kidney tumours and 5% of all TCC of the urinary tract (2). TCC of the ureter accounts for only 3% of all TCC (3). In upper urinary tract TCC, pain is an initial symptom in 18-30% of cases (4,5).

*4.2.2 **Origin of tumour-related pain***

4.2.2.1 Bladder TCC

The main causes of tumour-related pain in bladder TCC are:

- obstruction of the upper urinary tract due to growth of bladder tumour close to the ureteral orifices.
- invasion of the surrounding areas by a locally advanced tumour (pelvic wall, nerve roots, other organs such as bowel, or rectum)
- bone metastases
- soft tissue metastases (seldom painful)

4.2.2.2 Upper urinary tract TCC

The main causes of tumour-related pain in the upper urinary tract TCC are:

- obstruction of the upper urinary tract (presenting symptom in around 30% of cases)
- acute obstruction due to blood clots
- invasion of the surrounding areas by a locally advanced tumour (posterior abdominal wall, nerve roots, paraspinous muscles, other organs such as bowel, spleen, or liver)
- bone metastases
- soft tissue metastases (seldom painful)

*4.2.3 **Pain due to local impairment***

4.2.3.1 Bladder TCC

Obstruction of the ureteral orifices by tumour infiltration may lead to hydronephrosis and consecutive flank pain due to ureteral distension (visceral pain). Transurethral resection of the tumour may be effective in eliminating ureteral obstruction, but in palliative situations, hydronephrosis is mainly treated by temporary or permanent ureteral stenting or percutaneous/open nephrostomy, similar to the treatment of obstruction caused by prostate cancer (6).

In locally advanced disease, symptoms are comparable with those caused by T4 prostate cancer. Infiltration of the contiguous soft tissue and neighbouring organs can cause acute burning pain by infiltration of the pelvic nerves (neuropathic pain), sometimes associated with paraesthesia irradiating to the lower limb, or motor deficit. If the tumour invades adjacent organs (small bowel or rectum), there can be obstruction, and visceral pain due to distension of hollow organs. Growing bladder tumour can cause complete bladder outlet obstruction, with hypogastric abdominal pain from bladder distension. Obstruction of the lymphatic vessels by lymphadenopathy can cause lymphoedema of the lower limbs with pain due to distension of muscle fascia (somatic pain) (6).

In infiltrating and advanced bladder cancer, radical or debulking cystectomy and urinary diversion have a positive impact on pain, by removing the neoplastic mass invading the surrounding tissues (see EAU Guidelines on Muscle Invasive Bladder Cancer, Chapter 8.1). Extended operations, including excision of involved bowel, are sometimes indicated. Palliative surgery may be necessary in occlusive intestinal syndromes (7). In a small retrospective study of patients with tumour infiltration of the rectum by locally recurrent prostate cancer, total exenteration resulted in significant pain reduction in all patients, and 79% were completely pain free (8). In a mixed group of cancer patients (colorectal, urinary or gynaecological) with different symptoms such as bleeding, fistula, or pelvic pain or obstruction, palliative pelvic exenteration improved QoL in 88% (9).

First-line chemotherapy strategies that are mainly based on platinum-containing regimens have some effect in 12-75% of patients with advanced disease (see EAU Guidelines on Muscle Invasive Bladder Cancer Guidelines, Chapter 12). It probably relieves pain by decreasing the neoplastic mass in respondent patients (10-14) (LE: 1a), but pain control was one of the study end points in only one small study (15).

In a phase III trial vinflunine, as new second line chemotherapy agent, proved to be very effective in disease control with 76%, but pain control was not an end point. Quality of life stayed unchanged during chemotherapy despite drug toxicity (16).

Radiotherapy can be effective in controlling pelvic pain and other symptoms such as frequency and haematuria due to local disease progression. In a large randomised study with 500 participants, two radiotherapy schedules (35 Gy in 10 fractions and 21 Gy in 3 fractions) were compared for symptomatic improvement of bladder-related symptoms. 68% of the participants achieved symptomatic improvement, 71% with 35 Gy radiotherapy and 64% with 21Gy. Acute bowel toxicity was noticed in one third of the patients. There was no significant difference between the 2 study arms (17) (LE 1a). Some smaller studies have shown comparable results with respect to improvement of QoL by local radiotherapy (18).
The effect of radiotherapy in controlling local symptoms of advanced bladder cancer needs to be balanced against the risk of inducing proctitis.

4.2.3.2 Upper urinary tract TCC

Transitional cell carcinoma (TCC) of the upper urinary tract often presents with microscopic or gross haematuria (70-80%), but flank pain also occurs in 20-40% of patients due to obstruction or lumbar mass (see EAU Guidelines on Upper Urinary Tract Urothelial Cell Carcinomas, Chapter 3.4). A multi-institutional study with 654 patients has shown that local symptoms do not confer worse prognosis compared with patients with incidentally detected upper urinary tract TCC (19). Locally advanced primary tumours are usually managed by radical nephroureterectomy. Extended operations including excision of involved bowel, spleen or abdominal wall muscle are sometimes indicated.

With regard to chemotherapy, the same considerations are valid for upper urinary tract TCC as for bladder TCC (compare with EAU Guidelines on Upper Urinary Tract Urothelial Cell Carcinomas, Chapter 3.7.2). The standard chemotherapy regimens that provide moderately prolonged survival are MVAC (methotrexate, vinblastin, adriamycin, cisplatin) and gemcitabine/cisplatin as first-line drugs, as in bladder cancer (20). In a phase II study of 151 patients with locally advanced or metastatic urothelial cancer, 45 patients (29%) with upper urinary tract carcinoma were included, and vinflunine as second-line chemotherapy demonstrated moderate activity in these patients (21)

*4.2.4 **Pain due to metastases***

Haematogenous metastases to the bone are often found in advanced bladder or upper urinary tract TCC. No data are available in the literature concerning the specific effect of chemotherapy on bone metastases alone.

Radiotherapy has a palliative analgesic role in bone metastases (see Chapter 3.3.3) and pain reduction > 50% can be achieved in 50% of patients (22) (LE: 1b). All the data concerning radiotherapy or radionuclide therapy of bone metastases have been taken from series including different carcinomas such as prostate, breast or kidney cancer. There are no specific trials studying the effect of radiotherapy on painful bone metastases in bladder cancer. Single-fraction radiotherapy is as effective as multifraction radiotherapy in relieving metastatic bone pain (23,24) (LE: 1a). However, the rates of retreatment and pathological fractures are higher after single-fraction radiotherapy (23,24) (LE: 1a).

Radioisotope treatment (see Chapter 3.3.2) or hemi-body irradiation can be used in patients with multiple bone metastases (22). There are no specific studies of radioisotope therapy for bone metastasis in TCC.

Orthopaedic surgery can stabilise pathological fractures, as for those from prostate cancer (see Chapter 3.3.3.6).

*4.2.5 **Conclusion for symptomatic locally advanced or metastatic urothelial cancer***

- In locally advanced bladder cancer, palliative cystectomy or exenteration might be an option for symptom relief (LE 3; GR B)
- Chemotherapy in urothelial cell carcinoma is effective in terms of disease control (LE 1b, GR A)
- The effect on pain control and quality of life seems to be analogue (LE 2a)
- Radiotherapy reduces pain and symptoms of locally advanced bladder cancer (LE 1a, GR B), but this needs to be balanced against the risk of inducing proctitis
- Radiotherapy is effective in reducing pain due to bone metastases (LE 1b; GR A)

4.3. Pain management in renal cell carcinoma patients

*4.3.1 **Clinical presentation***

Renal cell carcinoma (RCC) is mainly diagnosed incidentally. There is no pain unless tumour invades adjacent areas or obstructs urine outflow due to haemorrhage and blood clot formation. Some 20-30% of patients present with metastases, and 30% of patients primarily presenting with a localised kidney tumour develop them during follow-up. RCC metastasises mainly to lung, bone, brain, liver and ipsilateral or contralateral adrenergic glands. Such patients have a maximal 2-year survival rate of 20%. Overall 50-60% of patients may need treatment for the symptoms of metastatic disease, mainly pain.

The main origins of tumour-related pain are:

- invasion of the surrounding areas by a locally advanced tumour (posterior abdominal wall, nerve roots, paraspinous muscles, other organs such as bowel, spleen, liver)
- obstruction of the upper urinary tract due to haemorrhage and subsequent formation of blood clots
- bone metastases
- soft tissue metastases (seldom painful).

*4.3.2 **Pain due to local impairment***

Patients with invasion of surrounding areas (e.g. the posterior abdominal wall, nerve roots, paraspinous muscles, other organs such as bowel, spleen, liver) by a locally advanced primary tumour without metastases usually present with pain. Surgical management is the only effective option for this type of tumour. Extended operations that include excision of involved bowel, spleen or abdominal wall muscle are sometimes indicated.

Adjuvant immunotherapy or radiotherapy is without proven benefit with regard to recurrence. Even in cases of metastatic disease, palliative nephrectomy is indicated for the control of severe symptoms such as haemorrhage, pain or paraneoplastic syndromes (GCP). The frequency with which each of these symptoms is controlled, however, is unclear and there are no data in the literature comparing efficacy of nephrectomy in palliative situations with other therapies such as angioinfarction of the tumour.

Standard pre-operative (30 Gy) or post-operative radiotherapy offers no survival benefit, and its role in delaying local progression is questionable (1). Radiotherapy of soft tissue has no proven benefit for pain and tumour control.

In metastatic disease, the European Organisation for Research and Treatment of Cancer (EORTC) Genitourinary Group study 30947 demonstrated a significant increase in survival with palliative nephrectomy plus immunotherapy compared with immunotherapy (interferon-alpha) alone (median survival of 17 compared with 7 months) (2) (LE: 2b). There is no special effect on pain relief from immunotherapy.

Obstruction of the upper urinary tract due to haemorrhage and subsequent formation of blood clots is effectively treated by radical nephrectomy in non-metastatic tumour (GCP). If the patient is physically fit for surgery, this should be done to increase the QoL, e.g. palliative nephrectomy in cases of metastatic tumour (GCP).

There are no data in the literature about the efficacy of other therapies such as angioinfarction of the tumour with regard to haemorrhage and pain relief in palliative situations. WHO guidelines recommend analgesic therapy and/or palliative drainage of the urinary tract if patients are not fit for major surgery.

*4.3.3 **Pain due to metastases***

Patients with bone metastases have a significantly better life expectancy (30 months) than those with visceral metastases (11.6 months) (3).

Surgery is indicated for solitary bone metastases that can be resected completely, intractable bone pain, and impending or demonstrable pathological fracture. In bone metastases with extensive soft tissue involvement and severe pain, amputation of a limb is sometimes required to maintain quality of life. Surgery for bone metastases achieves a significant decrease in pain in 89-91% of patients (4-6) (LE: 2b/3). Additionally, surgery prevents pathological fractures and spinal compression, and there is a significant impact on survival.

Pre-operative embolisation of bone metastases or embolisation alone achieves good pain relief in hypervascular bone metastases (7,8) (LE: 3).

High dose radiation therapy for palliation of painful bony metastases has been shown to be effective in 50-75% of all renal cancer patients (9-11) (LE: 3), and in 67% with general bone metastases (12) (LE: 2b). There is no impact on survival. Small studies of radionuclide therapy (e.g. with 89Sr) have shown good pain relief in bony metastases from RCC (13) (LE: 3).

Standard pre-operative (30 Gy) or post-operative radiotherapy offers no survival benefit; its role in delaying local progression is questionable (1); there is no proven benefit for pain and tumour control for soft tissue metastases.

Bone metastases show poor response to immunotherapy, and there is no proven benefit in pain relief. Hormonal therapy and chemotherapy are even less effective, and have no room in pain control.

Immunotherapy alone achieved an overall response in 15-27% of patients (14). Immunotherapy in combination with chemotherapy (interleukin-2 + interferon-alpha + 5-fluorouracil) is the most effective therapy, achieving partial tumour response in up to 46% of patients and complete response in a maximal 15%, although these rates are mainly for lung/lymph node metastases (15).

Pain due to soft tissue metastases probably behaves analogous to tumour response, but there are no data on immunotherapy for pain control. Hormonal therapy has no proven benefit for survival or pain relief.

First-line chemotherapy (docetaxel), second line chemotherapy (microtubule inhibitor cabazitaxel), and third generation anti-androgen therapy (abiraterone acetate)

4.4 Pain management in patients with adrenal carcinoma

Adrenal carcinoma is a rare disease and has a poor prognosis. Non-functional adrenal lesions of more than 5 cm in diameter should be removed because there is a high probability of malignancy (1).

*4.4.1 **Malignant phaeochromocytoma***

Phaeochromocytomas result from phaeochromocytes, which are the predominant cells of the adrenal medulla and are also found in the paraganglia near the aorta and in lesser numbers in the ganglia of the sympathetic nervous system (2). When correctly diagnosed and treated, the disease is curable, unless there are metastases.

Computed tomography (CT) and magnetic resonance imaging (MRI) have the highest sensitivity in detecting the tumour, achieving 94-100%. A 131J-metaiodobenzylguanidine (131J-MIBG) scan is positive in approximately 87% of cases (3).

Chemotherapy with cyclophosphamide, vincristine and dacarbazine has little effect on metastases (4) (LE: 2b), but therapeutic doses of 131J-MIBG (33 GBq = 900 mCi) may produce some results (5, 6) (LE: 2b). The hormone response rate is 50%. There are no data on pain relief with 131J-MIBG in metastatic phaeochromocytoma, but a response rate that is at least the same as for hormone levels should be expected.

Malignant phaeochromocytomas are considered radioresistant, although there are some cases in which radiation therapy induced partial remission (7) (LE: 3). There is no information about the efficacy of radiation concerning pain relief in cases of bone or soft tissue metastases.

*4.4.2 **Treatment of pain***

- Soft tissue and/or bone pain due to metastases are best treated by therapeutic doses of 131J-MIBG, if the phaeochromocytoma takes up this radionuclide (8) (LE: 2b). There is no literature concerning chemotherapy or radiotherapy and pain relief in metastatic phaeochromocytoma.
- Treat the pain symptomatically following the recommendations made in Section 3.4.

4.4.2.1 Adrenocortical carcinomas

Carcinoma of the adrenal cortex is highly malignant, with local and haematogenous metastasis, and 5-year

survival rates of 25-43% for all treatments. Patients with distant metastases have a mean survival of only 4 months (9). An autopsy study showed metastasis to lung (60%), liver (50%), lymph nodes (48%), bone (24%) and pleura/heart (10%) (10). These tumours often extend directly into adjacent structures, especially the kidney.

Chemotherapy is of low efficacy. The most effective drug is mitotane, an adrenolytic. The tumour-response rate is 25-35% (9,11) (LE: 2a). It remains to be proven whether chemotherapy prolongs survival. Radiation therapy has not been useful except for palliation and pain management (12) (LE: 2b).

4.4.2.2 Treatment of the pain depending on its origin

- Abdominal symptoms are typical on first presentation of the tumour. The treatment is surgical removal of the primary tumour, with attempts to remove the entire lesion even if resection of adjacent structures is necessary, as well as resection of local lymph nodes.
- Soft tissue and/or bone metastases causing local symptoms can be treated by radiotherapy (8,12). There are no data on chemotherapy or radiotherapy for pain relief in metastatic adrenocortical carcinomas.
- Treat the pain symptomatically following the recommendations given in Section 3.4.

4.5 Pain management in penile cancer patients

4.5.1 ***Clinical presentation***

Penile cancer is rare in Europe, with an annual incidence of 0.3-1.0 new cases per 100,000 men (1). It mostly affects men between the ages of 50 and 70 years, with only 19% of cases in those aged < 40 years and 7% in those < 30 years (2). The penile lesion itself usually alerts the patient to the presence of a penile cancer

but there is often a delay in seeking medical attention. Lymph node involvement is a critical component of treatment planning and prognosis. Up to 60% of the patients at the time of presentation have palpable inguinal lymphadenopathy, and up to 85% of them will be found to have metastatic disease (3). Pain can occur in both early and advanced penile cancer. In the early stages, acute pain is expressed mainly by voiding dysfunction (infravesical obstruction) due to invasion of the corpus spongiosum. In advanced disease, pain is also caused by enlarged inguinal or pelvic node metastases and lymphoedema of the scrotum and lower limbs. Azotemia can develop secondary to nodal obstruction of the ureters. Hypercalcemia was reported in 17-21% of patients in two series (4). This was attributed to the parathyroid-hormone-like substances secreted by bulky metastases that stimulate osteoclastic bone resorption.

4.5.2. ***Pain due to local impairment***

4.5.2.1 Soft tissue and hollow-viscus invasion

Bladder outlet and ureteric obstruction is managed in the same manner as that described in Section 4.1.2.2.

4.5.3 ***Lymphoedema***

Patients with a huge inguinal tumour mass, or scarred inguinal tissue after lymph node dissection, often show lymphoedema of the lower limbs. This is more frequent in cases involving both inguinal and iliac nodes.

Lymphoedema is treated with physiatric techniques (wraps, pressure stockings or pneumatic pumps), which can both improve function, and relieve pain and heaviness. Orthotics can immobilise and support painful or weakened structures, and assistive devices can benefit patients with pain on weight-bearing or ambulation.

4.5.4 ***Pain due to metastases***

Pain management begins with antitumour treatment; usually surgery that includes partial/total penectomy, and inguinal and pelvic lymphadenectomy, depending on the clinical stage of the disease. Advanced penile cancer has a poor prognosis and must be approached with a multimodal treatment regimen that includes neoadjuvant chemotherapy, radiotherapy, followed by surgical resection (6). The chemotherapy regimen that is so far most effective and well tolerated is paclitaxel, ifosfamide and cisplatin (TIP), although large randomised trials are lacking (5). The role of radiotherapy is mainly palliative because its use after chemotherapy might decrease the pain from fixed inguinal nodes, bone metastases, spinal cord compression and paraplegia (7). Treatment of hypercalcemia consists of administration of iv saline for volume expansion, furosemide to promote diuresis and bisphosphonates to prevent osteoclastic bone resorption. When tumour erosion into femoral vessels is suspected, emergency intervention with endoluminal vascular stents or transobturator bypass graft should be undertaken (8,9).

4.5.5 ***Conclusions***

Pain management related to advanced penile carcinoma should include a multimodality regimen that consists of cisplatin-based chemotherapy, radiotherapy and surgical resection. The goals of palliative care should be: alleviation of pain using systemic analgesic pharmacotherapy (WHO Ladder) if multimodality therapy is unsuccessful, wound care, treatment of hypercalcemia and tumor erosion of the large groin vessels.

4.6 Pain management in testicular cancer patients

*4.6.1 **Clinical presentation***

Testicular cancer generally affects men in the third or fourth decade of life. It is mainly diagnosed causally as an intrascrotal mass. Approximately 20% of patients present with scrotal or inguinal pain, which disappears after orchiectomy. Only 11% of patients complain of back or flank pain at first presentation (1). Primary advanced tumour with pain due to bone metastases is very rare, maximally 3% at first presentation. It should be treated causally by primary chemotherapy and adjuvant analgesics.

*4.6.2 **Pain due to local impairment***

Orchiectomy is an effective treatment for local pain due to scrotal masses.

*4.6.3 **Pain due to metastases***

- Back or flank pain due to retroperitoneal lymphadenopathy slowly disappears as chemotherapy causes the mass to decrease (LE: 2b) (see EAU Guidelines on Testicular Cancer). Temporary analgesia is advisable (see Section 3.4.4).
- Retroperitoneal lymph node metastases can also cause obstruction of the ureter, leading to a symptomatic hydronephrosis with back or flank pain and perhaps additional fever. The therapy of choice is the immediate treatment of the hydronephrosis by ureteral stenting or the insertion of a percutaneous nephrostomy.
- Bone pain due to bony metastases is very rare and occurs mainly in patients with primary advanced disease and relapse after chemotherapy (2,3). Treatment with chemotherapy or second-line chemotherapy may be possible (see EAU Guidelines on Testicular Cancer). There is no literature on radiotherapy in cases of relapse and limitation of further chemotherapy.
- Back pain and neurological symptoms due to spinal cord compression by vertebral metastases may require urgent surgery (4) (LE: 3).

5. POSTOPERATIVE PAIN MANAGEMENT

Key Words: Postoperative analgesia, postoperative pain, opioids, NSAIDs, coxibs, paracetamol, urological procedures, epidural, PCA, PCEA, ketamine, clonidine, local anaesthetics

5.1 Background

Postoperative pain is inevitable in surgical patients, and is associated with tissue damage, the presence of drains and tubes, or postoperative complications, or a combination of these (1,2).

Approximately 70% of surgical patients experience a certain degree (moderate, severe or extreme) of postoperative pain (3,4) (LE: 1a). This is usually underestimated and undertreated (1,3), leading to increased morbidity and mortality, mostly due to respiratory and thromboembolic complications, increased hospital stay, impaired QoL, and development of chronic pain (1,3,5-7) (LE: 1a).

5.2 Importance of effective postoperative pain management

The physiological consequences of postoperative pain are shown in Table 7. All of these can delay or impair postoperative recovery and increase the economic cost of surgery (longer hospitalisation) (13,14) (LE: 3). Inadequate postoperative pain control may also lead to development of chronic pain (15,16) (LE: 2b).

Table 7: Physiological consequences of postoperative pain

Condition	Consequences	Ref.	LE
Stress response to surgery	Tissue trauma results in release of mediators of inflammation and stress hormones Activation of this stress response leads to: - retention of water and sodium - increase in metabolic rate	8	2a
Respiratory complications	Shallow breathing Cough suppression Lobular collapse Retention of pulmonary secretions Infections	9	2b
Cardiovascular complications	Hypertension Tachycardia Increased myocardial work, - myocardial ischaemia - angina - infarction	10	2b
Thromboembolic complications	Reduced mobility due to inadequate pain management can lead to thromboembolic episodes	11	2a
Gastrointestinal complications	Gastric stasis Paralytic ileus mostly after open urological operations	12	2b
Musculoskeletal complications	Prolonged confinement to bed: - reduced mobility - muscle atrophy	13	3
Psychological complications	Perioperative pain may provoke fear and anxiety, which can lead to: - anger - resentment - hostility to medical and nursing personnel - insomnia	13, 14	3

5.2.1 ***Aims of effective postoperative pain management:***

- to improve patient comfort and satisfaction;
- to facilitate recovery and functional ability;
- to reduce morbidity;
- to promote rapid discharge from hospital (1-3) (LE: 1a).

Recommendation	GR
Postoperative pain should be treated adequately, to avoid complications and development of chronic pain.	B

5.3 Pre- and postoperative pain management methods

5.3.1 ***Preoperative patient preparation:***

- patient evaluation;
- adjustment or continuation of medication to avoid abstinence syndrome;
- premedication as part of multimodal analgesia;
- behavioural-cognitive interventions for patients and families to alleviate anxiety and fear of postoperative pain reduce post-opeative analgesic requirements and result in better pain management (1) (LE: 1a).

Recommendation	GR
Preoperative assessment and preparation of patients allow more effective pain management.	A

*5.3.2 **Pain assessment***

Careful pain assessment by the surgeon or the acute pain team before and after treatment can lead to more efficient pain control, and diminished morbidity and mortality (1,4) (LE: 2a). In the post-anaesthesia care unit, pain should be evaluated, treated and re-evaluated initially every 15 min and then every 1-2 h. After discharge to the surgical ward, pain should be assessed every 4-8 h before and after treatment (17,18).

Various rating scales have been described to measure postoperative pain, but their major disadvantage is that they are all subjective, making their results difficult to evaluate, especially in patients with communication difficulties (18).

Recommendation	GR
Adequate postoperative pain assessment can lead to more effective pain control and fewer complications.	B

*5.3.3 **Pre-emptive analgesia***

Pre-emptive or preventive analgesia is defined as the administration of analgesia before surgical incision to prevent central sensitisation from incision or inflammatory injury, to achieve optimal postoperative pain control (19). The results of clinical trials on its efficacy are controversial (19,20) (LE: 2b).

*5.3.4 **Systemic analgesic techniques***

5.3.4.1 Non-steroidal anti-inflammatory drugs (NSAIDs)

These drugs act by inhibiting cyclo-oxygenase (COX) and the subsequent production of prostaglandins . The main advantages of NSAIDs are that they do not produce respiratory depression or sedation, and seem to decrease the need for opioids (21). However, their analgesic effect is not strong enough for the management of severe postoperative pain (22). For NSAID dosage and administration, see Table 12.

Intravenous (iv) administration of NSAIDs should start 30-60 min before the estimated end of surgery, and oral administration should start as soon as possible. Intramuscular administration of analgesic drugs for postoperative pain control is generally avoided because of variability of serum drug concentrations (23).

Their main adverse effects are (22):

- gastric irritation, ulcer formation, bleeding;
- renal impairment;
- bronchospasm, deterioration of asthma;
- platelet dysfunction, inhibition of thromboxane A2;
- perioperative bleeding;
- inhibition of bone healing and osteogenesis.

COX-2 selective inhibitors are associated with fewer gastrointestinal complications and better bone healing. In addition, they cause minimal platelet inhibition compared with non-selective COX inhibitors (24). However, COX-2 inhibitors are contraindicated for long-term use in patients with cardiovascular problems (25). The use of COX-2 inhibitors is approved only for short-term postoperative pain therapy.

Recommendations	GR
NSAIDs are often effective after minor or moderate surgery.	B
NSAIDs often decrease the need for opioids.	B
Avoid long-term use of COX inhibitors in patients with atherosclerotic cardiovascular disease.	B

5.3.4.2 Paracetamol

Paracetamol (acetaminophen) is a relatively safe and effective antipyretic and analgesic for mild to moderate postoperative pain. In cases of severe postoperative pain, co-administration of paracetamol with strong opioids seems to reduce the consumption of opioids (26) (LE: 2). Its exact mode of action is unclear, although it may act by centrally inhibiting COX production (27).

Dosage and routes of administration

- 1 g four times daily (orally, iv or rectally). Dose should be reduced to 1 g three times daily in patients with hepatic impairment.
- iv administration of paracetamol should start 30 min before the end of surgery, and oral administration as soon as possible.

Adverse effects

No significant adverse effects have been observed in patients receiving paracetamol for acute postoperative pain. Caution should be taken when it is administered to patients with chronic alcoholism or hepatic failure. A dose > 6 g/day can cause acute renal failure.

Combinations of paracetamol with opioids

Paracetamol in combination with an opioid provides adequate postoperative analgesia for mild to moderate pain without the adverse effects of strong opioids. For dosage and administration of paracetamol/opioid combinations, see Table 13.

Recommendations	GR
Paracetamol can be very useful for postoperative pain management because it reduces consumption of opioids.	B
Paracetamol can alleviate mild postoperative pain as a single therapy without major adverse effects.	B

5.3.4.3 Metamizole (dipyrone)

Metamizole is an effective antipyretic and analgesic drug used for mild to moderate postoperative pain and renal colic. Its use is prohibited in the USA and some European countries because of single reported cases of neutropenia and agranulocytosis. Elsewhere, it is considered to be a useful analgesic and antipyretic drug for moderate pain. Long-term use of metamizole is best avoided (28,29) (LE: 2b).

Dosage and route of administration

The dose is 500-1000 mg qds (orally, iv or rectally).

Adverse effects

Apart from single sporadic cases of neutropenia and agranulocytosis, metamizole can cause minor side effects such as nausea, mild hypotension, and allergic reactions. Allergic reactions and the rare complication of agranulocytosis have been described only after direct iv administration, therefore, iv metamizole should be administered as a drip (1 g in 100 mL normal saline).

5.3.4.4 Opioids

Opioids are the first-line treatment for severe acute postoperative pain. Correct dose titration can minimise their unwanted effects (30). Opioid dosage and administration can be found in Table 14 and 15.

5.3.4.5 Patient-controlled analgesia (PCA)

Systemic administration of opioids may follow the “as needed” schedule or “around-the-clock” dosing. The most effective mode is PCA (31,32) (LE: 1a) (Table 8).

Table 8: Typical PCA dosing schedule

Drug (concentration)	Bolus size	Lockout interval (min)	Continuous infusion
Morphine (1 mg/mL)	0.5-2.5 mg	5-10	0.01-0.03 mg/kg/h
Fentanyl (0.01 mg/mL)	10-20 µg	5-10	0.5-0.1 µg/kg/h
Pethidine (10 mg/mL)	5-25 mg	5-10	-

Recommendation	GR
Intravenous patient controlled analgesia provides superior postoperative analgesia, improving patient satisfaction and decreasing risk of respiratory complications.	A

Opioids adverse effects are:

- respiratory depression, apnoea;
- sedation;
- nausea, vomiting;
- pruritus;
- constipation;
- hypotension.

5.3.4.6 Adjuncts to postoperative analgesia

Adjuncts to postoperative analgesia in low doses, such as ketamine, α2 agonists (clonidine, dexmedetomidine) gabapentinoids (gabapentin or pregabalin) in appropriate doses and monitored care are beneficial in improving analgesic efficacy and reducing opioid-related side effects, with good safety and tolerability (33,34) (LE:1a, GR: A).

Low-dose ketamine is defined as a bolus dose < 2 mg/kg when given intramuscularly or less than 1 mg/kg when administered via the intravenous or epidural route. For continuous i.v. administration, low-dose ketamine is defined as a rate of ≤ 20 g/kg/min (35). Its use is contraindicated in patients with coronary disease, uncontrolled hypertension, congestive heart failure and arterial aneurysms. There are insufficient data to confirm the neurotoxicity of ketamine, even though some animal studies have shown some degree of neurodegeneration after continuous use (36) (LE:2b).

Clonidine when given preoperatively, or epidurally postoperatively (1mcg/kg) can reduce opioid requirements (37) (LE:1a, GR: A).

More clinical evidence on dexmedetomidine is necessary to confirm its definite role in acute postoperative pain control (38).

In 17 studies up to 2007, patients received a single preoperative dose of 300-1200 mg gabapentin, 30 min-2 h before surgery in the remaining studies, the drug was administered at a dose of 1200-1800 mg/day at 1-24 h before the procedure and continued for 10 days. Gabapentin, used before, as well as before and after surgery, decreases pain severity and the need for analgesic supplementation (39) (LE:1a, GR:A).

Perioperative pregabalin (300 mg/day) reduces opioid consumption and opioid-related adverse effects after surgery, however postoperative pain intensity is not reduced by pregabalin (40).

Single-injection caudal blocks with clonidine or ketamine are beneficial in paediatric patients (41).

5.3.5 ***Regional analgesic techniques***

5.3.5.1 Local anaesthetic agents

The most commonly used local anaesthetics are:

- bupivacaine
- l-bupivacaine
- ropivacaine.

Bupivacaine is considered to be cardiotoxic in high doses. l-Bupivacaine and ropivacaine appear to be safer, but the degree of motor blockage they provide is not as good as that of bupivacaine. Ropivacaine has the longest duration of action.

5.3.5.2 Epidural analgesia

Epidural analgesia provides excellent postoperative pain relief for extended periods after major surgery, and reduces postoperative complications and consumption of opioids (1,2) (LE: 1a) (Table 9).

Table 9: Typical epidural dosing schemes*

Drug	Single dose	Continuous infusion
Morphine	1-5 mg	0.1-1 mg/h
Fentanyl	50-100 µg	25-100 µg/h
Sufentanil	10-50 µg	10-20 µg/h
Pethidine	10-30 mg	10-60 mg/h

Bupivacaine 0.125% or ropivacaine 0.2% + fentanyl 2 µg/mL	10-15 mL	2-6 mL/h

**l-bupivacaine doses are equivalent to those of bupivacaine.*

5.3.5.3 Patient-controlled epidural analgesia (PCEA)

PCEA has become very common because it allows individualisation of dosage, decreased drug use, and greater patient satisfaction. It also seems to provide better analgesia than intravenous PCA (42,43) (LE: 1a) (Table 10).

Table 10: Typical PCEA dosing schemes

Drug	Demand dose	Lockout interval (min)	Continuous rate
Morphine	100-200 µg	10-15	300-600 µg/h
Fentanyl	10-15 µg	6	80-120 µg/h
Pethidine	30 mg	30	-
Bupivacaine 0.125% + fentanyl 4 µg/mL	2 mL	10	4 mL/h
Ropivacaine 0.2% + fentanyl 5 µg/mL	2 mL	20	5 mL/h

Recommendation	GR
Epidural analgesia, especially PCEA, provides superior post-operative analgesia, reducing complications and improving patient satisfaction, and is therefore preferable to systemic techniques (2).	A

5.3.5.4 Neural blocks

Local anaesthetic blocks (intermittent and continuous) can be used after urological surgical operations to supplement postoperative analgesia (44) (LE: 2a) (Table 11).

Table 11: Examples of neural blocks

Procedure	Drug/dosage
Iliohypogastric or ilioinguinal nerve infiltration after hernia repair	10-20 mL bupivacaine or ropivacaine 0.25-0.5%
Intercostal nerve infiltration	5-10 mL bupivacaine or ropivacaine 0.25-0.5%
Continuous intrapleural infusion	10 mL/h bupivacaine or ropivacaine 0.1-0.2%

5.3.5.5 Wound infiltration

Intraoperative wound infiltration with local anaesthetic (usually 10-20 mL ropivacaine or 0.25-0.5% bupivacaine) can provide some postoperative analgesia and may reduce the requirement for systemic analgesia (45) (LE: 2b).

5.3.5.6 Continuous wound instillation

Continuous postoperative wound instillation of a local anaesthetic via a multi-hole catheter placed intraoperatively by the surgeon has been shown to provide satisfactory analgesia for moderate to severe postoperative pain, reducing consumption of systemic analgesics (46-48) (LE: 2b).

5.3.6 ***Multimodal analgesia***

The concept of multimodal (balanced) analgesia is that combining different doses and routes of administration of analgesics improves the effectiveness of pain relief after surgery and reduces the maximal dosage and adverse effects (49) (LE: 2b). It seems to be more effective when different drugs are administered via different routes than when different drugs are administered via a single route (1) (LE: 2b).

Recommendations	GR
Multimodal pain management should be used whenever possible because it helps to increase efficacy while minimising adverse effects.	B

*5.3.7 **Special populations***

5.3.7.1 Ambulatory surgical patients

A multimodal analgesic plan uses a combination of NSAIDs or paracetamol plus local anaesthetics used as peripheral nerve blocks, tissue infiltration, or wound instillation so as to avoid the use of opioids, which can prolong hospital stay (50,51, LE: 2a; 52, LE: 2b).

Recommendations	GR
For postoperative pain control in outpatients, multimodal analgesia with a combination of NSAIDs or paracetamol plus local anaesthetics should be used.	B
If possible, avoid opioids.	B

5.3.7.2 Geriatric patients

Pain perception appears to be reduced in geriatric patients, and requirement for analgesia generally decreases with increasing age (53,54). Geriatric patients can also suffer from emotional and cognitive impairment such as depression and dementia, which could affect adequate pain management (55). Postoperative delirium in elderly patients is a common complication and is often multifactorial. It may be associated with administration of pethidine (56). Multimodal postoperative analgesia may be the pain management technique of choice in elderly patients, as the drug doses required are lower. However, it is important to be vigilant for adverse reactions, because they tend to increase in number in the geriatric population (57) (LE: 2b). Epidural analgesia might diminish the risk of postoperative delirium and respiratory complications in elderly patients (58) (LE: 2b).

Recommendations	GR
Multimodal and epidural analgesia are preferable for postoperative pain management in elderly patients because these techniques are associated with fewer complications.	B

5.3.7.3 Obese patients

Obese patients appear to be at higher risk for certain postoperative complications, including respiratory, cardiovascular and thromboembolic episodes, and wound infections (59,60). Administration of opioids to obese patients is associated with sudden respiratory arrest, therefore, a combination of NSAIDs or paracetamol with an epidural local anaesthetic might be the safest analgesic solution (61,62) (LE: 2b).

If absolutely necessary, opioids should be used with caution under careful titration to avoid depression of the respiratory drive (62). Oxygen therapy should also be applied postoperatively to increase oxygen saturation (63).

Recommendations	GR
Postoperative use of opioids should be avoided in obese patients unless absolutely necessary.	B
An epidural local anaesthetic in combination with NSAIDs or paracetamol is preferable.	B

5.3.7.4 Drug- or alcohol-dependent patients

It has been proved that regional anaesthesia and analgesia are preferable to opioids in drug addicts. Moreover, clonidine is beneficial in those with withdrawal syndrome due to opioid or alcohol abstinence and postoperative delirium tremens (64) (LE:1a).

5.3.7.5 Other groups

Critically ill or cognitively impaired patients present special difficulties. Regional or multimodal analgesia might be more effective in such patients because drug doses are reduced and behavioural interventions and patient-controlled methods are unsuitable (LE: 3).

Recommendations	GR
There are no sufficient data to support a specific postoperative pain management plan for critically ill or cognitively impaired patients.	B

*5.3.8 **Postoperative pain management teams***

The importance of efficient postoperative pain management has led to the development of acute postoperative pain management teams, which generally consist of nursing and pharmacy personnel led by an anaesthesiologist. They have been shown to improve pain relief, decrease analgesic side effects, improve patient satisfaction, and decrease overall costs and morbidity rates (65-67) (LE: 2b). Improved pain control can lead to shorter hospitalisation and fewer unscheduled readmissions after day surgery (68) (LE: 3).

5.4 Specific pain treatment after different urological operations

*5.4.1 **Extracorporeal shock wave lithotripsy (ESWL)***

ESWL is a minimally invasive treatment, during and after which 33-59% of patients do not need any analgesia (69-71) (LE: 2b). Post-treatment pain is unlikely to be severe and oral analgesics are usually sufficient.

Analgesic plan

- Preoperative assessment (see Section 5.3.2)
- Intraoperatively: experience exists for alfentanil (0.5-1.0 mg/70 kg iv), given on demand during ESWL.

NSAIDs or midazolam given 30-45 min before treatment reduces the need for opioids during the procedure (LE: 2b). With diclofenac premedication (100 mg rectally), only 18% of patients needed pethidine during lithotripsy (72). After premedication with 5 mg midazolam orally, 70% of patients were completely free of pain during treatment, and if buprenorphine was added, this proportion rose to 87% (73). After premedication with midazolam (2 mg iv, 5 min before treatment), diclofenac or tramadol was safe and effective, with fewer side effects than fentanyl (74) (LE: 1b). Other effective regimes for intraoperative pain treatment are fentanyl (1 µg/kg iv [75]), sufentanil or remifentanil. These drugs are usually given by the anaesthesiologist because of the risk of respiratory depression, which was significantly lower (20% vs 53%) after the procedure if remifentanil was used instead of sufentanil (76,77) (LE: 1b).

- Postoperative: NSAIDs, metamizole, paracetamol, codeine and paracetamol combination or tramadol can all be used on an as needed or time-contingent basis. If pain is more severe or persistent, examination is generally necessary to exclude hydronephrosis or renal haematoma.

Recommendations	GR
Analgesics should be given on demand during and after ESWL because not all patients need pain relief.	B
Premedication with NSAIDs or midazolam often decreases the need for opioids during the procedure.	B
iv opioids and sedation can be used in combination during ESWL; dosage is limited by respiratory depression.	C

Post-ESWL, analgesics with a spasmolytic effect are preferable (C).

*5.4.2 **Endoscopic procedures***

5.4.2.1 Transurethral procedures

Transurethral operations are usually performed under spinal anaesthesia (epidural or subarachnoid block) with the patient awake or mildly sedated, and usually with analgesia for 4-6 h after surgery. Pain is generally caused by the indwelling catheter or the double-J (ureteral stent following ureterorenoscopy), which mimics overactive bladder syndrome. Drugs with an antimuscarinic effect have been proven to be useful in addition to the opioids (78) (LE: 1b).

Analgesic plan

- Preoperative assessment: see Section 5.3.2.
- Intraoperative: spinal (intrathecal or epidural) anaesthesia provides intraoperative analgesia and last for 4-6 h postoperatively.
- Postoperative: after 4-6 h, mild oral analgesics such as NSAIDs or paracetamol ± codeine, or stronger opioids; also orally. In the case of bladder discomfort from the indwelling catheter, metamizole (orally or iv), pethidine (iv) or piritramide (iv) is also effective. Antimuscarinic drugs such as oxybutynin (5 mg

orally three times daily) are useful and reduce the need for opioids (78) (LE: 1b).

Recommendations	GR
Postoperative analgesics with spasmolytic effect or mild opioids are preferable.	C
Antimuscarinic drugs could be helpful in reducing discomfort resulting from the indwelling catheter.	B
Antimuscarinic drugs may reduce the need for opioids.	B

5.4.2.2 Percutaneous endoscopic procedures

The analgesic plan is nearly the same as that for transurethral procedures. Local anaesthetic (e.g., 10 mL 0.5% bupivacaine) can be infiltrated locally into the skin incision. General anaesthesia is required for the procedure because of the uncomfortable decubitus (prone position) and the prolonged duration of the operation.

5.4.2.3 Laparoscopic procedures

These procedures are performed under general anaesthesia, therefore, patients cannot take oral medication for at least 4-6 h postoperatively, so parenteral analgesia should be used. Then, oral or systemic analgesia can be given, depending on bowel motility.

A particular problem after laparoscopic cholecystectomy is the development of shoulder pain as a result of diaphragmatic irritation following pneumoperitoneum. This seems to be dependent on the intra-abdominal pressure used during the procedure, because reduced CO2 insufflation reduces postoperative shoulder pain (79-81) (LE: 1b). The same could apply for some transabdominal urological laparoscopic interventions.

Analgesic plan

Preoperative assessment: see Section 5.3.2.

Intraoperative: iv opioids ± NSAIDs, paracetamol or metamizole administered by an anaesthesiologist. The infiltration of local anaesthetic into the port incisions reduces pain after laparoscopy (82).

Postoperative: administration of systemic opioids iv (im or sc), is very effective in the immediate postoperative period. NSAIDs (e.g., paracetamol and/or metamizole) and incisional local anaesthetics (multimodal concept) can be given to reduce the need for opioids (82,83).

Recommendations	GR
Low intra-abdominal pressure and good desufflation at the end of the procedure reduces postoperative pain.	A
NSAIDS are often sufficient for postoperative pain control.	B
NSAIDs decrease the need for opioids.	B

5.4.3 ***Open surgery***

5.4.3.1 Minor operations of the scrotum/penis and the inguinal approach

These two types of operations are relatively minor and nearly all patients can take oral analgesics afterwards. The operation is often performed as an ambulatory procedure under local anaesthesia, or with the aid of an ilioinguinal or iliohypogastric nerve block.

Recommendations	GR
For postoperative pain control, multimodal analgesia with a combination of NSAIDs or paracetamol plus local anaesthetics should be used.	B
If possible, avoid opioids for outpatients.	C

5.4.3.2 Transvaginal surgery

General, local or regional anaesthesia can be used for these operations.

Recommendations	GR
NSAIDS are often sufficiently effective after minor or moderate surgery.	B
NSAIDs decrease the need for opioids.	B

5.4.3.3 Perineal open surgery

Analgesic plan

- Preoperative assessment: see Section 5.3.2.
- Intraoperative: general anaesthesia is usually used, particularly for perineal radical prostatectomy, because of the uncomfortable exaggerated lithotomy position. Sometimes an intrathecal catheter (epidural) can be sited for intra- and postoperative pain control.
- Postoperative: continuous epidural infusion of a combination of opioids and local anaesthetic or PCA is usually used. When systemic opioids are required, it is advisable to use them in combination with NSAIDs so as to reduce their dose and side effects. When the patient is able to take oral analgesics, metamizole or paracetamol ± codeine can be used.

5.4.3.4 Transperitoneal laparotomy

Analgesic plan

- Preoperative assessment: see Section 5.3.2.
- Intraoperative: general anaesthetic and regional technique; sometimes an intrapleural catheter can be sited.
- Postoperative: continuous epidural infusion of a combination of opioids and local anaesthetic. Once the patient is able to take oral analgesics (depending on bowel motility) metamizole, paracetamol ± codeine or tramadol can be used. Multimodal concepts (combining NSAIDs with opioids, fast-track strategies, keeping abdominal and urinary drainage as short as possible) are useful in reducing the need for analgesia (84).

Recommendations	**GR**
The most effective method for systemic administration of opioids is PCA (see Section 5.3.4.5), which improves patient satisfaction and decreases the risk of respiratory complications.	A
Epidural analgesia, especially PCEA, provides superior postoperative analgesia, reducing complications and improving patient satisfaction, and is preferable to systemic techniques (see Sections 5.3.5.2 and 5.3.5.3).	A

5.4.3.5 Suprapubic/retropubic extraperitoneal laparotomy

Postoperatively, it is possible to use the oral route for analgesia earlier than after a transperitoneal procedure. Oral opioids, metamizole and/or paracetamol ± NSAIDs can be used.

Analgesic plan

- Preoperative assessment: see Section 5.3.2.
- Intraoperative: general anaesthetic and regional technique.
- Postoperative: continuous epidural infusion of a combination of opioids and local anaesthetic. Once the patient is able to take oral analgesics metamizole, paracetamol ± codeine, ± NSAIDs can be used.

5.4.3.6 Retroperitoneal approach - flank incision - thoracoabdominal approach

Analgesic plan

- Preoperative assessment: see Section 5.3.2.
- Intraoperative: general anaesthetic and regional technique; sometimes an intrapleural catheter can be inserted.
- Postoperative: continuous epidural infusion of a combination of opioids and local anaesthetic gives significantly better pain control compared with iv analgesics (85,86) . If epidural analgesia is not possible or refused, PCA should be provided. Once the patient is able to take oral analgesics (depending on bowel motility) paracetamol ± codeine or metamizole can be associated (to reduce the need for opioids) or used alone.

Recommendations	**GR**
Epidural analgesia, especially PCEA, provides superior postoperative analgesia, reducing complications and improving patient satisfaction and is therefore preferable to systemic techniques (see Sections 5.3.5.2 and 5.3.5.3.	A

5.5 Dosage and method of delivery of some important analgesics

5.5.1 ***NSAIDs***

Table 12: Dosage and delivery of NSAIDs

Drug	Daily dose	Route of administration
Conventional NSAIDs (non-selective COX inhibitors)		
Ketorolac	10-30 mg four times daily	Orally or iv
Ibuprofen	400 mg three times daily	Orally
Ketoprofen	50 mg four times daily	Orally or iv
Diclofenac	75 mg twice daily	Orally or iv
	50 mg three times daily	Orally or iv
	100 mg twice daily	Rectally
COX-2 selective inhibitors		
Meloxicam	15 mg once per day	Orally
Lornoxicam	4-8 mg twice daily	Orally or iv
Celecoxib	200 mg once per day	Orally
Parecoxib	40 mg once or twice daily	iv form only
Etoricoxib	90-120 mg once daily	Orally

Table 13: Dosage and delivery of paracetamol, metamizole and its combinations with opioids

Drug	Method of administration	Single dose (mg)	Maximal dose (mg/day)
Paracetamol	Orally	500-1000	4000 (50 mg/kg)
Paracetamol	iv	1000	4000 (50 mg/kg)
Metamizole	Orally	500-1000	4000
Metamizole	iv	1000-2500	5000

Paracetamol	Opioid	Times per day	Route of administration
Paracetamol 1 g	Codeine 60 mg	Four	Orally or rectally
Paracetamol 600-650 mg	Codeine 60 mg	Four	Orally or rectally
Paracetamol 500 mg	Codeine 30 mg	Four	Orally or rectally
Paracetamol 300 mg	Codeine 30 mg	Four	
Orally or rectally			
Paracetamol 650 mg	Dextropropoxyphene 65 mg	Four	Orally
Paracetamol 600-650 mg	Tramadol 75-100 mg	Four	Orally
Paracetamol 325 mg	Oxycodone 5 mg	Four	Orally

5.5.2 ***Opioids***

Table 14: Dose and delivery of opioids

Drug	Method of administration	Common single dose (mg)	Maximal dose (mg)
Tramadol	Orally	50	400-600
Tramadol	iv	50-100	400-600
Dihydrocodeine	Orally	60-120	240
Piritramid	sc/im	15-30	120

Pethidine	Orally	25-150	500
Pethidine	Rectally	100	500
Pethidine	sc/im	25-150	500
Pethidine	iv	25-100	500
Morphine*	Orally	Starting with 10	No maximal dose
Morphine*	Rectally	Starting with 10	No maximal dose
Morphine*	sc/im	Starting with 5	No maximal dose
Morphine*	iv	Starting with 2	No maximal dose
Morphine*	iv (PCA)	0.5-2.5 mg bolus 10-15 min lockout	No maximal dose

**Strong opioids have no real upper dose limit (except buprenorphine). The dose must be titrated in correlation with pain relief and depending on the individual strength of unwanted effects such as respiratory depression (see Section 5.3.4.4).*
**A simple way of calculating the daily dose of morphine for adults (20-75 years) is: 100 - patient's age = morphine per day in mg.*

Table 15: Common equi-analgesic doses for parenteral and oral administration of opioids*

Drug	Parenteral (mg)	Oral (mg)
Morphine	10	30
Fentanyl	0.1	-
Pethidine	75	300
Oxycodone	15	20-30
Dextropropoxyphene	-	50
Tramadol	37.5	150
Codeine	130	200

**All listed opioid doses are equivalent to parenteral morphine 10 mg. The intrathecal opioid dose is 1/100, and the epidural dose 1/10 of the dose required systemically.*

5.6 Perioperative pain management in children

*5.6.1 **Perioperative problems***

The main preoperative problems in children are fear of surgery, anxiety about separation from their parents, and the pain of procedures such as venipuncture. Contrary to the popular belief, the presence of parents during anaesthesia induction does not alleviate children's anxiety (87) (LE: 1a). The preoperative use of oral morphine sulphate, 0.1 mg/kg, can help to prevent crying in children and thereby reduce oxygen consumption and pulmonary vasoconstriction (Table 16). The prior application of EMLA (2.5% lidocaine and 2.5% prilocaine) cream helps to reduce the pain of venipuncture (88) (LE: 1a). Atropine, 0.01-0.02 mg/kg iv, im, orally or rectally, prevents bradycardia during anaesthesia induction.

Table 16: Premedication drugs in children

Drug	Dosing	Route of administration	Category
Ketamine	6 mg/kg	Oral, intranasal, im	NMDA antagonist
Midazolam	0.5 mg/kg	Oral, intranasal, rectally	Benzodiazepine
Dexmedetomidine	4 µg/kg	Oral, intranasal	α2-receptor agonist
Clonidine	4 µg/kg	Oral	α2-receptor agonist
Pentobarbital	4-6 mg/kg	im	Barbiturate
Chloral hydrate	50-100 mg/kg	Oral	Barbiturate
Methohexital	25-30 mg/kg	Rectally	Barbiturate

Recommendations	GR
EMLA local application alleviates significantly venipuncture pain in children.	A

*5.6.2 **Postoperative analgesia***

Postoperatively, paracetamol, NSAIDs, opioids and their combinations are used according to the severity of the surgical procedure (Table 17).

Table 17: Dosage of analgesics in children for postoperative analgesia

Drug	Dose	Route of administration	Severity of surgical procedure
Paracetamol	10-15 mg/kg every 4 h 20-30 mg/kg every 6 h	Oral Rectally	Minor Minor
Ibuprofen	10-15 mg/kg every 6 h	Oral, iv, rectally	Minor, medium
Naproxen	6-8 mg/kg every 8-12 h	Oral, iv, rectally	Minor, medium
Codeine	0.5-1 mg/kg every 3-4 h	Oral	Minor, medium
Morphine	0.1 mg/kg every 2-4 h Infusion: 0.03 mg/kg/h 0.3 mg/kg every 3-4 h	iv, sc Oral	Medium, major
Oxycodone	0.1-0.2 mg/kg every 3-4 h	Oral	Medium
Hydromorphone	0.04-0.08 mg/kg every 3-4 h	Oral	Medium
Tramadol	1 mg/kg every 4-6 h	iv	Medium, major
Pethidine	2-3 mg/kg every 3-4 h	iv	Medium, major

The postoperative use of COX-2 inhibitors in children is still controversial. PCA can be used safely in children older than 6 years. Nurse-controlled analgesia is effective in infants and children unable to use PCA (89).

Locoregional techniques such as wound infiltration, nerve blocks, and caudal and epidural analgesia are also successful (90,91). The most commonly drugs used are bupivacaine and ropivacaine (Table 18). Higher volumes of lower drug concentrations appear to be more effective than lower volumes of higher concentrations (92) (LE: 1a). The addition of opioids, ketamine or clonidine increases the duration of pain relief and reduces the need for rescue analgesia, thus providing more effective pain relief than local anaesthesia alone in caudal analgesia (93-95) (LE: 1a).

Table 18: Epidural dose of local anaesthesia

Drug	Bolus 0-12 months	Bolus > 1 year	Infusion for 0-12 months	Infusion > 1year
Bupivacaine	2 mg/kg	2.5 mg/kg	0.2 mg/kg/h	0.4 mg/kg/h
Ropivacaine	2.5 mg/kg	3.5 mg/kg	0.3 mg/kg/h	0.6 mg/kg/h

6. NON-TRAUMATIC ACUTE FLANK PAIN

6.1 Background

Acute flank pain is a frequently occuring and complex medical problem. Ureterolithiasis is the most common non-traumatic cause. However, half of all renal colics are not caused by urolithiasis (1-3) (Table 32).

Table 32: Main urological and non-urological causes of flank pain

Urological causes	Non-urological causes
Renal or ureteral stones	Aortic aneurysm
Urinary tract infection (pyelonephritis, pyonephrosis, renal abscess)	Gallbladder disorder
Uretero-pelvic junction obstruction	Gastrointestinal disorders
Renal vascular disorders (renal infarction, renal vein thrombosis)	Pancreatic disease
Papillary necrosis	Gynaecological disorders
Intra- or peri-renal bleeding	Musculoskeletal disease
Testicular cord torsion.	

6.2 Initial diagnostic approach

*6.2.1 **Symptomatology***

History and physical examination, including body temperature, can be very helpful in the differential diagnosis of acute flank pain (4).

- **Acute renal colic** is indicated by pain of short duration (< 12 hours), nausea, vomiting, loin tenderness and haematuria (erythrocytes > 10,000/mm3) (4).
- Because the signs and symptoms can be very similar, **acute uncomplicated pyelonephritis** should be immediately differentiated from complicated renal colic:
  - concomitant fever (> 38°C) makes imaging obligatory (5). A radiological evaluation of the upper urinary tract should be offered to every patient presenting with flank pain and fever to rule out urinary tract obstruction irrespective of the accompanying symptoms, duration of the episode and urine macroscopic or microscopic findings.
  - imaging is also imperative in patients with acute flank pain and a solitary kidney (LE: 4).
- **Acute flank pain in patients with an increased risk for thromboembolic events should raise the** suspicion of **renal infarction** (6).
- Careful abdominal examination can reveal an abdominal **aortic aneurysm** (misdiagnosed in 30% of patients).
- **Renal vein thrombosis** (RVT) may often present with symptoms of acute flank pain, proteinuria, haematuria, hypotension and renal insufficiency.
- **Obstruction of the UPJ** can result in acute flank or abdominal pain after a high fluid volume intake, especially in paediatric patients.
- **Renal papillary necrosis** is not uncommon in the course of systemic diseases such as diabetes mellitus or analgesic nephropathy; the passage of sloughed papillae down the ureter may cause flank pain and haematuria.
- **Testicular torsion** should always be excluded in children with acute abdominal/flank pain.
- **Torsion of the appendix testis** can also result in abdominal pain or radiate to the flank.
- **Spontaneous bleeding** either within the kidney or to the retroperitoneum can be caused by kidney tumours (including angiomyolipomas), bleeding disorders or anticoagulation; acute flank pain is sometimes the presenting symptom.

Recommendation	GR
Febrile patients (> 38°C) with acute flank pain and/or with a solitary kidney need urgent imaging.	B

*6.2.2 **Laboratory evaluation***

All patients with acute flank pain require a urine test (red and white cells, bacteria or urine nitrite), blood cell count, and serum creatinine measurement. In addition, febrile patients with flank pain require C-reactive protein and urine culture. Pyelonephritis ± obstructive uropathy should be suspected when the white blood count exceeds 15,000/mm^3.

*6.2.3 **Diagnostic imaging***

6.2.3.1 Ultrasonography

Unenhanced helical computed tomography has high sensitivity and specificity for the evaluation of acute flank pain (7,8) (LE: 1a). Unenhanced helical computed tomography is superior because it detects ureteral stones with a sensitivity and specificity of 94-100%, regardless of stone size, location and chemical composition, and identifies extraurinary causes of flank pain in about one-third of all patients presenting with it. In addition, it does not need contrast agent, and is a time-saving technique (8,9) (LE: 1a).

6.2.3.2 Intravenous urography (IVU)

The use of US in the management of acute flank pain has been increasing. If the findings of pelvic and/or ureteral dilatation, stone visualisation and the absence of ureteral ejaculation are combined, sensitivity to ureteral dilatation can be 96% (7,10,11) (LE: 2a). Together with a plain abdominal radiograph, US can be accepted when computed tomography (CT) is not available (7,12-16) (LE: 1b).The disadvantages of US include inability to differentiate dilatation from true obstruction and the need for highly specialised personnel (12). Sensitivity varies from 58-96% in untrained staff in emergency rooms (15), but evidence suggests that, with even short training, non-specialists can be highly effective at excluding disorders such as abdominal aortic aneurysm, free abdominal fluids, gallstones and obstructive uropathy (15) (LE: 2b). US is the diagnostic imaging modality of choice during pregnancy.

6.2.3.3 Unenhanced helical CT (UHCT)

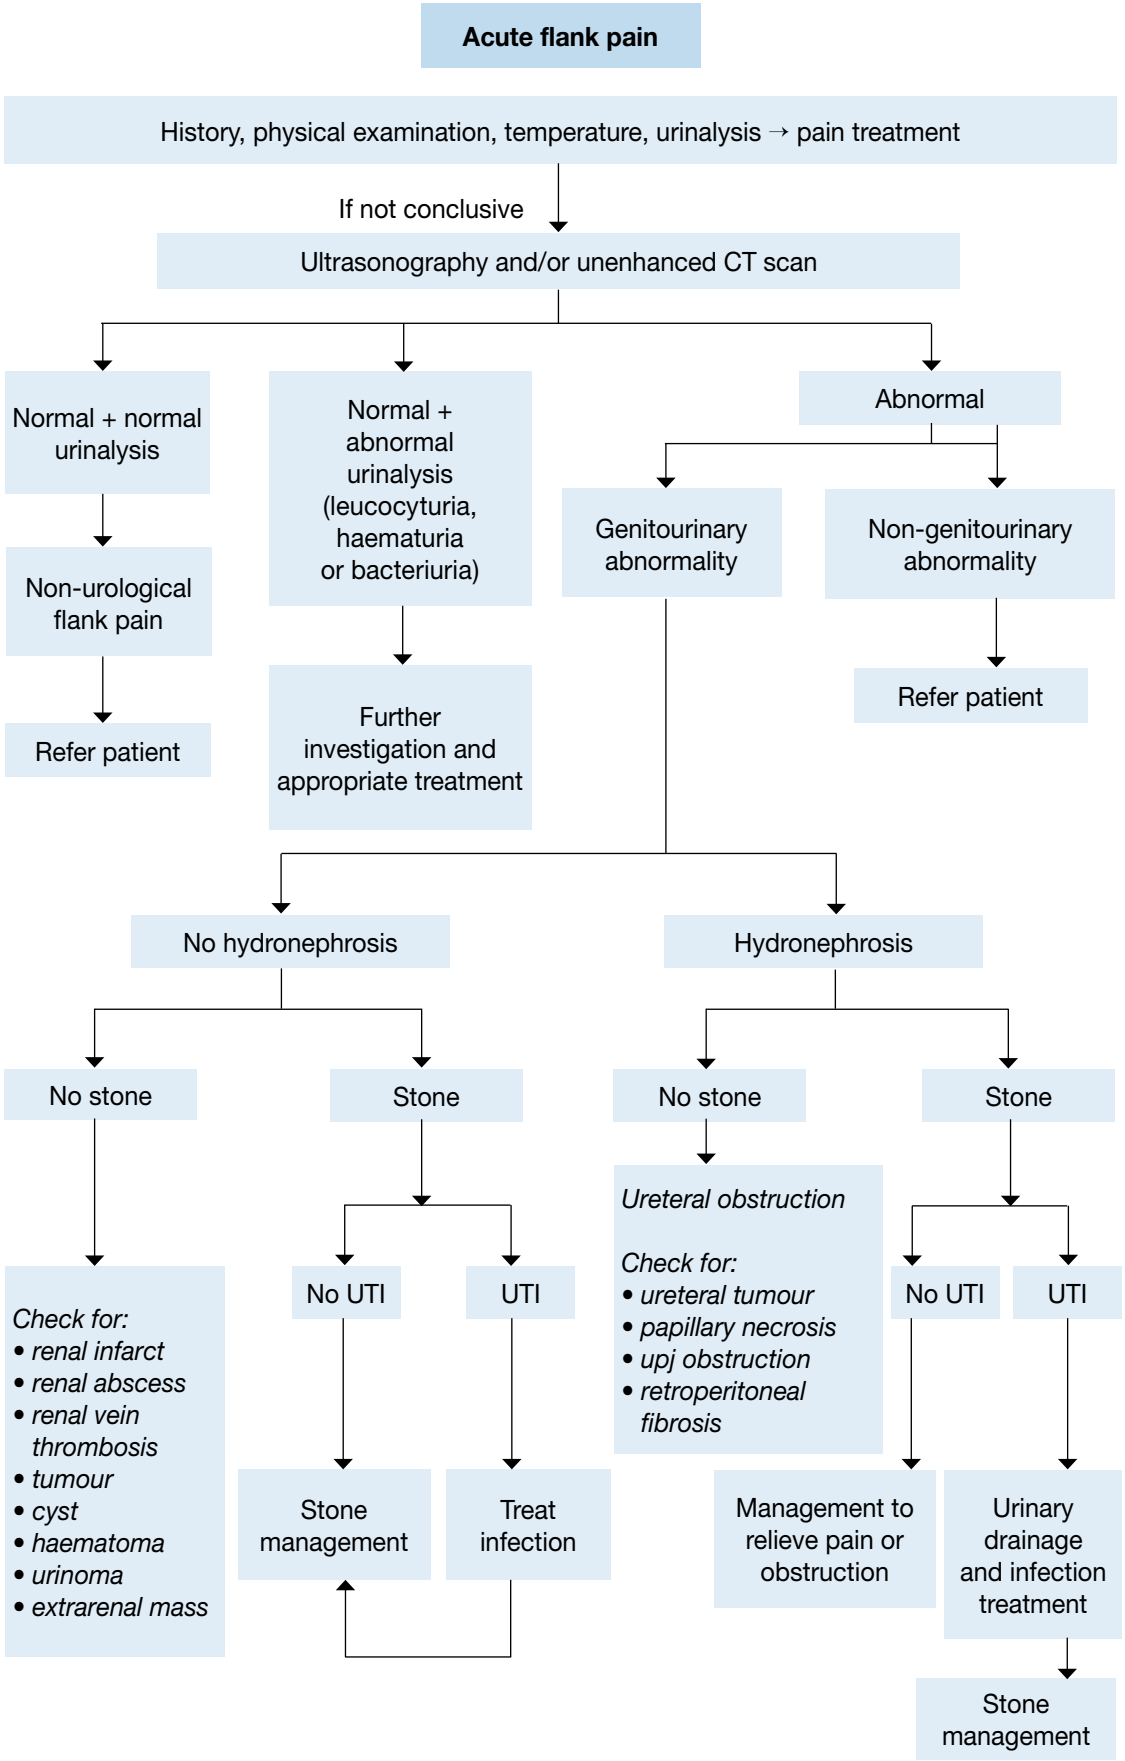
IVU reliably provides information on the anatomy of the urinary collecting system (ureteral and renal pelvic dilatation) in 80-90% of cases and can indentify ureteral calculi in 40-60% of cases.

Direct identification of ureteral calculi can be achieved in 40-60% of cases, whereas indirect signs (e.g. ureteral and renal pelvic dilatation) allows detection in 80-90% of cases. Drawback is that IVU results can be hampered by poor quality related to suboptimal bowel preparation, toxicity of contrast agents, allergic and anaphylactic reactions, and by significant radiation exposure. In emergency cases, IVU should be avoided due to the risk of fornix rupture.

UHCT or IVU should be considered in patients initially evaluated by other means who are still febrile after 72 h of treatment to rule out further complicating factors (renal, perinephric or prostatic abscesses) (8,9).

Table 33 shows comparative results of UHCT US and IVU in assessing acute flank pain and suspicion of ureterolithiasis (17-19). Figure 2 summarises the diagnostic approach to non-traumatic acute flank pain.

Figure 2: Diagnostic approach to non-traumatic acute flank pain



CT = computed tomography; UTI = urinary tract infection.

Recommendations	GR
Unenhanced helical computed tomography is the diagnostic imaging modality with the highest sensitivity and specificity for evaluation of non-traumatic acute flank pain.	A
Ultrasound can be an alternative to unenhanced helical computed tomography in the initial approach to non-traumatic acute flank pain.	A

Table 33: Comparative results of UHCT, US and IVU in assessment of acute flank pain and suspected ureterolithiasis (12)

Imaging modality	Performance	Ref. no.
UHCT	Sensitivity 100%, specificity 96%, accuracy 98%	17
Abdominal radiograph + US versus UHCT	UHCT: sensitivity and specificity of 100% US: sensitivity 100%, specificity 90%	18
Low-dose UHCT versus IVU	UHCT: sensitivity 97%, specificity 96% Low-dose UHCT is superior to IVU	19

6.3 Initial emergency treatment

*6.3.1 **Systemic analgesia***

Pain relief is usually the first, most urgent, therapeutic step (20,21):

- Intravenous (iv) non-steroidal anti-inflammatory drugs (nsaids) are very effective in most cases, e.g. a bolus of diclofenac sodium, 75 mg (le: 1a) (21); a slow iv injection of ketorolac, 30 mg, 4 times daily, is equivalent to diclofenac in the treatment of renal colic (22).
- Tests have shown a single dose of dipyrone to be less effective than diclofenac, 75 mg (23) (le: 1a), but a slow iv infusion of dipyrone, 1 g or 2 g, is just as effective as diclofenac (24).
- In cases of unresponsiveness to diclofenac (25) (le: 1b), or contraindication of NSAIDs (24) (le: 1b), iv papaverine hydrochloride (120 mg) is a safe and effective alternative.
- Large-scale studies have shown that NSAIDs and opioids are both effective analgesics, but vomiting is more prevalent with opioids (particularly pethidine) (21).
- The combination of iv morphine + ketorolac seems superior to either drug alone, and appears to be associated with a decrease in the need for rescue doses of analgesia (26).
- Antimuscarinics are often used in acute renal colic; there is no evidence that hyoscine butylbromide reduces opioid requirements in this condition (26) (LE: 1b).

The origin of the pain should be immediately clarified in febrile patients and those with a solitary kidney.

Recommendation	GR
In patiens presenting with acute flank pain NSAIDs such as diclofenac (75 mg bolus) and dipyrone (1-2 g slow iv injection) are the drugs of first choice.	A

*6.3.2 **Local analgesia***

A number of manipulations have been tested in the field of acute renal colic.

- Local warming of the abdomen and lower back region seems to decrease pain in patients with acute renal colic (27) (LE: 1a).
- Trigger-point injection of lidocaine can provide effective pain relief in 50% of patients with renal colic (28); it is significantly better than iv butylscopolamine bromide + sulpyrine (28) (LE: 1a). There are no comparative studies with NSAIDs.

*6.3.3 **Supportive therapy***

Patients with acute flank pain often present with moderate to severe dehydration. Fever, vomiting and anorexia produce serious discomfort and should be treated from the outset. If possible, iv fluids should be generous (60 mL/h normal saline and 60 mL/h 5% glucose solution), but maintenance iv fluids (20 mL/h normal saline) can be as effective as forced hydration with regard to pain perception and analgesic use (29) (LE: 1b). No clear evidence supports using diuretics to treat acute ureteral colic (30). Metoclopramide chloride (0.5 mg/kg/24 h in three divided doses) can be effective in controlling nausea and vomiting irrespective of aetiology (infectious, obstructive, oncological).

*6.3.4 **Upper urinary tract decompression***

If pain relief cannot be achieved using medical therapy and there are signs of infection and impaired renal

function, upper urinary tract drainage should be undertaken. The main indications for stenting for urgent relief of obstruction include (31):

- urine infection with urinary tract obstruction
- urosepsis
- intractable pain and/or vomiting
- obstruction of a solitary or transplanted kidney
- bilateral obstructing stones
- ureteral calculus obstruction in pregnancy.

6.4 Aetiological treatment

*6.4.1 **Urolithiasis***

General concepts for treating urolithiasis have been defined in the EAU Guidelines on Urolithiasis (32).

*6.4.2 **Infectious conditions***

Infectious uncomplicated conditions (i.e. acute pyelonephritis in otherwise healthy individuals) should be treated with appropriate antibiotics and analgesics according to the EAU Guidelines on Urological Infections (33).

The first-line treatment of mild cases should be an oral fluoroquinolone (twice daily for 7 days) in areas with low rates of fluoroquinolone-resistant Escherichia coli. In areas with raised resistance rates, or in pregnancy, lactation or adolescence, a second- or third-generation oral cephalosporin is recommended. Pain can usually be controlled with oral NSAIDs (diclofenac 75 mg, three times daily, or dipyrone 500 mg three times daily) except in pregnant or lactating women.

*6.4.3 **Other conditions***

6.4.3.1 Uretero-pelvic junction obstruction

Uretero-pelvic junction obstruction obstruction can result in intermittent flank or abdominal pain. Symptoms may worsen during brisk diuresis (after consumption of caffeine or alcohol). Dismembered or non-dismembered pyeloplasty is standard. A ureteral stent can help to relieve pain in very symptomatic patients prior to definitive surgery. Outcomes are excellent, with resolution of the obstruction in 90-95% of cases, including newborns (34).

6.4.3.2 Papillary necrosis

Papillary necrosis commonly presents as painless macroscopic haematuria, but can be complicated by ureteral obstruction. As well as symptomatic treatment, treatment should be given for the underlying cause of papillary necrosis, such as interstitial nephritis, acute pyelonephritis, diabetes mellitus, analgesic abuse or sickle cell disease. Ureteral obstruction due to sloughed papillae can be successfully treated with ureteroscopy or temporary ureteral stenting (35).

6.4.3.3 Renal infarction

There is no specific treatment for acute renal infarction, but the underlying disease (atrial fibrillation, left ventricular thrombus or a hypercoagulable state) may require anticoagulation with iv heparin followed by warfarin to prevent future events (36).

6.4.3.4 RVT

RVT is often clinically silent, but can present with acute flank pain. Systemic anticoagulation with heparin to prevent further propagation of thrombus or other thromboembolic phenomena (37) is standard, but the successful use of fibrinolytic agents in selected patients without clinical contraindications has been reported (38). Thrombectomy or nephrectomy is reserved for cases refractory to medical therapy.

6.4.3.5 Intra- or peri-renal bleeding

Acute spontaneous intra- or peri-renal bleeding often results in acute flank pain. Spontaneous renal haemorrhage (Wunderlich's syndrome), is an unusual and life-threatening cause of acute abdomen. Nephrectomy is usually the only therapeutic alternative (39,40).

6.4.3.6 Testicular cord torsion

Testicular cord torsion can produce lower abdomen and flank pain; it should be treated surgically at once.

7. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations.

AMPA	α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate
ATC	around-the-clock
CNS	central nervous system
COX	cyclo-oxygenase
CT	computed tomography
EDTMP	ethylenediaminetetramethylenephosphonate
EORTC	European Organisation for Research and Treatment of Cancer
ESWL	extracorporeal shock wave lithotripsy
GABA	gamma-aminobutyric acid
GFR	glomerular filtration rate
GCP	good clinical practice
IASP	International Association for the Study of Pain
Im	intramuscular
iv	intravenous
IVU	intravenous urography
^{131}J-MIBG	131J-metaiodobenzylguanidine
MRI	magnetic resonance imaging
NMDA	N-methyl-D-aspartate
NRS	numerical rating scale
NSAIDs	non-steroidal anti-inflammatory drugs
PACU	post-anaesthesia care unit
PCa	prostate cancer
PCA	patient-controlled analgesia
PCEA	patient-controlled epidural analgesia
prn	as needed
PRPE	perineal radical prostatectomy
RCC	renal cell carcinoma
RLND	retroperitoneal lymph node dissection
sc	subcutaneous
^{153}Sm	samarium-153
^{89}Sr	strontium-89
SRI	selective serotonin reuptake inhibitors
SPECT	single photon emission computed tomography
TCA	tricyclic antidepressants
TCC	transitional cell carcinoma
TURB	transurethral resection of bladder tumour
TURP	transurethral resection of prostate
UHCT	unenhanced helical CT
VAS	visual analogue scale
VRS	verbal rating scale
WHO	World Health Organization

Conflict of interest

All members of the General Pain Management Guidelines working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on
Chronic Pelvic Pain

1. INTRODUCTION

1.1 The Guideline

Chronic pelvic pain (CPP) is a prevalent condition which can present a major challenge to health care providers due to its complex aetiology and poor response to therapy.
Chronic pelvic pain is a multifactorial condition and therefore, quite often, poorly managed. Management requires knowledge of all pelvic organ systems and their association with other systems and conditions, including musculoskeletal, neurologic, urologic, gynaecologic and psychological aspects, promoting a multidisciplinary approach.
The European Association of Urology (EAU) Guidelines Working Group for Chronic Pelvic Pain prepared this guidelines document to assist urologists and medical professionals from associated specialties, such as gynaecologists, psychologists, gastroenterologists and sexologists, in assessing the evidence-based management of CPP and to incorporate evidence-based recommendations into their every-day clinical practice.

*1.1.1 **Panel composition***

The panel of experts responsible for this document include urologists, a neuro-urologist, consultants in pain medicine, a gynaecologist, a psychologist, a gastroenterologist and a sexologist.

*1.1.2 **Publication history***

The EAU Guidelines on Chronic Pelvic Pain were first published in 2003 (1) which formed the basis of a scientific publication in European Urology in 2004 (2). Also, in the 2003 edition the concept of Chronic Pelvic Pain Syndromes (CPPS) was introduced, which is now referred to as “pain as a disease process”.

Partial updates of the CPP guidelines were published in 2008 and formed the basis for another scientific publication in European Urology in the year 2010 (3,4).

For this 2012 update the panel focused on:

1. restructuring the text to emphasise the significance of holistic management of CPP;
2. addressing the changes in the management of CPPS based on the concept of pain as a disease process.

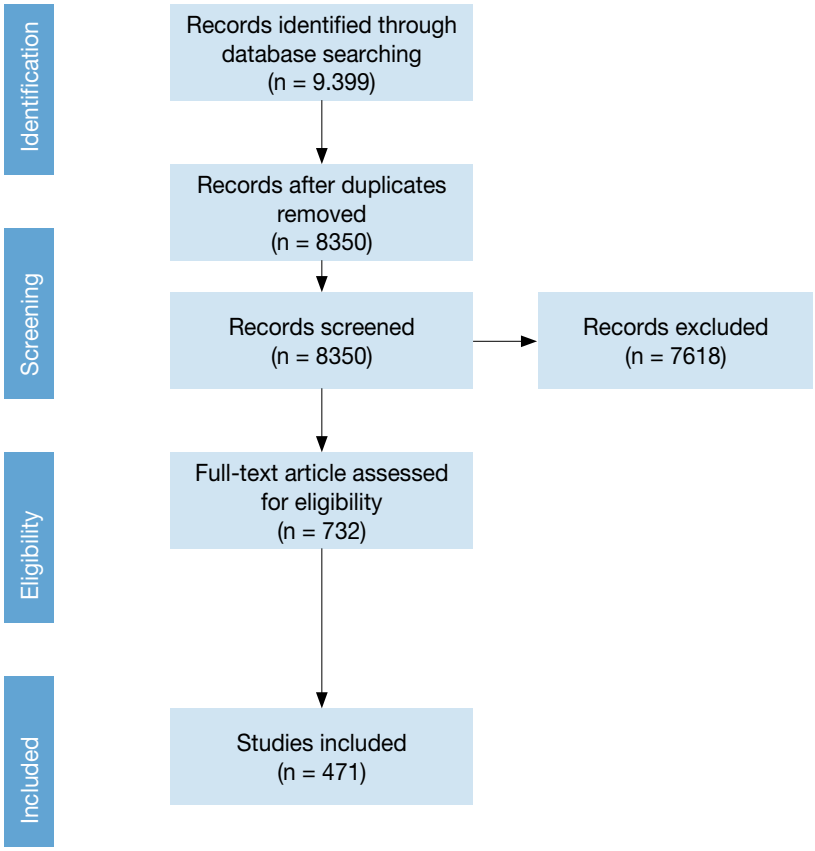
As a result, two new chapters have been added; Chapter 5 ‘Gastrointestinal aspects of chronic pelvic pain’ and Chapter 7 ‘Sexological aspects of chronic pelvic pain.

A quick reference document presenting the main findings of these CPP guidelines (pocket guidelines) is also available and has been updated. All texts, alongside scientific publications, can be viewed and downloaded for personal use at the EAU website: http://www.uroweb.org/guidelines/online-guidelines/.

1.2 Methodology

The full text update is based on a systematic review of literature using the Embase and Medline databases, the Cochrane Central Register of controlled trials and the PsycInfo and Bandolier databases to identify the best evidence from RCTs, Level of Evidence 1 (LE1), according to the rating schedule adapted from the Oxford Centre for Evidence-based Medicine Levels of Evidence (Table 1) [5]. Where no LE1 literature could be identified the search was moved down to the next lower level on the rating scale. Extensive use of free text ensured the sensitivity of the searches, resulting in a substantial body of literature to scan. Searches covered the period January 1995 and May 2011 and were restricted to English language publications.

Flowdiagram update procedure



*1.2.1 **Level of evidence and grade of guideline recommendations****

References used in the text have been assessed according to their level of evidence (Table 1), and recommendations have been graded (Table 2) according to the Oxford Centre for Evidence-based Medicine Levels of Evidence (5). The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence (LE)*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected Authorities

Modified from Sackett et al. (5)

It should be noted that when recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of randomised controlled trials (RCTs) may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Alternatively, absence of high level evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful for the reader. The quality of the underlying scientific evidence - although a very important factor - has to be balanced against benefits and

burdens, values and preferences and cost when a grade is assigned (6-8).

The EAU Guidelines Office, do not perform cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever this data is available, the expert panels will include the information.

Table 2: Grade of recommendation (GR)*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett et al. (5)*

*1.2.2 **Formal review***

A formal review was carried out prior to publication by a multidisciplinary team of international experts, covering the different fields of expertise described in these guidelines.

1.3 Acknowledgements

The expert panel should like to express their gratitude to professor Magnus Fall, former chairman and patriarch of the CPP panel who established the foundation of these guidelines, the current expert panel can now build on.

Prof. Jan Borovicka, gastro-enterologist at the Kantonsspital St. Gallen, Switzerland, authored Chapter 5 'Gastrointestinal aspects of chronic pelvic pain' of this document.

Dr. Yacov Reisman, urologist at the Amstelland Hospital in Amstelveen and sexologist at the Academic Medical Center in Amsterdam, the Netherlands, authored Chapter 7 'Sexological aspects of chronic pelvic pain'.

The CPP panel are most grateful for their assistance and willingness to lend their expertise to the EAU and their Guidelines Office. Their input greatly enhance these guidelines.

The support provided by research scientist Drs. J. Krabshuis has proved to be highly valuable in enhancing the methodological quality of this publication.

2. CHRONIC PELVIC PAIN

2.1 Introduction to chronic urogenital pain syndromes

Over the years much of the focus for CPP has been on peripheral-end-organ mechanisms, such as inflammatory or infective conditions. However, both animal and clinical research have indicated that many of the mechanisms for the CPP syndromes are based within the central nervous system (CNS). Although a peripheral stimulus such as infection may initiate the start of a CPP condition, the condition may become self-perpetuating as a result of CNS modulation, independent of the original cause. As well as pain, these central mechanisms are associated with several other sensory, functional, behavioural and psychological phenomena. It is this collection of phenomena that forms the basis of the pain syndrome diagnosis and individual phenomena need to be addressed in their own right through multispecialty and multidisciplinary care.

Although ongoing peripheral organ pathology can produce persistent and chronic pain, the main focus of these guidelines is on CPP syndromes in which no peripheral ongoing pathology (such as infection or neoplastic disease) is detected. The main exception is when pain is due to peripheral nerve damage, which will be discussed in chapter 6.

2.2 Pain mechanisms - pain as a disease process

Chronic pelvic pain mechanisms may involve:

1. Ongoing acute pain mechanisms (1) (such as those associated with inflammation or infection) - which may involve somatic or visceral tissue.
2. Chronic pain mechanisms, which especially involve the CNS (2).
3. Emotional, cognitive, behavioural and sexual responses and mechanisms (3-6).These will be covered in chapter 8.

Table 3 illustrates some of the differences between the somatic and visceral pain mechanisms. They underlie some of the mechanisms that may produce the classical features of visceral pain; in particular, referred pain and hyperalgesia.

Table 3: comparison between visceral and somatic pain

	Visceral pain	**Somatic pain**
Effective painful stimuli	Stretching and distension, producing poorly localised pain.	Mechanical, thermal, chemical and electrical stimuli, producing well localised pain.
Summation	Widespread stimulation produces significantly magnified pain.	Widespread stimulation produces a modest increase in pain.
Autonomic involvement	Autonomic features (e.g., nausea and sweating) frequently present.	Autonomic features less frequent.
Referred pain	Pain perceived at a site distant to the cause of the pain is common.	Pain is relatively well localised but well recognised.
Referred hyperalgesia	Referred cutaneous and muscle hyperalgesia is common, as is involvement of other visceral organs.	Hyperalgesia tends to be localised.
Innervation	Low density, unmyelinated C fibres and thinly myelinated A∂ fibres.	Dense innervation with a wide range of nerve fibres.
Primary afferent physiology	Intensity coding. As stimulation increases afferent firing increases with an increase in sensation and ultimately pain.	Two fibre coding. Separate fibres for pain and normal sensation.
Silent afferents	50-90% of visceral afferents are silent until the time they are switched on. These fibres are very important in the central sensitisation process.	Silent afferents present, but form a lower percentage.

Central mechanisms	Play an important part in the hyperalgesia, viscero-visceral, viscero-muscular and musculo-visceral hyperalgesia. Sensations not normally perceived become perceived and non-noxious sensations become painful.	Responsible for the allodynia and hyperalgesia of chronic somatic pain.
Abnormalities of function	Central mechanisms associated with visceral pain may be responsible for organ dysfunction.	Somatic pain associated with somatic dysfunction, e.g., muscle spasm.
Central pathways and representation	As well as classical pathways, there is evidence for a separate dorsal horn pathway and central representation.	Classical pain pathways.

*2.2.1 **Ongoing peripheral visceral pain mechanisms as a cause of CPP***

In most cases of CPP, ongoing tissue trauma, inflammation or infection is not present (7-10). However, conditions that produce recurrent trauma, infection or ongoing inflammation may result in CPP in a small proportion of cases. It is for this reason that the early stages of assessment include looking for these pathologies (11). Once excluded, ongoing investigations for these causes are rarely helpful and indeed may be detrimental.

When acute pain mechanisms are activated by a nociceptive event, as well as direct activation of the peripheral nociceptor transducers, sensitisation of those transducers may also occur, thus magnifying the afferent signalling. Afferents that are not normally active may also become activated by the change, that is, there may be activation of the so-called silent afferents. Although these are mechanisms of acute pain, the increased afferent signalling is often a trigger for the chronic pain mechanisms that maintain the perception of pain in the absence of ongoing peripheral pathology (see below) (12,13).

There are a number of mechanisms by which the peripheral transducers may exhibit an increase in sensibility.

1. Modification of the peripheral tissue, which may result in the transducers being more exposed to peripheral stimulation.
2. There may be an increase in the chemicals that stimulates the receptors of the transducers (14).
3. There are many modifications in the receptors that result in them being more sensitive.

In general, the effect of 1 and 2 is to lower the threshold and the effect of 3 is to increase responsiveness to external stimuli.

Some of the chemicals responsible for the above changes may be released from those cells associated with inflammation, but the peripheral nervous system may also release chemicals in the form of positive and inhibitory loops (Table 4) (15).

Table 4: mechanisms in the periphery that effect nociceptor response to a nociceptive stimulus

Nerve growth factor (NGF)	May activate primary afferents directly, but also indirectly such as through bradykinin (16). The result is an increase in response of the primary afferents, with multiple action potentials being generated in response to a stimulus, as opposed to just one or two. The TrkA-NGF complex formed on the afferent neurons may also be transmitted centrally where it may alter gene expression. Such long-term gene modification may underlie some of the mechanisms of chronic NGF-induced hypersensitivity.
Adenosinetriphosphate (ATP)	Is thought to be released in increased amounts from certain viscera when stimulated by noxious stimuli. As well as this increased ATP producing an increased stimulation of its receptors, when inflammation is present, the ATP receptors have their properties changed so that there is an increased response per unit of ATP contributing to the nociceptor activation. ATP is thought to act on P2X3 purine receptors, which are found on visceral afferents and small-diameter dorsal root ganglion (DRG) neurons.
Substance P and other neurokinins (17)	Act on afferent tachykinin receptors, such as TRPV1, which is a transducer for noxious heat and protons, and are thought to play a primary role in inflammatory hyperalgesia.

Voltage-gated ion channels	E.g., tetrodotoxin-resistant sodium channel, NaV1.8 are also implicated in peripheral sensitisation. These channels open or close in response to changes in membrane potential. Changes in potassium and calcium voltage-gated channels may also underlie a part of the mechanism responsible for peripheral sensitisation.
Second messenger pathways	Within the primary afferents enable amplification of peripheral messages that they receive. In general, these pathways are balanced by others that are responsible for reducing any activation. During chronic pain, these mechanisms may become imbalanced.

*2.2.2 **Central sensitisation - spinal and higher mechanisms of visceral pain***

There are essentially three processes at the spinal cord level that are involved in central sensitisation (17). Changes in existing protein activity (post-translational processing) are the earliest (within minutes); however, changes in genetic transcription of proteins and even structural changes in neuron connectivity may also have roles to play. These latter changes may occur within days (18).

The chemicals involved in the early phase include several neurotransmitters such as glutamate, substance P, calcitonin gene-related peptide (CGRP), prostaglandin E2 and brain-derived neurotrophic factor (BDNF) (15).

Increased levels of glutamate, due to recurrent afferent nociceptive fibre activity, remove the magnesium ion block of N-methyl-D-aspartate (NMDA). This allows calcium ions to enter the secondary afferents with enhanced depolarisation. Glutamate also binds to amino-methylene-phosphonic acid (AMPA), which may be another pathway by which it increases intracellular calcium. Other transmitters/modulators released centrally include: substance P, which acts on neural kinin receptors; PGE2, which binds to endogenous prostanoid receptors; and BDNF, which acts on tyrosine kinase B receptors and all of these may also increase intracellular calcium.

The calcium ions act to lower the threshold for second-order neuron firing, with increased signalling being transmitted to the higher centres. The second important feature of this increase in calcium ions is inpost-translational processing; this usually involves the addition of phosphate groups to amino acids by kinases. Phosphorylation can dramatically alter the properties of a protein, typically lowering the threshold at which channels open, but also, the channels remain open for longer. The result is that a stimulus produces a magnified evoked response in these neurons.

*2.2.3 **Spinal mechanisms and visceral hyperalgesia***

Central sensitisation (18) is responsible for a decrease in threshold and increase in response duration and magnitude of dorsal horn neurons. It is associated with an expansion of the receptive field. As a result, sensitisation increases signalling to the CNS and amplifies what we perceive from a peripheral stimulus. As an example, for cutaneous stimuli, light touch would not normally produce pain, however, when central sensitisation is present, light touch may be perceived as painful (allodynia). In visceral hyperalgesia (so called because the afferents are primarily small fibres), visceral stimuli that are normally subthreshold and not usually perceived may be perceived. For instance, with central sensitisation, stimuli that are normally subthreshold may result in a sensation of fullness and a need to void the bladder or to defecate. Stimuli normally perceived may be interpreted as pain and stimuli that are normally noxious may be magnified (true hyperalgesia) with an increased perception of pain. As a consequence, one can see that many of the symptoms of the bladder pain syndrome (BPS) (formally known as interstitial cystitis (IC) and irritable bowel syndrome (IBS) may be explained by central sensitisation. A similar explanation exists for the muscle pain of fibromyalgia.

*2.2.4 **Supraspinal modulation of pain perception***

It is important to appreciate that nociception is the process of transmitting to centres involved in perception information about a stimulus that has the potential to cause tissue damage. Pain is far more complex and involves activation of the nociceptive pathways but also the emotional response. Pain is defined by the International Association for the Study of Pain (IASP) as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage” (19). The brain may affect the modulation of pain pathways at the spinal cord level.

*2.2.5 **Higher centre modulation of spinal nociceptive pathways***

It is now well accepted that there are both descending pain-inhibitory and descending pain-facilitary pathways that originate from the brain (20).

The midbrain periaqueductal grey (PAG) plays an important part in spinal modulation. It receives inputs from centres associated with thought and emotion. Projections from the PAG (via several relay systems) to the dorsal horn can inhibit nociceptive messages from reaching conscious perception by spinal mechanisms. The PAG and its associated centres may also be involved in diffuse noxious inhibitory control (DNIC). DNIC is when a nociceptive stimulus in an area far from the receptive fields of a second nociceptive stimulus can prevent or reduce pain from that second area. This is thought to be the mechanism for the paradigm of counter-irritation.

Several neurotransmitters and neuromodulators are involved in descending pain-inhibitory pathways. The main contenders are the opioids, 5-hydroxytryptamine and noradrenaline.

The pathways and chemicals for the facilitary modulation are even less well understood, but the mechanisms are well accepted.

*2.2.6 **Neuromodulation and psychology***

Psychological processes of emotions, thought and behaviour involve networks rather than distinct centres. Some of these processes are sophisticated and others fundamental in evolutionary terms, and their interaction with pain processing is complex. As indicated above, many of the areas involved in relevant psychological processes interact with the PAG, and this is therefore one mechanism by which they may influence pain transmission at the spinal level.

At the spinal level, visceral nociception is dependent upon a system of intensity coding. In the viscera, primary afferents for normal sensations and nociception appear to be the same small fibres arriving at the spinal cord, and the difference between a normal and a noxious message depends upon the number of afferent signals transmitted to the dorsal horn (as opposed to the dual fibre, A/C fibre for nociception and A for light touch, seen in somatic tissue). It is thought that psychological modulation can alter intensity coding more easily than dual-fibre coding, and hence, pain perception.

Various psychological processes affect pain neuromodulation at the higher level. Inhibiting or facilitating both the nociceptive signal reaching the consciousness and appraisal and interpretation of that signal; they will also modulate the response to the nociceptive message and hence the pain experience. Further, descending pathways represent cognitive, emotional and behavioural states at spinal and peripheral levels.

Functional Magnetic Resonance Imaging (FMRI) has indicated that the psychological modulation of visceral pain probably involves multiple pathways. For instance, mood and attentional focus probably act through different areas of the brain when involved in reducing pain (21).

This psychological modulation may act to reduce nociception within a rapid time frame but may also result in long-term vulnerability to chronic visceral pain, through long-term potentiation. This involvement of higher centre learning may be at both a conscious and subconscious level, and is clearly significant in the supratentorial neuroprocessing of nociception and pain. Long-term potentiation (22) may also occur at any level within the nervous system, so that pathways for specific or combinations of stimuli may become established, resulting in an individual being vulnerable to perceiving sensations that would not normally be experienced as painful.

Stress is an intrinsic or extrinsic force that threatens the homeostasis of an organism and can be physical or psychological. Stress induces an adaptive response that involves the endocrine, autonomic nervous and immune systems, and these systems in turn appear to have feedback loops. Stress can modify the nervous system by long-term potentiation so that there are long-term actual or potential changes within these systems. It is this process that may be responsible for the effect of early life and significant adverse life events associated with chronic pain syndromes. It is through all of these factors that stress can play a significant role in nociceptive and pain neuromodulation, with the increased experience of pain as well as the more general effect that stress may have on coping resources (23). Significant adverse life events include, rape, sexual abuse, sexual trauma and sexual threat, such as during internment or torture. These events may produce long-term physical changes in the CNS (biological response), as well as having an effect on a patient's, emotional, cognitive, behavioural and sexual responses (24-26).

*2.2.7 **Autonomic nervous system***

The role of the autonomic nervous system in chronic pain is poorly understood, however, there is good evidence that damaged afferent fibres may develop a sensitivity to sympathetic stimulation, both at the site of injury and more centrally, particularly the dorsal horns. In visceral pain, the efferent output of the CNS may be

influenced by central changes (again, those changes may be throughout the neuraxis), and such modification of the efferent message may produce significant end-organ dysfunction. These functional abnormalities can have a significant effect on quality of life (QoL) and must be managed as appropriate.

2.2.8 ***Endocrine system***

The endocrine system is involved in visceral function. Significant life events, and in particular, early life events may alter the development of the hypothalamic-pituitary-adrenal axis and the chemicals released. Increased vulnerability to stress may occur following such events and is thought to be partly due to increased corticotrophin-releasing hormone (CRH) gene expression. Upregulation of CRH has been implicated in several pain states such as rectal hypersensitivity to rectal distension. This model suggests an action of CRH on mast cells.

A range of stress-related illnesses have been suggested, with IBS and BPS being examples. There is also evidence accumulating to suggest that the sex hormones also modulate both nociception and pain perception.

2.2.9 ***Genetics and chronic pain***

An individual who has had one chronic pain syndrome is more likely to develop another. Family clusters of pain conditions are also observed and animals can be bred that are more prone to an apparent chronic pain state. A whole range of genetic variations have been described that may explain the pain in certain cases; many of these are to do with subtle changes in transmitters and their receptors. However, the picture is more complicated in that development, environment and social factors also influence the situation.

2.3 Clinical paradigms and CPP

2.3.1 ***Referred pain***

Referred pain is frequently observed and its identification is important for diagnosis and treatment. Referral is usually somatic to somatic, or visceral to somatic. However, there is no reason why pain cannot also be perceived within the area of an organ with the nociceptive signal having arisen from a somatic area. Referred pain may occur as a result of several mechanisms but the main theory is one of convergence-projection. In the convergence-projection theory, as an example, afferent fibres from the viscera and the somatic site of referred pain converge onto the same second order projection neurons. The higher centres receiving messages from these projection neurons are unable to separate the two possible sites for the origin of the nociceptive signal (9,13,27).

2.3.2 ***Referred pain to somatic tissues with hyperalgesia in the somatic tissues***

Hyperalgesia refers to an increased sensitivity to normally painful stimuli. In patients that have passed a renal stone, somatic muscle hyperalgesia is frequently present, even a year after expulsion of the stone. Pain to non-painful stimuli (allodynia) may also be present in certain individuals. Somatic tissue hyperaesthesia is associated with urinary and bilary colic, IBS, endometriosis, dysmenorrhoea, and recurrent bladder infection. Vulvar pain syndromes are examples of cutaneous allodynia that, in certain cases, may be associated with visceral pain syndromes, such as BPS. Referred pain with hyperalgesia is thought to be due to central sensitisation of the converging viscero-somatic neurones. Central sensitisation also stimulates efferent activity that could explain the trophic changes that are often found in the somatic tissues.

2.3.3 ***Muscles and pelvic pain***

In the urogenital pain syndromes muscle tenderness and trigger points may be implicated as a source of pain. Central mechanisms are of great importance in the pathogenesis of this muscle hyperalgesia. The muscles involved may be a part of the spinal, abdominal or pelvic complex of muscles. It is not unknown for adjacent muscles of the lower limbs and the thorax to become involved. Pain may be localised to the trigger points but is more often associated with classical referral patterns. As well as trigger points, inflammation of the attachments to the bones (enthesitis) and of the bursa (bursitis) may be found (28-30).

Certain postures affect the different muscles in different ways, and as a consequence, may exacerbate or reduce the pain. Stress has been implicated as both an initiator of pelvic myalgia and as a maintenance factor. As a result, negative sexual encounters may also have a precipitating effect (23).

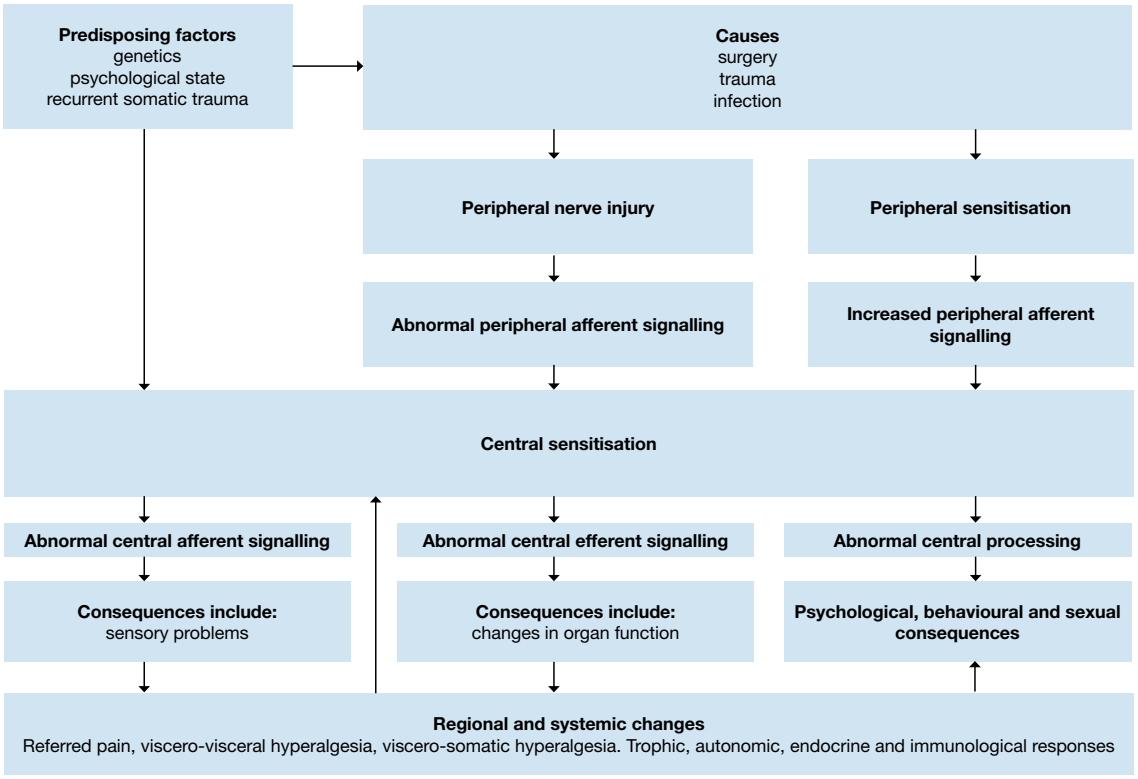
2.3.4 ***Visceral hyperalgesia***

The increased perception of stimuli in the viscera is known as visceral hyperalgesia, and the underlying mechanisms are thought to be responsible for IBS, BPS and dysmenorrhoea. The mechanisms involved are often acute afferent input (e.g., due to infection) followed by long-term central sensitisation.

2.3.5 *Viscero-visceral hyperalgesia*

Viscero-visceral hyperalgesia is thought to be due to two or more organs with converging sensory projections and central sensitisation. For instance, overlap of bladder and uterine afferents or uterine and colon afferents.

Figure 1: Predisposing factors, cause, central en peripheral mechanisms



2.4 Definitions of CPP terminology

2.4.1 *Classification*

Much debate over the classification of CPP has occurred, is ongoing and will continue in the future. Classification involves three aspects of defining a condition, phenotyping, terminology and taxonomy.

2.4.2 *Phenotyping*

Phenotyping is describing the condition. For example, chronic bladder pain may be associated with the presence of Hunner's ulcers and glomerulation on cystoscopy, whereas other bladder pain conditions may have a normal appearance on cystoscopy. These are two different phenotypes. The same is true for IBS, which may be subdivided into that with primarily diarrhoea or that with constipation. Phenotyping is based upon mechanisms when they are known (e.g., infection, ischaemic, autoimmune, or neuropathic). In the absence of well-defined mechanisms, describing the condition by its symptoms, signs and, where possible, by investigations, has been demonstrated to have clinical and research validity in many situations. When pain is the main symptom and pain as a disease process is considered the cause, the condition is often referred to as a pain syndrome - a well-defined collection of symptoms, signs and investigation results associated with pain mechanisms and pain perception as the primary complaint.

2.4.3 *Terminology*

Terminology is the words that are used within classification, both to name the phenotype and within the definition of the phenotype. Examples of names for phenotypes associated with the bladder include interstitial cystitis, painful bladder syndrome or BPS. The EAU, the International Society for the study of BPS (ESSIC), the International Association for the Study of Pain (IASP) and several other groups now prefer the term bladder pain syndrome. In the pain syndromes, the role of the nervous system in generating the sensations is thought to be pivotal, but the term syndrome is also holistic and takes into account the emotional, cognitive, behavioural, sexual and functional consequences of the chronic pain.

When defining the phenotype, the terminology used in that definition must also be clear and if necessary defined. One of the most important guiding principles is that spurious terminology should be avoided. Terms that end in "itis" in particular should be avoided unless infection and or inflammation is proven and considered

to be the cause of the pain (7). It must be appreciated that end-organ inflammation may be secondary and neurogenic in origin and not a primary cause of the pain.

*2.4.4 **Taxonomy***

Taxonomy places the phenotypes into a relationship hierarchy. The EAU approach subdivides CPP into conditions that are pain syndromes and those that are non-pain syndromes. The latter are conditions that have well-recognised pathology (e.g., infection, neuropathy or inflammation), whereas the former syndromes do not and pain as a disease process is the mechanism. Other terms for the non-pain syndromes include "classical conditions", "well-defined conditions" and "confusable diseases". Although the EAU approach deals primarily with urological conditions, this approach to classification can be applied to all conditions associated with pain perception within the pelvis; the classification has been developed to include non-urological pain and was accepted by the IASP for publication in January 2012.

2.5 Classification of CPP syndromes

*2.5.1 **Importance of classification***

It should be obvious to all that a condition cannot be treated unless it is defined. However, the reasons for classifying CPP go far beyond that.

Clues to the mechanism

As a result of systematic phenotypic and taxonomic classification, similarities and differences between conditions become clear. Drawing comparisons between the phenotypes of different disorders allows one to compare disorders such as bladder and bowel pain syndromes, thus facilitating research and treatment.

Guidelines for best treatment options

As conditions become better defined, more specific treatment approaches can be adopted. In particular, there will be a move away from treatments based upon spurious terms (e.g., antibiotics and non-steroidal anti-inflammatory drugs for the "-itis" conditions). Generic treatments aimed at groups of conditions will be more commonplace and based upon research evidence.

Research platform

Only by clearly defining the phenotype being investigated can research be valued or applied in the clinical situation.

Patient needs

A diagnosis, or name, for a set of symptoms can provide patients with a sense of being understood, as well as hope for relief. It may therefore help in acceptance of the problem as chronic, resolution of unfounded fears about its implications (if not life-threatening), and engagement in therapeutic endeavours, as well as in self-management. However, it may also lead to accessing information of variable quality associated with the diagnosis or name, and the possibility of generating new concerns about long term consequences or about appropriateness of treatment.

Remuneration

In certain countries, having a defined condition is necessary for the patient to receive treatment for their condition.

*2.5.2 **IASP definitions***

Subdividing pain syndromes

There is much debate on the subdivisions of the pain syndromes within the hierarchical taxonomy. The EAU has led the way in this regard and the guiding principles are as follows (31):

1. The pain syndromes are defined by a process of exclusion. In particular, there should be no evidence of infection or inflammation. Investigations by end-organ specialists should thus be aimed at obtaining a differential diagnosis; repeated, unnecessary investigations are detrimental in the management of chronic pain syndromes.
2. A subdivision phenotype should only be used if there is adequate evidence to support its use. For instance, in non-specific, poorly localised pelvic pain without obvious pathology, only the term chronic pelvic pain syndrome (CPPS) should be used. If the pain can be localised to an organ, then a more specific term, such as rectal pain syndrome, may be used. If the pain is localised to multiple organs, then the syndrome is a regional pain syndrome and the term CPPS should once again be considered. As well as defining the patient by a specific end-organ phenotype, there are several other more general descriptors that need to be considered. These are primarily psychological (e.g., cognitive

or emotional), sexual, behavioural and functional. Psychological and behavioural factors are well established to relate to QoL issues and prognosis. In North America a research programme, the MAPP program (Multi-disciplinary Approach to the study of chronic Pelvic Pain research) has been devised to investigate the importance of these factors and looks at all types of pelvic pain irrespective of the end organ where the pain is perceived. It also looks at systemic disorder associations, such as the co-ocurrence of fibromyalgia, facial pain, or autoimmune disorders.

3. In 2004 this expert panel introduced the concept of managing the polysymptomatic nature of CPP, since then others have developed their own schemes, such as Nickel's UPOINT (32), modified by Magri et al. (33). In the light of these and other publications, the symptom classification table has been updated (Table 5).

The debate in relation to subdividing the pain syndromes remains ongoing. As more information is collected suggesting that the CNS is involved, and indeed may be the main cause of many CPP conditions (e.g., bladder, genitalia, colorectal or myofascial), there is a general tendency to move away from end-organ nomenclature. Whether this is appropriate, only time and good research will tell. To enable such research, it is essential to have a framework of classification within which to work. Any hierarchical taxonomy must be flexible to allow change.

In table 5 the classification has been set up according to the axis system used by IASP. The panel used this table from their first edition and found it very useful for clinical purpose.

Table 5: EAU classification of chronic urogenital pain syndromes

Axis I Region		Axis II System	Axis III End organ as pain sundrome as identified from Hx, Ex and Ix		Axis IV Referral characteristics	Axis V Temporal characteristics	Axis VI Character	Axis VII Associated symptoms	Axis VIII Psychological symptoms
Chronic pelvic pain	Specific disease associated pelvic pain OR Pelvic pain syndrome	Urological	Prostate		Suprapubic Inguinal Urethral Penile/clitoral Perineal Rectal Back Buttocks Thighs	ONSET Acute Chronic ONGOING Sporadic Cyclical Continuous TIME Filling Emptying Immediate post Late post TRIGGER Provoked Spontaneous	Aching Burning Stabbing Electric	UROLOGICAL Frequency Nocturia Hesitance Dysfunctional flow Urge Incontinence GYNAECOLOGICAL Menstrual Menopause GASTROINTESTINAL Constipation Diarrhoea Bloatedness Urge Incontinence NEUROLOGICAL Dysaesthesia Hyperaesthesia Allodynia Hyperalegesie SEXUOLOGICAL Satisfaction Female dyspareunia Sexual avoidance Erectile dysfunction Medication MUSCLE Function impairment Fasciculation CUTANEOUS Trophic changes Sensory changes	ANXIETY About pain or putative cause of pain Catastrofic thinking about pain DEPRESSION Attributed to pain or impact of pain Attributed to other causes Unattributed PTSD SYMPTOMS Re-experiencing Avoidance
				Bladder					
				Scrotal Testicular Epididymal					
				Penile Urethral					
				Post-vasectomy					
		Gynaecological	Vulvar Vestibular Clitoral						
			Endometriosis associated						
			CPPS with cyclical exacerbations						
			Dysmenorrhoea						
		Gastrointestinal	Irritable blowel						
			Chronic anal						
			Intermittent chronic anal						
		Peripheral nervers	Pudendal pain syndrome						
		Sexological	Dyspareunia						
			Pelvic pain with sexual dysfunction						
		Psychological	Any pelvic organ						
		Musculo-skeletal	Pelvic floor muscle Abdominal muscle Spinal						
			Coccyx						

2.5.3 ***Pain syndromes***

The original EAU classification (31) was inspired by the IASP classification (19) and much work around what has become known as “pain as a disease” and its associated psychological, behavioural, sexual and functional correlates. After 10 years work developing the initial ideas an updated version was accepted by IASP Council for publication January 2012.

2.5.3.1 Definition of chronic pelvic pain (CPP)

Chronic pelvic pain is chronic or persistent pain perceived* in structures related to the pelvis of either men or women. It is often associated with negative cognitive, behavioral, sexual and emotional consequences as well as with symptoms suggestive of lower urinary tract, sexual, bowel, pelvic floor or gynaecological dysfunction.

[*Perceived indicates that the patient and clinician, to the best of their ability from the history, examination and investigations (where appropriate) has localised the pain as being perceived in the specified anatomical pelvic area].

In the case of documented nociceptive pain that becomes chronic/persistent through time, pain must have been continuous or recurrent for at least 6 months. That is, it can be cyclical over a 6-month period, such as the cyclical pain of dysmenorrhoea. Six months is arbitrary, however, it was chosen because 3 months was not considered long enough if we include cyclical pain conditions. If non-acute and central sensitisation pain mechanisms are well documented, then the pain may be regarded as chronic, irrespective of the time period.

Cyclical pain is included in the classification and hence dysmenorrhoea needs to be considered as a chronic pain syndrome if it is persistent and associated with negative cognitive, behavioural, sexual, or emotional consequences.

Chronic pelvic pain may be subdivided into conditions with well-defined classical pathology (such as infection or cancer) and those with no obvious pathology. For the purpose of this classification, the term “specific disease-associated pelvic pain” is proposed for the former, and “chronic pelvic pain syndrome” for the latter. The following classification only deals with CPPS.

2.5.3.2 Definition of chronic pelvic pain syndrome (CPPS)

Chronic pelvic pain syndrome is the occurrence of CPP when there is no proven infection or other obvious local pathology that may account for the pain. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. CPPS is a subdivision of CPP.

2.5.3.2.1 Further subdivision of CPPS

Pain perception in CPPS may be focused within a single organ, more than one pelvic organ and even associated with systemic symptoms such as chronic fatigue syndrome, fibromyalgia or Sjögren’s syndrome. When the pain is localised to a single organ, some specialists may wish to consider using an end-organ term such as BPS (Table 6). The use of such a phrase with the terminology “syndrome” indicates that, although peripheral mechanisms may exist, CNS neuromodulation may be more important and systemic associations may occur. When the pain is localised to more than one organ site, the term CPPS should be used. Many, including some of the authors of this text, never subdivide by anatomy and prefer to refer to patients with pain perceived within the pelvis and no specific disease process as suffering from CPPS, subdivided by psychological and functional symptoms.

2.5.3.2.2 Psychological considerations for classification

Many CPPSs are associated with a range of concurrent negative psychological, behavioural and sexual consequences that must be described and assessed. Examples that need to be considered are depression, anxiety, fears about pain or its implications, unhelpful coping strategies, and distress in relationships. Both anxiety and depression can be significant important concomitant symptoms that are relevant to pain, disability and poor QoL. Catastrophic interpretation of pain has been shown to be a particularly salient variable, predicting patients’ report of pain, disability, and poor QoL, over and above psychosocial variables such as depression or behavioural factors such as self-reported sexual dysfunction. It is suggested that CPPS sometimes creates a sense of helplessness that can be reported as overwhelming, and may be associated with the refractory nature of the patients’ symptoms. It is important to note that many of these biopsychosocial consequences are common to other persistent pain problems but may show varying degrees of salience for any one individual suffering from CPPS. In all patients with CPPS, these consequences must be clearly described as part of the phenotype (where the term phenotype is used to indicate the observable

characteristics of the syndrome).

2.5.3.2.3 Functional considerations for classification

Functional disorders, for the purpose of this document, are pathologies that have arisen secondary to changes in the control mechanisms of an organ or system. That is they are disorders characterised by disturbance of function. As an example, slow colonic transit is a functional disorder of the bowel - the normal function of the bowel is not occurring as a result of changes in the mechanisms that produce defecation, and hence the bowel control is abnormal. The term is not used in the sense of a psychiatric functional disorder. Many CPPSs are associated with functional abnormalities at a local and even systemic level. These also need to be defined as a part of the phenotype.

Functional pain disorders may not express significant pathology in the organs that appear responsible for the primary symptoms, but they are associated with substantial neurobiological, physiological and sometimes anatomical changes in the CNS.

2.5.3.2.4 Multisystem subdivision

It is recognised that the end organ where the pain is perceived may not be the centre of pain generation. This classification is based upon the most effective accepted method of classifying and identifying different pain syndromes, that is, by site of presentation. It is argued that keeping the end organ name in the classification is inappropriate because, in most cases, there are multisystemic causes and effects, with the result that symptoms are perceived in several areas. This is an area in which discussions are ongoing, and despite there being strong arguments for both keeping and dispensing with end-organ classification, the authors have not taken the umbrella approach of referring to all pain perceived in the pelvis as CPPS.

2.5.3.2.5 Dyspareunia

Dyspareunia is defined as pain perceived within the pelvis associated with penetrative sex. It tells us nothing about the mechanism and may be applied to women and men. It is usually applied to penile penetration, but is often associated with pain during insertion of any object. It may apply to anal as well as vaginal intercourse. It is classically subdivided into superficial and deep.

2.5.3.2.6 Perineal pain syndrome

Perineal pain syndrome is a neuropathic-type pain that is perceived in the distribution area of the pudendal nerve, and may be associated with symptoms and signs of rectal, urinary tract or sexual dysfunction. There is no proven obvious pathology. It is often associated with negative cognitive, behavioural, sexual and emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction.

Perineal pain syndrome should be distinguished from pudendal neuralgia, which is a specific disease associated with pelvic pain that is caused by nerve damage.

Table 6: Urologicalpain syndromes

Urological Pain Syndromes - Chapter 3	
Prostate pain syndrome	PPS is the occurrence of persistent or recurrent episodic pain (which is convincingly reproduced by prostate palpation). There is no proven infection or other obvious local pathology. PPS is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. The term “chronic prostatitis” continues to be equated with that of PPS. In the author’s and others’ opinion, this is an inappropriate term, although it is recognised that it has a long history of use. The National Institutes of Health (NIH) consensus (34) includes infection (types I and II), which the authors feel should not be considered under PPS, but as specific disease-associated pelvic pain. The term prostadynia has also been used in the past but is no longer recommended by the expert panel. Please note that some of the authors of the IASP document disagree with this term and suggest that CPPS of the male is used instead of PPS, which has been agreed by the majority.
Bladder pain syndrome	BPS is the occurrence of persistent or recurrent pain perceived in the urinary bladder region, accompanied by at least one other symptom, such as pain worsening with bladder filling and day-time and/or night-time urinary frequency. There is no proven infection or other obvious local pathology. BPS is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. BPS is believed to represent a heterogeneous spectrum of disorders. There may be specific types of inflammation as a feature in subsets of patients. Localisation of the pain can be difficult by examination, and consequently, another localising symptom is required. Cystoscopy with hydrodistension and biopsy may be indicated to define phenotypes. Recently, ESSIC has suggested a standardised scheme of subclassifications (11) to acknowledge differences and make it easier to compare various studies. Other terms that have been used include “interstitial cystitis”, “painful bladder syndrome”, and “PBS/IC” or “BPS/IC”; these terms are no longer recommended.
Scrotal pain syndrome	Scrotal pain syndrome is the occurrence of persistent or recurrent episodic pain localised within the organs of the scrotum, and may be associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven infection or other obvious local pathology. Scrotal pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. Scrotal pain syndrome is a generic term and is used when the site of the pain is not clearly testicular or epididymal. The pain is not in the skin of the scrotum as such, but perceived within its contents, in a similar way to idiopathic chest pain.
Testicular pain syndrome	Testicular pain syndrome is the occurrence of persistent or recurrent episodic pain perceived in the testes, and may be associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven infection or other obvious local pathology. Testicular pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. Previous terms have included orchitis, orchialgia and orchiodynia. These terms are no longer recommended.
Epididymal pain syndrome	Epididymal pain syndrome is the occurrence of persistent or recurrent episodic pain perceived in the epididymis, and may be associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven infection or other obvious local pathology. Epididymal pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction.

Penile pain syndrome	Penile pain syndrome is the occurrence of pain within the penis that is not primarily in the urethra, in the absence of proven infection or other obvious local pathology. Penile pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction.
Urethral pain syndrome	Urethral pain syndrome is the occurrence of chronic or recurrent episodic pain perceived in the urethra, in the absence of proven infection or other obvious local pathology. Urethral pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. Urethral pain syndrome may occur in men and women.
Postvasectomy scrotal pain syndrome	Postvasectomy scrotal pain syndrome is a scrotal pain syndrome that follows vasectomy. Postvasectomy scrotal pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. Postvasectomy pain may be as frequent as 1% following vasectomy, possibly more frequent. The mechanisms are poorly understood and it is for that reason considered a special form of scrotal pain syndrome.
Gynaecological Pain Syndromes: external genitalia - Chapter 4	
Vulvar pain syndrome	Vulvar pain syndrome is the occurrence of persistent or recurrent episodic vulvar pain. There is no proven infection or other local obvious pathology. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. Although pain perceived in the vulva was subsumed under sexual disorders in the DSM-IV-R manual for classifying psychiatric disorders, there is no scientific basis for this classification, and pain perceived in the vulva is best understood as a pain problem that usually has psychological consequences. There is no evidence for its classification as a psychiatric disorder. The International Society for the Study of Vulvovaginal Disease (ISSVD) has used the term vulvodynia, where we use the term vulvar pain syndrome. According to the ISSVD, vulvodynia is vulvar pain that is not accounted for by any physical findings. The ISSVD has defined vulvodynia as “vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder”. If physical findings are present, the patient is said to have vulvar pain due to a specified cause. The ISSVD has subdivided vulvodynia based on pain location and temporal characteristics of the pain (e.g., provoked or unprovoked). The following definitions are based on that approach.
Generalised vulvar pain syndrome	Generalised vulvar pain syndrome refers to a vulvar pain syndrome in which the pain/burning cannot be consistently and precisely localised by point-pressure mapping via probing with a cotton-tipped applicator or similar instrument. Rather, the pain is diffuse and affects all parts of the vulva. The vulvar vestibule (the part that lies between the labia minora into which the urethral meatus and vaginal introitus open) may be involved but the discomfort is not limited to the vestibule. This pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences. Previous terms have included “dysesthetic vulvodynia” and “essential vulvodynia”, but are no longer recommended.
Localised vulvar pain syndrome	Localised vulvar pain syndrome refers to pain that can be consistently and precisely localised by point-pressure mapping to one or more portions of the vulva. Clinically, the pain usually occurs as a result of provocation (touch, pressure or friction). Localised vulvar pain syndrome can be subdivided into vestibular pain syndrome and clitoral pain syndrome.
Vestibular pain syndrome	Refers to pain that can be localised by point-pressure mapping to the vestibule or is well perceived in the area of the vestibule.
Clitoral pain syndrome	Refers to pain that can be localised by point-pressure mapping to the clitoris or is well perceived in the area of the clitoris. Gynaecological system: internal pelvic pain syndromes - Chapter 4

Endometriosis-associated pain syndrome	Endometriosis-associated pain syndrome is chronic or recurrent pelvic pain in patients with laparoscopically confirmed endometriosis, and the term is used when the symptoms persist despite adequate endometriosis treatment. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. Many patients have pain above and beyond the endometriotic lesions; this term is used to cover that group of patients. Endometriosis may be an incidental finding, is not always painful, and the degree of disease seen laparoscopically does not correlate with severity of symptoms. As with other patients, they often have more than one end organ involved. It has been suggested that this phenotype should be removed from the classification because the endometriosis may be irrelevant.
CPPS with cyclical exacerbations	CPPS with cyclical exacerbations covers the non-gynaecological organ pain that frequently shows cyclical exacerbations (e.g., IBS or BPS) as well as pain similar to that associated with endometriosis/adenomyosis but where no pathology is identified. This condition is different from dysmenorrhoea, in which pain is only present with menstruation.
Dysmenorrhoea	Dysmenorrhoea is pain with menstruation that is not associated with well-defined pathology. Dysmenorrhoea needs to be considered as a chronic pain syndrome if it is persistent and associated with negative cognitive, behavioural, sexual or emotional consequences.
Musculoskeletal System - Chapter 9	
Pelvic floor muscle pain syndrome	Pelvic floor muscle pain syndrome is the occurrence of persistent or recurrent episodic pelvic floor pain. There is no proven well-defined local pathology. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. This syndrome may be associated with overactivity of or trigger points within the pelvic floor muscles. Trigger points may also be found in several muscles, such as the abdominal, thigh and paraspinal muscles and even those not directly related to the pelvis.
Coccyx pain syndrome	Coccyx pain syndrome is the occurrence of chronic or recurrent episodic pain perceived in the region of the coccyx, in the absence of proven infection or other obvious local pathology. Coccyx pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. The term “coccydynia” was used but is no longer recommended.
Gastrointestinal Pelvic Pain Syndromes - Chapter 5	
Irritable bowel syndrome	IBS is the occurrence of chronic or recurrent episodic pain perceived in the bowel, in the absence of proven infection or other obvious local pathology. Bowel dysfunction is frequent. IBS is often associated with worry and preoccupation about bowel function, and negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract or gynaecological dysfunction. The above classification is based upon the Rome III Criteria (35): 3 months of continuous or recurring symptoms of abdominal pain or irritation that may be relieved with a bowel movement, may be coupled with a change in frequency, or may be related to a change in stool consistency. Two or more of the following are present at least 25% of the time: change in stool frequency (> 3 bowel movements per day or < 3 per week); noticeable difference in stool form (hard, loose, watery or poorly formed stools); passage of mucus in stools; bloating or feeling of abdominal distension; or altered stool passage (e.g., sensation of incomplete evacuation, straining, or urgency). Extra- intestinal symptoms include: nausea, fatigue, full sensation after even a small meal, and vomiting.

Chronic anal pain syndrome	Chronic anal pain syndrome is the occurrence of chronic or recurrent episodic pain perceived in the anus, in the absence of proven infection or other obvious local pathology. Chronic anal pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction.
Intermittent chronic anal pain syndrome	Intermittent chronic anal pain syndrome refers to severe, brief, episodic pain that seems to arise in the rectum or anal canal and occurs at irregular intervals. This is unrelated to the need to or the process of defecation. It may be considered a subgroup of the chronic anal pain syndromes. It was previously known as "proctalgia fugax"; this term is no longer recommended.

2.6 Conclusions and recommendations: CPP and mechanisms

Conclusions	**LE**
CPPS mechanisms are well defined and involve mechanisms of neuroplasticity and neuropathic pain.	2
The mechanisms of neuroplasticity and neuropathic pain result in increased perception of afferent stimuli which may produce abnormal sensations as well as pain.	1
End organ function can also be altered by the mechanisms of neuroplasticity and neuropathic pain, so that symptoms of function can also occur.	1
CPP is associated with a high impact on QoL.	1
The diagnosis of a CPPS as a pain syndrome is essential as it encourages a holistic approach to management with multispecialty and multidisciplinary care.	2

Recommendations	**GR**
All of those involved in the management of CPP should have an understanding and training in CPPS pain mechanisms.	A
The early assessment of patients should involve not only investigations aimed at specific disease-associated pelvic pain but also to assess functional, emotional, behavioural, sexual and other quality of life issues, such as effect on work and socialisation.*	A
CPPS patients should be managed in a multispecialty and multidisciplinary environment with consideration of all their symptoms.	A
Future classification should involve consideration of all three recommendations above.	A

CPP = chronic pelvic pain; CPPS = chronic pelvic pain syndrome.
* Instruments for assessment *see* Chapter 8.

2.7 An algorithm for CPP diagnosis and treatment

The algorithm for diagnosing and treating CPP (Figure 2) has been developed to guide a physician through the process from diagnosis to management. A physician should follow the lines by answering the appropriate questions with yes or no. By doing this the clinician will end up at a box that refers to the chapter in this guideline that contains all the information needed.

Because CPP is pain perceived in structures related to the pelvis, it is necessary to approach diagnosis of a patient with CPP as a chronic pain patient. Confining the diagnosis to a specific organ may overlook multisystem functional abnormalities requiring individual treatment and general aspects of pain in planning investigation and treatment. This idea is easily recognised in the algorithm where the division in specific disease associated pain is made on one hand and pelvic pain syndrome on the other.

The algorithm also illustrates that we advocate early involvement of a multidisciplinary pain team. In practice, this should mean that well-known diseases, e.g. 'true' cystitis and endometriosis, will be diagnosed and treated early. If treating such conditions does not reduce symptoms, or such well-defined conditions are not found, then further investigation may be necessary, depending on where the pain is localised.

Every chapter of this guideline shows specific algorithms that assist the clinician in decision making. It should be noted, however, that over-investigation may be as harmful as not performing appropriate investigations. The EAU algorithms introduce the concept of the 'minimum investigations' required to exclude a well-defined condition.

Figure 2: an algorithm for diagnosing and managing CPP

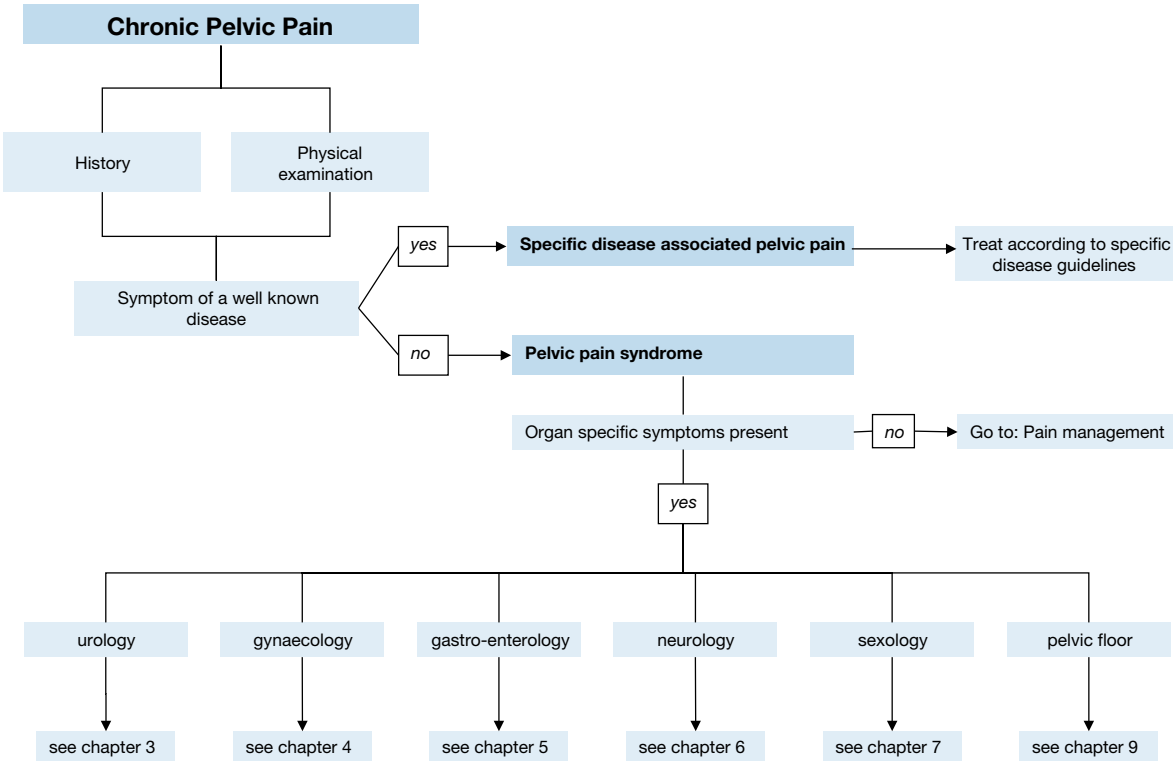


Figure 3: an algorithm for pain management

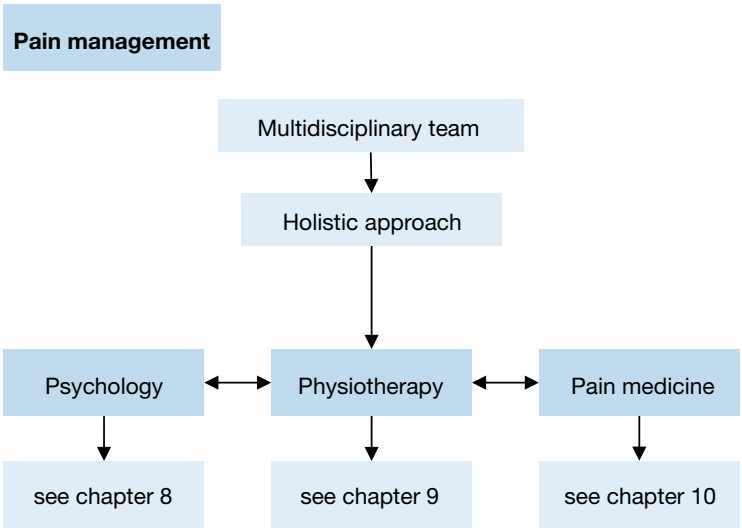

Figure 4: phenotyping and assessment algorithm for CPP

Phenotyping	Assessment
Urology	Urinary flow, micturition diary, cystoscopy, ultrasound, uroflowmetry
Psychology	History of negative experiences, important loss, coping mechanism, depression
Organ specific	Ask for gynaecological, gastro-intestinal, ano-rectal, sexological complaints Gynaecological examination, rectal examination
Infection	Semen culture and urine culture, vaginal swab, stool culture
Neurological	Ask for neurological complaints (sensory loss, dysaesthesia). Neurological testing during physical examination: sensory problems, sacral reflexes and muscular function
Tender muscle	Palpation of the pelvic floor muscles, the abdominal muscles and the gluteal muscles

3. UROLOGICAL ASPECTS OF CHRONIC PELVIC PAIN

3.1 Prostate pain syndrome (PPS)

*3.1.1 **Introduction***

Chronic pain in the region of the prostate has been linked to the term “prostatitis” in the past, although there is a proven bacterial infection in only 10% of the cases (1). The remaining 90% should be classified as PPS, based on the fact that there is no proven infection or other obvious pathology. If CPP cannot be clearly ascribed to the prostate or another organ of the pelvis, the condition is defined more generally as CPPS, as outlined in Chapter 2.

*3.1.2 **Definition***

Prostate pain syndrome is the occurrence of persistent or recurrent episodic pain in the region of the prostate over at least 3 out of the past 6 months, which is convincingly reproduced by prostate palpation. There is no proven infection or other obvious local pathology. PPS is often associated with negative cognitive, behavioural, sexual, or emotional consequences (2), as well as with symptoms suggestive of lower urinary tract and sexual dysfunction (3,4). According to the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) classification, this correlates to CP/CPPS (Cat. III). Laboratory diagnosis goes along with sterile specimen cultures and either significant, or insignificant, white blood cell counts in prostate-specific specimens (i.e. semen, expressed prostatic secretions and urine collected after prostate massage) (5). At present, there are no clinically relevant diagnostic or therapeutic consequences arising from differentiating inflammatory from non-inflammatory PPS (according to NIH definition), therefore, they are considered here as one entity.

*3.1.3 **Pathogenesis***

Pain is the main symptom in PPS. As a common feature of chronic pain syndromes, no single aetiological explanation has been found. One explanation (6) is that the condition probably occurs in susceptible men exposed to one or more initiating factors, which may be single, repetitive or continuous. Several of these potential initiating factors have been proposed, including infectious, genetic, anatomical, neuromuscular, endocrine, immune (including autoimmune), or psychological mechanisms. These factors may then lead to a peripheral self-perpetuating immunological inflammatory state and/or neurogenic injury, creating acute and then chronic pain. Based on the peripheral and the CNS, sensitisation involving neuroplasticity may lead to a centralised neuropathic pain state (see Chapter 2) (6). This could also explain why tissue damage is not usually found in PPS. There is growing evidence for a neuropathic origin and association with CNS changes of pain in PPS. As outlined earlier, PPS patients have been shown to report higher visual analogue scale scores than controls to short bursts of noxious stimuli to the perineum but not to the anterior thigh (7). This implies an altered sensation in the perineum compared with healthy controls similar to other chronic pain syndromes.

*3.1.4 **Epidemiology***

There is only limited information on the true prevalence of PPS in the population. As a result of significant overlap of symptoms with other conditions (e.g. benign prostate syndrome and BPS), purely symptom-based case definitions may not reflect the true prevalence of PPS (8,9). Prostatitis was diagnosed in 8% of all visits

to urologists and 1% of all primary care physicians annually in the USA (10). In a systematic review of the literature, the population-based prevalence of prostatitis symptoms was found to be 8.2% (range: 2.2-9.7%) (11). In two recent studies not included in this review, prevalence was found to be 2.7% (4) and 2% (12) . A prospective Italian survey of visits to a urologist for a physician-assigned diagnosis of prostatitis revealed a prevalence of 12.8%. Among these, ~40% had clinical features of PPS (13). In a self-reported, population-based, cross sectional study of Finnish men aged 20-59 years, the overall lifetime prevalence of prostatitis was as high as 14.2% (14). The risk of prostatitis increased with age (men aged 50-59 years had a 3.1-fold greater risk than those aged 20-39 years). Usual clinical treatment in North American populations has been studied in two studies of sufficient quality. In the follow-up of a cohort of men with PPS-like symptoms based on the NIH Prostatitis Symptom Index (NIH-CPSI) pain and voiding domains, 63% still suffered from persistent symptoms, in contrast to 3% of controls with newly developing symptoms (15). Patients with more severe symptoms were more likely to report symptoms 1 year later. In addition, symptoms substantially improved for up to 6 months follow-up, but then remained unchanged (16).

3.1.5 ***Diagnosis***

Prostate pain syndrome is a symptomatic diagnosis, which is diagnosed from a history of pain perceived in the region of the prostate (convincingly reproduced by prostate palpation), and absence of other lower urinary tract pathology, for a minimum of 3 out of the past 6 months. This implies that specific disease-associated pelvic pain caused by bacterial infection, urogenital cancer, urinary tract disease, urethral stricture, and neurogenic disease of the bladder must be ruled out. A thorough history is an important first step in the evaluation of PPS. It should include type of pain and localisation. Pain is often reported in other pelvic areas outside the prostate such as perineum, rectum, penis, testicles and abdomen (17). In addition, associated lower urinary tract symptoms (LUTS), sexual function, psychological, social and economic factors should be addressed. Determination of the severity of disease, its progression and treatment response can be assessed only by means of a validated symptom-scoring instrument. QoL should also be measured because it can be as poor as in acute myocardial infarction, unstable angina pectoris or Crohn's disease (19,20). In a study by Tripp et al. (2) more pain, pain-contingent rest, and urinary symptoms were associated with greater disability (also measured by self-report), and pain was predicted by depression and by catastrophising (helplessness subscale).

Demographic and social support variables were not associated with either pain or adjustment. Reliable, valid indexes of symptoms and QoL are the NIH-CPSI (17) and the International Prostate Symptom Score (I-PSS) (18). These subjective outcome measures are recommended for the basic evaluation and therapeutic monitoring of patients in urological practice and have been translated and validated for many European languages.

There is no single "gold standard" diagnostic test for PPS, therefore, procedures are on the one hand directed towards identification and exclusion of specific diseases associated with pelvic pain, and on the other hand may be used for phenotypic description. Physical examination including digital rectal examination should be carried out. Muscle tenderness and trigger points in the pelvic floor may be palpated. Measurement of resting urine by ultrasound should exclude incomplete voiding. Prostate-specific antigen testing does not help to diagnose PPS but can exclude prostate cancer in patients at risk.

Laboratory diagnosis has been classically based on the four-glass test for bacterial localisation (21) Besides sterile pre-massage urine (voided bladder urine-2), PPS shows < 10,000 cfu of uropathogenic bacteria in expressed prostatic secretions and insignificant numbers of leukocytes or bacterial growth in ejaculates. However, this test is too complex for use by practising urologists. Diagnostic efficiency may be enhanced cost-effectively by a simple screening procedure, that is, the two-glass test or pre-post-massage test (PPMT) (22). In an extensive analysis of both tests, PPMT was able to indicate the correct diagnosis in > 96% of patients (23). Overall, these tests help only a little in the diagnosis of PPS, because 8% of patients with suggested PPS have been found to have positive prostatic localisation cultures, similar to the percentage of asymptomatic (24).

In PPS, urodynamic studies should be considered in patients with significant LUTS. They may demonstrate decreased urinary flow rates, incomplete relaxation of the bladder neck and prostatic urethra, as well as abnormally high urethral closure pressure at rest. The external urethral sphincter may be dysfunctional (non-relaxing) during voiding (25). As for non-PPS cases, cystoscopy may be considered for further evaluation of micturition symptoms to exclude bladder outlet or urethral pathology, or if haematuria or infection has been found to exclude intravesical pathology.

A general algorithm for assessment and treatment of PPS is shown in Figure 5.

3.1.6 *Conclusions and recommendations: assessment/diagnosis PPS*

Conclusions	LE
PPS is associated with negative cognitive, behavioural, sexual, or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction.	2b
PPS has no known single aetiology.	3
Pain in PPS involves mechanisms of neuroplasticity and neuropathic pain.	2a
PPS has a high impact on QoL.	2b
Depression and catastrophic thinking are associated with more pain and poorer adjustment.	3
The prevalence of PPS-like symptoms is high in population-based studies (> 2%).	2b
There is significant overlap of symptoms with other conditions.	2b
Reliable instruments assessing symptom severity as well as phenotypic differences exist.	2b

Recommendations	GR
Specific diseases with similar symptoms must be excluded. It is therefore recommended to adapt diagnostic procedures to the patient and to aim at identifying them.	A
After primary exclusion of specific diseases, patients with symptoms according to the above definition should be diagnosed with prostate pain syndrome.	A
A validated symptom and quality of life scoring instrument, such as the NIH-CPSI, should be considered for initial assessment as well as for follow-up.	B
It is recommended to assess prostate pain syndrome associated negative cognitive, behavioural, sexual, or emotional consequences, as well as symptoms of lower urinary tract and sexual dysfunctions.	B

3.1.7 *Treatment*

There is a large discrepancy in the treatment effects reported in case series and controlled trials that results from a large placebo effect or publication bias. As a result of the multifactorial origin of PPS, one reason for treatment failure in some large randomised placebo-controlled trials may be the heterogeneity of the patient population. Thus, one strategy for improving treatment effects may be stratification of patient phenotypes. A prospective series of phenotypically directed treatment for PPS has shown significant improvement of symptoms and QoL (26). Monotherapeutic strategies for the treatment of PPS may fail (27), therefore, most patients require multimodal treatment aimed at the main symptoms, and taking comorbidity into account. In the past 10 years, results from RCTs have led to advances in standard and novel treatment options.

3.1.7.1 *Alpha-blockers*

Positive results from RCTs of alpha-blockers, i.e. terazosin (28,29), alfuzosin (30) doxazosin (31,32) and tamsulosin (33) have led to widespread use of alpha-antagonists in the treatment of PPS in recent years. The effects of alpha-antagonists may include improved outflow performance by blocking the alpha-receptors of the bladder neck and prostate and by direct action on alpha1A/1D receptors in the CNS (33). In contrast, an earlier meta-analysis of nine trials (n = 734) did not show a beneficial effect on pain (34). Moreover, in accordance with an earlier negative report on tamsulosin (35), one adequately powered large placebo-controlled randomised trial of 12 weeks treatment with alfuzosin failed to show any significant difference in the outcome measures, with the exception of the score for ejaculation of the Male Sexual Health Questionnaire scores (showing significant improvement in the alfuzosin group compared to the placebo group, P= 0.04) (36). Regarding safety, this large trial reported similar adverse event rates in the treatment and placebo groups. The most recent in-depth systematic review and network meta-analysis of alpha-blockers (37) has shown significant improvement in symptoms, with standardised mean differences in total symptom, pain, voiding, and QoL scores of -1.7 [95% confidence interval (CI): -1.8 to -0.3], -1.1 (95% CI: -1.8 to -0.3), 1.4 (95% CI: -2.3 to -0.5), and -1.0 (95% CI: -1.8 to 0.2), respectively. In addition, they had a higher rate of favourable response compared to placebo (pooled relative risk of 1.6 (95% CI: 1.1-2.3). However, this finding was associated with publication bias for smaller studies. Overall, alpha-blockers seem to have moderate but significant beneficial effects. This probably is not the case for long-standing PPS patients (36). Future studies should show if longer duration of therapy or some sort of phenotypically directed (e.g. patients with PPS and relevant voiding dysfunction) treatment strategies will improve treatment outcomes.

3.1.7.2 Antibiotic therapy

Empirical antibiotic therapy is widely used because some patients have improved with antimicrobial therapy. Patients responding to antibiotics should be maintained on medication for 4-6 weeks or even longer. Unfortunately, culture, leukocyte and antibody status of prostate-specific specimens does not predict antibiotic response in patients with PPS (38), and prostate biopsy culture findings do not differ from those of healthy controls (39). The only randomised placebo-controlled trials of sufficient quality have been done for oral antibiotic treatment with ciprofloxacin (6 weeks) (35), levofloxacin (6 weeks) (40), and tetracycline hydrochloride (12 weeks) (41). These have been analysed in a recently published meta-analysis (37). Although direct meta-analysis has not shown significant differences in outcome measures, network meta-analysis has suggested significant effects in decreasing total symptom scores (-9.8; 95% CI: -15.1 to -4.6), pain scores (-4.4; 95% CI: -7.0 to -1.9), voiding scores (-2.8; 95% CI: -4.1 to -1.6), and QoL scores (-1.9; 95% CI: -3.6 to -0.2) compared with placebo. Overall, antibiotic treatment of PPS is based only on weak evidence. Combination therapy of antibiotics with alpha-blockers has shown even better outcomes in network meta-analysis. However, sample sizes of the studies were relatively small and treatment effects were only modest and most of the time below clinical significance. It may be speculated that patients profiting from treatment have had some unrecognised uropathogens. If antibiotics are used, other therapeutic options should be offered after one unsuccessful course of a quinolone or tetracycline antibiotic over 6 weeks.

3.1.7.3 Anti-inflammatory drugs

For non-steroidal anti-inflammatory drugs, only two RCTs have been published. The first was for rofecoxib, which is no longer on the market; statistical significance over placebo was achieved in some of the outcome measures (42). In the second trial with celecoxib, pain subscore, QoL subscore, and total NIH-CPSI score were in favour of the treatment arm versus placebo, but effects were limited to the duration of therapy (43). A leukotriene antagonist, zafirlukast, has been evaluated in a small randomised placebo-controlled study of patients treated with concomitant doxycycline (44). This study was negative but had a lack of power. For corticosteroids, no significant benefits were shown in a low-power, placebo-controlled, randomised pilot study of a short course of oral prednisolone (45). In a recent meta-analysis, two studies of NSAIDs (40,43) and one with prednisolone (45) were pooled. Anti-inflammatory drugs were 80% more likely to have a favourable response than placebo (total n = 190, RR: 1.8; 95% CI: 1.2-2.6). Overall, a moderate treatment effect has been shown for anti-inflammatory drugs, but larger studies should be done for final confirmation, and long-term side effects have to be taken into account.

3.1.7.4 Opioids

Opioids produce modest pain relief in some patients with refractory PPS, although there are limited data on the long-term efficacy of opioids in non-cancer pain. Opioid treatment carries the risks of side effects, reduced QoL, addiction, opioid tolerance and opioid-induced hyperalgesia (46). Urologists should use opioids for PPS only in collaboration with pain clinics and with other treatments.

3.1.7.5 5-alpha-reductase inhibitors

After a few small pilot studies with 5-alpha-reductase inhibitors supported the view that finasteride may improve voiding and pain, the first placebo-controlled randomised trial published in a peer-reviewed journal did not support this, but the study did lack power (47). In another RCT, finasteride provided better amelioration of symptoms compared to saw palmetto over a 1-year period, but lacked a placebo-control arm (48). A 6-month placebo-controlled study showed a non-significant tendency towards better outcome in favour of finasteride, possibly because of a lack of statistical power (49). Based on these data, 5-alpha-reductase inhibitors cannot be recommended for use in PPS.

3.1.7.6 Allopurinol

An RCT of allopurinol was conducted based on the hypothesis that urine reflux intoprostatic ducts causes prostatic inflammation via high concentrations of purine and pyrimidine base-containing metabolites in prostatic secretions (50). However, positive results have not been considered sufficient for recommendation by reviewers of the Cochrane Database (51). In addition, a recent randomised placebo-controlled trial of allopurinol as an adjunct to ofloxacin has not shown any benefit (52).

3.1.7.7 Phytotherapy

Positive effects of phytotherapy have been documented. Although a validated symptom score was not used, an RCT of a pollen extract (Prostat/Poltit) showed significant symptom improvement (53). An adequately powered randomised placebo-controlled study of Cernilton, another pollen extract, showed clinically significant symptom improvement over a 12-week period in inflammatory PPS patients (NIH Cat. IIIA) (54). The effect was mainly based on a significant effect on pain. Quercetin, a polyphenolic bioflavonoid with documented

antioxidant and anti-inflammatory properties, improved NIH-CPSI scores significantly in a small RCT (55). In contrast, treatment with saw palmetto, most commonly used for benign prostatic hyperplasia, did not improve symptoms over a 1-year period (47). In a systematic review and meta-analysis, patients treated with phytotherapy were found to have significantly lower pain scores than those treated with placebo (37). In addition, overall response rate in network analysis was in favour of phytotherapy (RR: 1.6; 95% CI: 1.1-1.6).

3.1.7.8 Pentosan polysulphate

High-dose oral pentosan polysulphate (3 300 mg/day), as for BPS, is able to improve clinical global assessment and QoL significantly over placebo in men with PPS, suggesting a possible common aetiology (56).

3.1.7.9 Muscle relaxants

Muscle relaxants (diazepam, baclofen) are claimed to be helpful in sphincter dysfunction or pelvic floor/perineal muscle spasm, but there have been only a few prospective clinical trials to support these claims. In a recent RCT, a triple combination of a muscle relaxant (tiocolchicoside), an anti-inflammatory drug (ibuprofen) and an alpha-blocker (doxazosin) was effective in treatment-naïve patients, but not superior to an alpha-blocker alone (32).

3.1.7.10 Pregabalin

Pregabalin is an antiepileptic drug that has been approved for use in chronic postherpetic neuralgia, fibromyalgia, and diabetic neuropathy. In an adequately powered randomised placebo-controlled study, a 6-week course of pregabalin (n = 218) compared to placebo (n = 106) did not result in a significant reduction of NIH-CPSI total score by at least 6 points (57).

3.1.7.11 Botulinum toxin A (BTX-A)

Botulinum toxin A (BTX-A) may have pain-alleviating effects through non-neuromuscular action on afferent nociceptive pathways. Local treatment with periurethral injection of BTX-A (200 U) has been tested in a small pilot study with improvement in pain and changes in urethral pressure profile (58). A small randomised placebo-controlled study of perineal skeletal muscle injection (100 U) has been published recently (59). Some effect was found in the global response assessment and the NIH-CPSI pain subdomain score. However, patient number was too low (13 in the BTX-A group and 16 in the placebo group), and follow-up was too short to draw definitive conclusions.

3.1.7.12 Physical treatments

- *Electromagnetic therapy*. In a small, sham-controlled, double-blind study, 4 weeks electromagnetic therapy showed a significant, sustained effect over a 1-year period (60).
- *Microwave thermotherapy.* Significant symptomatic improvement has been reported from heat therapy, for example, transrectal and transurethral thermotherapy (61,62), but there was no sham-control.
- *Extracorporeal shock wave therapy.* A recent sham-controlled double-blind study of four times weekly perineal extracorporeal shock wave therapy (n = 30) showed significant improvement in pain, QoL, and voiding compared to the control group (n = 30) over 12 weeks (63). Confirmatory studies are awaited because of an absent placebo-effect, which is very unusual in PPS trials.
- *Electroacupuncture.* In a small three-arm randomised trial, electroacupuncture was superior to sham treatment and advice and exercise alone (64). In a recent prospective case series of 6 weeks of weekly electroacupuncture of 97 patients with PPS, 92% showed significant improvement in total NIH-CPSI score. Based on these studies, no definitive conclusion can be drawn.
- *Posterior tibial nerve stimulation.* One sham-controlled medium-sized study (n = 89) demonstrated significant improvement in total NIH-CPSI score and visual analogue scale for pain (65).
- *Myofascial physical therapy.* A randomised feasibility trial of myofascial physical therapy including PPS (n = 21) and patients with BPS showed a clinical benefit compared to global therapeutic massage (66). In the PPS group alone, there was no difference in the effect between the two treatment arms.

3.1.7.13 Surgical management

Surgical management, including transurethral incision of the bladder neck, radical transurethral resection of the prostate, or in particular, radical prostatectomy, has a very limited role and requires an additional, specific indication. In addition, the treatment effect of transurethral needle ablation of the prostate (TUNA) was only comparable to sham treatment in two small randomised trials (67,68).

3.1.7.14 Psychological treatment

It is of note that QoL decreases as symptoms increase. Given prediction of QoL by psychological problems

(depression and catastrophising in particular), this means that psychological status should also be targeted in treatment, and the development of a psychologically focused treatment for patients refractory to drug treatment has been noted by the authors of the summary findings from the NIH Chronic Prostatitis Collaborative Research Network studies (69). There are no RCTs of psychological treatment for men with CPP, but Tripp et al. (70) have completed a feasibility trial, which represents the only known account of psychological treatment. Their 8-h intervention improved pain, catastrophising, and QoL, but not depression or some urinary symptoms. Details concerning appropriate treatment content and delivery are contained in Chapter 8.

*3.1.8 **Conclusions and recommendations: treatment of PPS***

Conclusions	**LE**
Monotherapeutic treatment regimens in PPS may fail.	3
Phenotypically directed treatment may improve treatment success.	3
Alpha-blockers have moderate treatment effect regarding total, pain, voiding, and QoL scores in PPS.	1a
Antimicrobial therapy has a moderate effect on total, pain, voiding, and QoL scores in PPS.	1a
NSAIDs have moderate overall treatment effects on PPS.	1a
There are insufficient data on the effectiveness of steroids in PPS.	2b
There are insufficient data on the effectiveness of opioids in PPS.	4
There are insufficient data on the effectiveness of 5-alpha-reductase inhibitors in PPS.	2b
There are insufficient data on the effectiveness of allopurinol in PPS.	2b
Phytotherapy has some beneficial effect on pain and overall favourable treatment response in PPS.	1a
Pentosan polysulphate improves global assessment and QoL score in PPS.	1b
There are insufficient data on the effectiveness of muscle relaxants in PPS.	2b
Pregabalin is not effective for the treatment of PPS.	1b
BTX-A injection into the pelvic floor may have a modest effect in PPS.	2b
There are only limited data on the effectiveness of electromagnetic therapy in PPS.	2b
There are only limited data on the effectiveness of microwave thermotherapy in PPS.	3
Perineal extracorporeal shock wave therapy probably is effective for the treatment of PPS.	1b
There are limited data on the effectiveness of electroacupuncture for the treatment of PPS.	2b
Posterior tibial nerve stimulation is probably effective for the treatment of PPS.	1b
There are insufficient data on the effectiveness of myofascial physical therapy for the treatment of PPS.	2b
There are limited data on lack of effectiveness of TUNA of the prostate for PPS.	2b
There are insufficient data supporting the use of other surgical treatments, such as transurethral incision of the bladder neck, transurethral resection of the prostate, or radical prostatectomy in patients with PPS.	3
Cognitive behavioural therapy designed for PPS may improve pain, and quality of life.	3

Recommendations	GR
Consider multimodal and phenotypically directed treatment options for PPS.	B
Alpha-blockers are recommended for patients with a duration of PPS < 1 year.	A
Single use of antimicrobial therapy (quinolones or tetracyclines) is recommended in treatment-naïve patients over a minimum of 6 weeks with a duration of PPS < 1 year.	A
NSAIDs are recommended for use in PPS, but long-term side effects have to be considered.	B
Allopurinol is not recommended for use in PPS.	B
Phytotherapy might be used in patients with PPS.	B
Consider high-dose pentosan polysulphate to improve symptoms and quality of life in PPS.	A
Pregabalin is not recommended for use in PPS.	A
Perineal extracorporeal shock wave therapy might be considered for the treatment of PPS.	B
Electroacupuncture might be considered for the treatment of PPS.	B
Posterior tibial nerve stimulation might be considered for the treatment of PPS.	B
TUNA of the prostate is not recommended for the treatment of PPS.	B
For PPS with significant psychological distress, psychological treatment focussed on PPS should be attempted.	B

PPS = prostate pain syndrome; TUNA = transurethral needle ablation.

3.2 Bladder pain syndrome (BPS)

*3.2.1 **Introduction***

Interstitial cystitis (IC) describes a chronic, distressing bladder condition (1). The so-called ulcer, which is a typical cystoscopic finding in 10-50% of IC patients, was first described by Guy Hunner at the beginning of the last century (2,3). Subsequent research (4-6) has shown that IC encompassed a heterogeneous spectrum of disorders, with different endoscopic and histopathological presentations, with inflammation an important feature in only a subset of patients. To embrace all patients suffering from bladder pain, the terms painful bladder syndrome (PBS) or BPS have been suggested as more accurate when referring to pain in the bladder region, while assuming IC with Hunner's lesion as a specific type of chronic inflammation of the bladder (7,8).

The term BPS was put forward by the International Society for the Study of BPS (ESSIC) and will be used in these guidelines. In accordance Classic IC (Hunner's lesion and inflammation) will be refered to as BPS type 3 C (See Chapter 2, section 2.4 'Definitions of CPP terminology').

*3.2.2 **Definition***

Although generally accepted, the NIDDK criteria provide only a minimum framework to establish the diagnosis and have been felt to be too restrictive for clinical use (9-12). Recently, the ESSIC has suggested a standardised scheme of diagnostic criteria (13) to make it easier to compare different studies. BPS was preferred as the general term to match the current taxonomy of chronic pain syndromes.

*3.2.3 **Diagnosis***

Bladder pain syndrome should be diagnosed on the basis of pain, pressure or discomfort associated with the urinary bladder, accompanied by at least one other symptom, such as daytime and/or night-time increased urinary frequency, the exclusion of confusable diseases as the cause of symptoms, and if indicated, cystoscopy with hydrodistension and biopsy (Table7) (8).

Table 7: ESSIC classification of types of BPS according to the results of cystoscopy with hydrodistension and biopsies (8)

		Cystoscopy with hydrodistension		
	Not done	**Normal**	**Glomerulations[a]**	**Hunner's lesion[b]**
Biopsy				
Not done	XX	1X	2X	3X
Normal	XA	1A	2A	3A
Inconclusive	XB	1B	2B	3B
Positive[c]	XC	1C	2C	3C

[a]*Cystoscopy: glomerulations grade 2-3*
[b]*Lesion per Fall's definition with/without glomerulations*
[c]*Histology showing inflammatory infiltrates and/or detrusor mastocytosis and/or granulation tissue and/or intrafascicular fibrosis.*

Beyond subtyping, recent work has indicated the need to phenotype BPS patients. The - Urinary, Psychosocial, Organ Specific, Inflammation, Neurological/Systemic, Tenderness - UPOINT phenotyping system classifies patients according to clinically relevant domains, facilitating the use and appraisal of multimodal therapies (14).

*3.2.4 **Pathogenesis***

Current thought implicates an initial unidentified insult to the bladder, triggering inflammatory, endocrine and neural phenomena (15-17). This may happen in patients with an underlying systemic defect. In fact, BPS is similar and frequently precedes, coexists or follows other so-called functional somatic syndromes (FSSs), occurring predominantly in women, with pain as the main symptom, no abnormal laboratory or anatomical findings, and exacerbated by stress, namely fibromyalgia (FM), IBS and chronic fatigue syndrome (CFS) (17-19). At the bladder level, multiple aetiological or pathophysiological mechanisms have been and are still sought after.

No infection has as yet been implicated (20-25). BPS patients and controls have equal UTI frequency (18,26). Nevertheless, UTI and urgency are significantly more frequent during childhood and adolescence, in patients who later develop BPS in adulthood (27). Pancystitis, with associated perineural inflammatory infiltrates, is an essential part of BPS type 3 C (23), but is scant in non-ulcer BPS (6). There is a 10-fold increase in the mast cell count in bladder tissue from patients with BPS type 3 C compared with controls. Mast-cell-secreted mediators (28,29) can indeed induce symptoms and findings of BPS type 3 C (30). In non-ulcer BPS, however, the mast cell count is normal or only slightly increased (6,29,31,32).

Cystoscopic and biopsy findings in both ulcer and non-ulcer BPS are consistent with defects in the urothelial glycosaminoglycan (GAG) layer, which might expose the submucosal nerve filaments to noxious urine components (33-37). Furthermore, urinary uronate, and sulphated GAG levels are increased in patients with severe BPS (38). Uroplakin III-delta 4, caveolin-1, acid-sensing channels 2a and 3, muscarinic (M2-5)

and purinergic receptors (P2X2 and P2X1), bradykinin B1 receptor, and cannabinoid receptor CB1 are also upregulated and bladder urothelial sensitivity to carbachol enhanced in urothelial cells of BPS patients (39-41). In contrast, tight junction proteins zona occludens-1, junctional adherins molecule -1, and occludin genes are downregulated. Luminal nitric oxide (NO) urinary levels and inducible NO synthetase activity (iNOS) are increased in BPS patients (43). Urinary NO is significantly increased in ulcer patients and decreases with treatment, but not in non-ulcer BPS patients (44). iNOS-dependent NO production may have a role in urothelial dysfunction (44). Altogether, these data further point to increased urothelial permeability. Moreover, constituents of urine may exert a cytotoxic effect (45), especially in situations such as altered urothelial barrier or existence of unsialylated Tamm-Horsefall protein observed in BPS (46,47). Along with altered gene regulation, post translational epigenetic conditioning through micro RNA interference with messenger RNA transcription, may perpetuate the answer to agression mode, induced on urethelial cells by an initial insult (39,48).

Microvascular alterations are present in BPS. Despite unaltered number of microvessels, the ratio of mature to total vessels is significantly lower (49) and decreased bladder perfusion upon filling is observed in BPS patients (50). Adding to that, proangiogenic vascular endothelial growth factor and hypoxia inducible factor (HIF)-1 expression is increased in the urothelium of BPS patients (49,51).

Involvement of neurogenic inflammation as the trigger to a cascade of events in BPS has been confirmed by multiple observations documenting its occurrence, followed by neuroplasticity and neuronal sensitisation, both in the peripheral and CNS of BPS patients. Thus, bladder sensory nerve fibres can induce bladder wall events through neurogenic inflammation sparked by an initial insult, as well as pain regionalisation and centralisation. In fact, several data have shown enhanced bladder peripheral nerve density and increased peripheral neuromediator release, along with neurotrophin and nerve fibre receptor increases, especially in sensory and sympathetic nerves. Furthermore, besides cytokines from umbrella cells, activation of mast cells in close proximity to nerve terminals can be influenced by oestradiol as well as corticotrophin-releasing hormone (52-58). Regionalisation of pain is observed frequently in BPS patients (59). Moreover, autonomic responses and CNS processing of afferent stimuli are altered in patients with BPS (55,59,60).

Some of the clinical and histopathological characteristics are similar to autoimmune phenomena. However, only some BPS patients demonstrate autoantibodies, immune deposits or complement activation (61-68). Of note, differing T-cell infiltrates and B-cell nodules are seen in BPS type 3 C (69).

3.2.5 ***Epidemiology***

Reports of the prevalence of BPS have varied greatly, along with the diagnostic criteria and populations studied. Recent reports generally show higher figures than earlier ones, ranging from 0.06% to 30% (71-80) There is a female predominance of about 10:1 (4,71,81,82) but contrary to prior belief, possibly no difference in race or ethnicity (80-83). The relative proportions of classic and non-ulcer disease are unclear. Incidence in various studies has ranged from 5 to 50% (5,12,86,87).

Evidence that BPS may have a genetic component has been presented in several studies, but may contribute to less than one third of total variation in susceptibility for BPS, with the remainder being environmental (19,88-91).

BPS has significant economic costs. Direct annual costs in the USA have been estimated to be $750 million (92).

3.2.7 ***Association with other diseases***

An association has been reported between BPS and non-bladder syndromes (NBSs) - IBS, FM, CFS, vulvodynia, depression, panic disorders, migraine, sicca syndrome, temporomandibular joint disorder, allergy, asthma, systemic lupus erythematosus, inflammatory bowel disease (1-7). Risk of BPS correlates with number of NBSs in each patient (8). Recent work showing non-ulcer BPS to have significantly more FM, migraine, temporomandibular joint disorder and depression than ulcer patients emphasises the need for subtyping (9).

3.2.8 ***Diagnosis***

The diagnosis of BPS is one of exclusion, using symptoms, examination, urine analysis, cystoscopy with hydrodistension, and biopsy (Figure 6).

The nature of the pain is the key symptom of the disease:

- Pain, pressure or discomfort perceived to be related to the bladder, increasing with increasing bladder content.
- It is located suprapubically, sometimes radiating to the groins, vagina, rectum or sacrum.
- Pain is relieved by voiding but soon returns (10-14).
- Pain is aggravated by food or drink (13).

The differences between the two BPS subtypes, BPS type 3 C and non-ulcer, include clinical presentation, age distribution (15), molecular features (16-22), which may be discriminated non-invasively (23), and response to treatment (24-27). BPS type 3 C is a highly damaging inflammation that often leads to a small-capacity fibrotic bladder or upper urinary tract outflow obstruction. This type of progression is not observed in non-ulcer disease (14,28). Endoscopically, BPS type 3 C displays reddened mucosal areas often associated with small vessels radiating towards a central scar, sometimes covered by a small clot or fibrin deposit - the

Hunner lesion (14). The scar ruptures with increasing bladder distension, producing a characteristic waterfall-type of bleeding. There is a strong association between BPS type 3 C and reduced bladder capacity under anaesthesia (14,29,30).

Cystoscopy
Non-ulcer disease displays a normal bladder mucosa at initial cystoscopy. The development of glomerulations after hydrodistension is considered to be a positive diagnostic sign. A recent report has shown that there is no difference in the cystoscopic appearance between patients with non-ulcer disease and women without bladder symptoms about to undergo tubal ligation (31). The observation of glomerulations may however not always be constant over time (32).

Some authors maintain that cystoscopy with hydrodistension provides little useful information in addition to the history and physical examination findings (33,34). In contrast, others have found a strong correlation between pain and cystoscopic findings in patients with untreated BPS, and this difference from the results of other studies may have been due to treatment effects (35). Glomerulations may be involved in the disease mechanism, because such findings are highly associated with overexpression of angiogenic growth factors in the bladder and neovascularisation (36). A recent pilot study has demonstrated feasibility of bladder distension and biopsy under local anaesthesia (37). ESSIC believes objective findings are important and that a standardised scheme of diagnostic criteria would help improve the uniformity and comparability of different studies (38).

Biopsies are helpful in establishing or supporting the clinical diagnosis of both classic and non-ulcer types of the disease (17, 38-41). Important differential diagnoses to exclude by histological examination are carcinoma in situ and tuberculous cystitis.

Potassium chloride bladder permeability test has been used in the diagnosis of BPS (41), but recent reports have suggested that it lacks discriminating power (42,43). A modified test using less concentrated solution has been suggested. This test, although painless in contrast to the original procedure, decreases the maximum cystometric volume in 90% of patients with BPS, but not in controls (44). Furthermore, it has been suggested that the potassium sensitivity test can help to predict the response to GAG treatment (45).

Symptom scores may help to describe symptoms in an individual patient and as outcome measures. The O'Leary-Sant Symptom Index, also known as the Interstitial Cystitis Symptom Index (ICSI) has recently been validated successfully in a large study (46).

Biological markers. It is an attractive idea to support or, even better, to confirm the clinical diagnosis using a biological marker. Finding a universally helpful one is hampered by heterogeneity within the diagnostic group of BPS. Antiproliferative factor, heparin-binding epidermal growth factor-like growth factor, uroplakin III delta-4 mRNA, and YKL-40 have all presented as potential candidates (47-49). NO is interesting because of its ability to discriminate classic from non-ulcer disease with minimal invasiveness However all putative markers to date have yet to be validated (50).

3.2.9 ***BPS in children and males***
According to NIDDK criteria, children aged < 18 years is an exclusion criterion. However, occasional cases of BPS of both subtypes have been identified in patients under this age (51). There is increasing evidence that children aged 2-11 may also be affected, although prevalence figures are low (52). Thus, BPS cannot be excluded on the basis of age.
It has been argued that PPS and BPS are inter-related (53,54). However, differences in urinary markers suggest that BPS and PPS are different disorders with distinct pathophysiology (55).

3.2.10 *Conclusions and recommendations: assessment and diagnosis BPS*

Conclusions	LE
BPS has no known single aetiology.	3
Pain in BPS does not correlate with bladder cystoscopic or histologic findings.	2a
BPS Type 3 C is not surely distinguishable by non-invasive means.	2a
Ulcer non-ulcer disease ratios of BPS are highly variable between studies.	2a
The prevalence of BPS-like symptoms is high in population-based studies.	2a
BPS associated non bladder diseases are extremely prevalent, differ in BPS subtypes and correlate with BPS risk.	2a
BPS has a high impact on quality of life.	2a
There is significant overlap of symptoms with other conditions.	2a
Reliable instruments assessing symptom severity as well as phenotypical differences exist.	2a

Recommendations	GR
Specific diseases with similar symptoms have to be excluded. It is therefore recommended to adapt diagnostic procedures to each patient and aim at identifying them.	A
After primary exclusion of specific diseases, patients with symptoms according to the above definition should be diagnosed with BPS by subtype and phenotype.	A
A validated symptom and quality of life scoring instrument should be considered for initial assessment as well as for follow-up.	B
BPS associated non bladder diseases should be assessed systematically.	A
BPS associated negative cognitive, behavioural, sexual, or emotional consequences should be assessed.	A

BPS = Bladder pain syndrome.

3.2.12 ***Medical treatment***

Analgesics. Pain is often a dominant symptom, therefore, many patients try commonly used analgesics at some stage of the disease. However, pain relief is disappointing because the visceral pain experienced in BPS responds poorly to analgesic drugs. No systematic studies have been conducted on conventional analgesics. Short-term opioids may be indicated for breakthrough or exacerbated pain and periodic flare-ups. Long-term opioids may be considered after all other available therapeutic options have been exhausted. Urologists should obtain informed consent, arrange for regular follow-up, and be prepared to recognise opioid-induced side effects (1). BPS is a chronic disease, therefore, long-term opioids should be used only exceptionally and under close surveillance.

Corticosteroids. Reports on outcome with corticosteroid therapy have been both promising (2) and discouraging (3). Soucy et al. (4) have suggested a trial of prednisone (25 mg daily for 1-2 months, afterwards reduced to the minimum required for symptom relief) in patients with severe ulcerative BPS, which is otherwise unresponsive to conventional treatment. The side effects of steroids can be very serious, making it difficult to justify their use.

Antiallergics. Mast cells may play a role in BPS. Histamine is one of the substances released by mast cells. Histamine receptor antagonists have been used to block the H1 (5) as well as the H2 (6) receptor subtypes, with variable results.

Hydroxyzine is a histamine H1-receptor antagonist, which blocks neuronal activation of mast cells by inhibiting serotonin secretion from thalamic mast cells and neurons (7). Hydroxyzine hydrochloride (Atarax) is usually given, starting with 25 mg at bedtime, increasing to 50 mg/day, or if tolerated, 75 mg. The most common side effects are sedation and generalised weakness, which usually resolve after a period of treatment. In the first series using hydroxyzine, > 90% of patients showed improvement across the whole range of symptoms. Interestingly, improvement was noted in associated symptoms including migraine, IBS and allergies (5).

Although these initial results were supported by a further uncontrolled study (5,8), a prospective RCT of hydroxyzine or sodium pentosan polysulphate compared to placebo failed to show a statistically significant effect (9). However, the study was underpowered, which may be why it failed to demonstrate a statistically significant outcome for either drug compared to placebo. Combination therapy showed the highest response

rate of 40%, with a placebo response rate of 13%.

Amitriptyline. The tricyclic antidepressant amitriptyline has alleviated symptoms in BPS, probably via mechanisms such as blockade of acetylcholine receptors, inhibition of reuptake of released serotonin and noradrenalin, and blockade of histamine H1 receptors. It is also an anxiolytic agent (10). Several reports have indicated amelioration after oral amitriptyline (11-13). In a prospective RCT, 48 patients (14) were treated for 4 months with amitriptyline.

Drug dosages were escalated in 25-mg increments at 1-week intervals up to a maximum dosage of 100 mg. Amitriptyline significantly improved the mean symptom score, pain and urgency intensity, whereas frequency and functional bladder capacity improved but not significantly. In a subsequent, prospective, open-label study (15), a response rate of 64% with an overall mean dose of 55 mg was seen with long-term amitriptyline for 20 months. Patient overall satisfaction was good to excellent in 46%, with significant improvement in symptoms.

A therapeutic response was observed in all 28 patients fulfilling NIDDK criteria and those with a clinical diagnosis of BPS. Anticholinergic side effects (mouth dryness and weight gain) were common and considered to be a drawback of amitriptyline. A multicentre, randomised, double-blind, placebo-controlled clinical trial comparing amitriptyline and placebo plus behavioural modification in 273 patients concluded that amitriptyline may be beneficial at ≥ 50 mg/daily (16). In clinical practice drowsiness is also a limiting factor with amitriptyline and a lower starting dose of 10mg is often suggested. Nortriptyline is sometimes considered in place of amitriptyline when drowsiness is the limiting factor.

Pentosan polysulphate sodium (Elmiron) has been evaluated in double-blind, placebo-controlled studies. Pentosan polysulphate sodium is thought to substitute for a defect in the GAG layer. Subjective improvement of pain, urgency, frequency, but not nocturia, has been reported in patients taking the drug compared to placebo (17,18). In an open multicentre study, pentosan polysulphate sodium had a more favourable effect in BPS type 3 C than in non-ulcer disease (19). The normal dose is 150-200 mg twice daily between meals. However, absorption is incomplete. An RCT has compared 300 mg pentosan polysulphate sodium with evaluated dosages of 600 and 900 mg in 380 BPS patients. Mean ICSI scores improved significantly for all dosages (20). However, treatment response was not dose-dependent but related more to treatment duration. At 32 weeks, about half of all patients were responders. Most adverse events were mild and resolved without intervention. In contrast, a prospective RCT comparing pentosan polysulphate sodium and hydroxyzine against placebo failed to demonstrate a statistically significant outcome for either drug, although the former approached statistical significance (P = 0.064) (9). Combination therapy showed the highest response rate of 40% compared to 13% with placebo. For patients with an initial minor response to pentosan polysulphate sodium, additional subcutaneous administration of heparin appeared to be helpful (21).

Antibiotics have a limited role in the treatment of BPS. A prospective pilot RCT of sequential oral antibiotics in 50 patients found that overall improvement occurred in 12/25 patients in the antibiotic group and 6/25 in the placebo group, whereas 10 and five patients reported an improvement in pain and urgency, respectively. Antibiotics alone or in combination may be associated with decreased symptoms in some patients, but do not represent a major advance in therapy for BPS (22).

Immunosuppressants. Azathioprine, 50-100 mg daily, was given to 38 patients, resulting in disappearance of pain in 22 and urinary frequency in 20 (23). Cyclosporin A (CyA) (24) and methotrexate (25) were initially evaluated in open studies, with a good effect on pain, but a limited effect on urgency and frequency.

More recent studies of CyA have reported promising results (26,27). In 23 patients, daily voiding, maximal bladder capacity, and voided volume improved significantly after 1 year of treatment. The effect was maintained throughout 5 years follow-up, with 20/23 patients reporting no bladder pain. However, symptoms recurred within a few months of discontinuing CyA.

In a subsequent randomised study (27), 64 patients fulfilling the NIH criteria were randomised to 1.5 mg/kg CyA twice daily or low-dose (3 100 mg) pentosan polysulphate sodium for 6 months. CyA was superior to pentosan polysulphate sodium in all clinical outcome parameters, with the frequency of micturition significantly reduced in CyA-treated patients, and clinical global response rates of 75% (CyA) and 19% (pentosan polysulphate sodium) (P < 0.001). However, there were more adverse events in the CyA arm (including induced hair growth, gingival pain and hyperplasia, paraesthesia in the extremities, abdominal pain, flushing, muscle pain and shaking), and only 29 patients completed the 6 months follow-up in both groups. During CyA therapy, careful follow-up is mandatory, including regular blood pressure measurement and serum creatinine.

Gabapentin is an antiepileptic drug, which is used as adjunctive treatment in painful disorders. Gabapentin

may reduce the use of concomitant therapeutics, such as opioids. Two patients with BPS showed improved functional capacity and received adequate pain control when gabapentin was added to their regimen (28). In an uncontrolled dose-escalation protocol with 21 chronic genitourinary pain patients (29), 10 improved with gabapentin at 6 months. The study included eight BPS patients, of whom, five responded to gabapentin.

Pregabalin is an alpha (2)-delta ligand that binds to and modulates voltage-gated calcium channels, exerting its intended effect to reduce neuropathic pain (30). Pregabalin is the second of only two medications that are US FDA-approved for the treatment of neuropathic pain associated with diabetic peripheral neuropathy; it is used for the treatment of postherpetic neuralgia. Studies on BPS are still lacking.

Suplatast tosilate (IPD-1151T) is an oral immunoregulator that suppresses helper-T-cell-mediated allergic processes. Fourteen women with BPS treated with suplatast tosilate reported significantly increased bladder capacity and decreased symptoms after 1 year of treatment. No major side effects occurred and therapeutic effects correlated with a reduction in blood eosinophils, IgE and urinary T cells (31). Comparative controlled data are unavailable.

Quercetin is a bioflavonoid that may be effective in male pelvic pain syndrome. It was first tested in a small open-label study of 29 patients, with hopeful results (32). Theoharides et al. (33) have studied the dietary supplement CystoProtek formulated from quercetin and the natural GAG components, chondroitin sulphate and sodium hyaluronate. In an uncontrolled study, symptoms were significantly improved in 37 BPS patients (NIH criteria), who had failed all forms of therapy and who took six capsules per day for 6 months. Larger controlled studies are warranted by this result.

3.2.13 ***Intravesical treatment***

Intravesical application of medications establishes high concentrations at the target, with few systemic side effects. Disadvantages include the need for intermittent catheterisation, which can be painful in BPS patients, cost, and risk of infection.

Local anaesthetics. There are sporadic reports of successful treatment of BPS with intravesical lidocaine (1,2). Alkalisation of lidocaine before intravesical application improves pharmacokinetics (3). In an uncontrolled study, significant immediate symptom relief was reported in 94% of patients and sustained relief after 2 weeks in 80%, using instillations of combined heparin and alkalinised lidocaine [40,000 U heparin, 2% lidocaine (160 mg), and 3 mL 8.4% sodium bicarbonate] (4). One hundred and two adult patients (99 women) with a clinical diagnosis of BPS were randomised from 19 centres in the USA and Canada to receive a daily intravesical instillation of alkalinised lidocaine or placebo (double-blind), for 5 consecutive days. Treated patients had significant sustained symptom relief for up to 1 month (5).

Pentosan polysulphate sodium is a glycoprotein aimed at replenishing the GAG layer, which is applied intravesically due to poor bioavailability following oral administration. A double-blind placebo-controlled study (6) was performed in 20 patients, of whom 10 received intravesical pentosan polysulphate sodium (300 mg in 50 mL 0.9% saline) twice weekly for 3 months, and 10 received placebo.
At 3 months, four patients in the pentosan polysulphate sodium group and two in the placebo group achieved significant symptomatic relief. Bladder capacity showed a significant increase only in patients treated with pentosan polysulphate sodium. At 18 months, symptoms were relieved in eight patients, who were still receiving pentosan polysulphate sodium instillation, and in four patients not receiving the drug. In another study, a total of 41 women diagnosed with BPS were randomised to receive a combination of intravesical plus oral pentosan polysulphate sodium (21 in treatment group) or intravesical placebo plus oral pentosan polysulphate sodium (20 in placebo group) for 6 weeks. All subjects continued to receive oral pentosan polysulphate sodium for a further 12 weeks. At week 18, the treatment group showed significant improvement in all health-related QoL domains compared to baseline ($P \leq .01$), whereas the placebo group showed significant improvement in only three domains, ($P \leq .05$) compared to baseline (7).

Intravesical heparin has been proposed as a coating agent. In an open, prospective, uncontrolled trial (8), 48 BPS patients received instillations of 10,000 U in 10 mL sterile water three times weekly for 3 months. In over half of the patients, intravesical heparin controlled the symptoms, with continued improvement after 1 year of therapy. Kuo et al. (9) have reported another uncontrolled trial of intravesical heparin (25,000 U twice weekly for 3 months) in women with frequency-urgency syndrome and a positive potassium test. The study included 10 patients with BPS, of whom eight reported symptomatic improvement. Baykal et al. (10) have evaluated intravesical heparin plus dorsal tibial nerve stimulation in 10 refractory BPS patients. Voiding frequency, pain scores and maximum cystometric capacity were significantly better after 2 and 12 months compared to pretreatment values.

Hyaluronic acid (hyaluronan) is a natural proteoglycan aimed at repairing defects in the GAG layer. A response rate of 56% at week 4 and 71% at week 7 was reported in 25 patients treated with hyaluronic acid (11). After week 24, effectiveness decreased, but there was no significant toxicity. Nordling et al. (12) and Kallestrup (13) have reported a 3-year follow-up of a 3-month, prospective, non-randomised study evaluating the effect of intravesical hyaluronic acid on BPS symptoms. Of the 20 patients, 11 chose to continue treatment beyond the initial trial, and modest beneficial long-term effects were noted in about two-thirds of patients. Reduction in urinary frequency was less effective and mostly due to an improvement in night-time voids.

Another study (14) has demonstrated a similar favourable effect of hyaluronic acid on pain reduction. Forty-eight patients with typical symptoms and a positive potassium (0.4 M) sensitivity test were treated with weekly instillations of 40 mg hyaluronic acid for 10 weeks. Visual analogue scale scores showed symptom relief due to hyaluronic acid therapy, irrespective of bladder capacity. The improvement was particularly evident in patients with a reduction in $C_{max} < 30\%$ compared to patients with a reduction of < 30% with 0.2 M KCl solution ($P = 0.003$). Long-term effects were investigated in a study of 70 patients previously treated with hyaluronan. Of the 70 patients initially treated, 48 were available for evaluation. Of these, 50% reported complete remission with no further therapy. Another 41.7% of patients with symptom recurrence improved after retreatment (15).

Chondroitin sulphate. Intravesical chondroitin sulphate (16) demonstrated beneficial effects in patients with a positive potassium stimulation test, in two non-randomised, uncontrolled, open-label pilot studies. Steinhoff (17) treated 18 patients with 40 mL instilled intravesically once weekly for 4 weeks and then once monthly for 12 months. Thirteen of 18 patients were followed for the entire 13-month study. Twelve of these patients responded to treatment within 3-12 weeks. A total of 6/13 (46.2%) showed a good response, 2/13 (15.4%) had a fair response, 4/13 (30.8%) had a partial response, and 1/13 (7.7%) showed no response. In a second trial (18), 24 refractory patients with BPS were treated with high-dose (2.0%) chondroitin sulphate instillations twice weekly for 2 weeks, then weekly with 0.2% solution for 4 weeks, and monthly thereafter for 1 year. The average symptom improvement reported in 20 patients completing the trial was 73.1% (range: 50-95%). The time to optimum response was 4-6 months. A more concentrated 2.0% solution was needed in eight patients to maintain results.
Sixty-five patients with BPS were treated in a prospective, randomised, double-blind, inactive vehicle-controlled, 12-week study (6 weeks treatment, followed by 6 weeks follow-up). At the primary endpoint analysis (week 7), 22.6% of the vehicle control group were responders compared with 39.4% of the active therapy group, however, the difference was not significant, probably due to underpowering of the study (19,20).

Dimethyl sulphoxide (DMSO) is a chemical solvent and water-soluble liquid that penetrates cell membranes. It is claimed to have analgesic, anti-inflammatory, collagenolytic, and muscle relaxant effects. It is also a scavenger of the intracellular OH radical, which is believed to be an important trigger of the inflammatory process. It has been tested empirically and found to alleviate symptoms in BPS. DMSO is now a standard treatment. In a controlled crossover trial (21), 33 patients received instillations of 50% DMSO solution and placebo (saline). All patients received both regimens, which were administered intravesically every 2 weeks for two sessions of four treatments each. Subjective improvement was noted in 53% of patients receiving DMSO versus 18% receiving placebo, and objective improvement in 93% and 35%, respectively.

Other uncontrolled trials with DMSO have reported response rates of 50-70% for a period of 1-2 months (22). Rossberger et al. (23) have evaluated the discomfort and long-term effects of DMSO instillations in a total of 28 patients. Side effects were no more common or pronounced in patients with classic compared to non-ulcer disease. After DMSO instillations, a residual treatment effect lasting 16-72 months could be seen. DMSO is contraindicated during UTIs or shortly after bladder biopsy. It temporarily causes a garlic-like odour. There is a case report in which DMSO treatment may have caused pigmented eye lens deposits (24), therefore, ophthalmic review should be considered during treatment.

Bacillus Calmette Guérin (BCG). The tuberculosis BCG vaccine is used for its immunomodulatory properties in the intravesical treatment of superficial bladder carcinoma. In 1997, a small prospective, double-blind pilot study showed that intravesical BCG demonstrated a 60% response rate versus 27% in the placebo group in 30 patients who received six weekly instillations of Tice strain BCG or placebo (25). In a subsequent 24-33-month follow-up study, eight of the nine responders reported BPS symptom amelioration. BCG did not worsen symptoms in non-responders (26). However, these results are at variance with two controlled trials. In a prospective, double-blind crossover trial of BCG and DMSO (86), BCG treatment failed to demonstrate any benefit.
Another randomised, placebo-controlled, double-blind trial of 260 refractory BPS patients (27) reported global response rates of 12% for placebo and 21% for BCG (P = 0.062). Small improvements were observed for all secondary outcomes (voiding diary, pain, urgency, symptom indexes, and adverse events), some of which were greater with BCG, but with only borderline statistical significance.
In a subsequent study (28), 156 non-responders from both groups were offered treatment with open-label BCG. The low response rate (18%) for BCG in this series and the results of the same group's (Interstitial Cystitis Clinical Trials Group; ICCTG) follow-up on the responders, which found no differences, have substantiated the argument against the routine use of BCG for BPS (29).

Vanilloids disrupt sensory neurons (30). Resiniferatoxin (RTX) is an ultrapotent analogue of the chilli pepper extract capsaicin, causing less pain on instillation and therefore no anaesthesia. Chen et al. (31) have investigated RTX tolerability (0.05 or 0.10 μM) in 22 BPS patients versus placebo. The most commonly reported adverse event was pain during instillation (RTX > 80.0%, placebo 25.0%) but no serious adverse events were reported. In a small RCT on 18 patients with hypersensitive bladder disorder and pain (32), RTX significantly reduced mean frequency, nocturia, and pain scores by about 50%. In another study of seven patients with detrusor hyper-reflexia, RTX improved urinary frequency, incontinence and bladder capacity (33). In a small open-label study with single-dose RTX in patients with frequency and urgency (34), RTX significantly improved LUTS, urodynamic parameters, and QoL for up to 6 months. These results are in contrast with an RCT in 163 BPS patients randomly assigned to receive a single intravesical dose of 50 mL of either placebo or RTX (0.01, 0.05 or 0.10 μM) (35). RTX resulted in a dose-dependent increase in instillation pain, but otherwise was well

tolerated. It did not improve overall symptoms, pain, urgency, frequency, nocturia, or average void volume during 12 weeks follow-up.

More favourable results have been reported from a prospective study on multiple intravesical instillations of RTX (36) (0.01 μM once weekly for 4 weeks). Among 12 patients (one drop-out for severe pain), the overall satisfaction rate was 58.3%, with several scales of symptom and QoL significantly improved after RTX treatment. There was no significant increase in functional bladder capacity or change in urodynamic parameters. A prospective, randomised, double-blind, crossover study was performed in 26 women, who received instillations with various pH values. There was no evidence that changes in urinary pH affected the pain associated with BPS (37).

3.2.14 ***Interventional treatments***

Bladder distension. A frequently cited report by Bumpus *et al*. (1) claims that hydrodistension achieved symptom improvement in 100 patients over several months. However, the study did not define either patient population or symptoms and the methods used were inadequately described. Reports by Ormond (2) and Longacre (3) were just as vague during the 1930s. In 1957, an uncontrolled retrospective study was presented by Franksson (4), who treated 33 patients with repeated, up to 10-fold, distensions. Twelve patients had improved symptoms for up to 4 weeks, in 14 patients for up to 6 months, and in seven patients for up to 1 year. British studies from the 1970s have reported contradictory results. Dunn et al. (5) have claimed to have achieved complete absence of symptoms in 16/25 patients during a mean follow-up of 14 months using the Helmstein method (6), in which an intravesical balloon is distended at the level of systolic blood pressure for 3 h. Bladder rupture occurred in two cases. These results disagree with those of Badenoch (7), who failed to note any improvement in 44/56 patients after hydrodistension. Twenty years later, McCahy (8) rejected balloon hydrodistension because of inefficacy and a complication rate of 20%. In the recent literature, bladder necrosis following hydrodistension has been extremely rare (9).

In 2002, Glemain *et al*. (10) reported an uncontrolled study on 65 BPS patients treated by 3 h balloon hydrodistension. Treatment efficacy in the 33 retrospectively and 32 prospectively studied patients was 38% and 60% at 6 months, and 22% and 43% at 1 year, respectively. Results were superior for bladder capacities > 150 mL.

Ottem and Teichmann (2006) reported a retrospective study of 84 BPS patients (11), and 56% reported short-lived improvement from hydrodistension. Rose et al. have investigated bladder distension using electromotive drug administration (EMDA) (12,13), as an alternative to general anaesthesia. Among 11 patients, the distension capacity achieved by EMDA was nearly identical to that in the operating room and cystoscopic findings were similar. Yamada et al. (14) have reported on repeated hydrodistension in 52 BPS patients (NIH criteria). Under epidural anaesthesia, the bladder was repeatedly distended to maximal capacity and distension was repeated on the following day for 30 min. Five patients were classified as good responders, 30 as moderate and 17 as poor. Overall, hydrodistension was effective for ~70% of patients for > 3 months, without serious complications.

According to a study by Erickson et al. (15), the median symptom score for newly diagnosed patients decreased after distension, but only a few patients had at least 30% symptom improvement. Bladder distension altered levels of urine antiproliferative factor and heparin-binding epidermal-growth-factor-like growth factor towards normal. However, the mechanism of symptom relief after distension remains unknown.

In a retrospective review of 185 patients who underwent hydrodistension (16), results failed to identify any statistically significant differences in objective findings (anaesthetic capacity, glomerulations) following distension, or any therapeutic benefits, when patients were categorised according to presenting symptoms.

Although bladder hydrodistension is a common treatment for BPS, scientific justification is scarce. It represents a diagnostic tool, but has a limited therapeutic role.

EMDA enhances tissue penetration of ionised drugs by iontophoresis. When adapted for the bladder, EMDA uses a transurethral anode and a suprapubic skin cathode. EMDA is expensive and has been the subject of uncontrolled studies only.

Six BPS patients were treated with EMDA using lidocaine (1.5%) and 1:100,000 adrenaline in aqueous solution, while the bladder was dilated to maximum tolerance (17). Significant bladder enlargement was achieved and voiding symptoms and pain decreased. In four patients, the results were reported as durable.

Rosamilia et al. (18) treated 21 women using EMDA with lidocaine and dexamethasone, followed by bladder distension. A good response was seen in 85% of patients at 2 weeks, with 63% still responding at 2 months. Complete resolution of pain was achieved in 25% of patients reviewed at 6 months. Using a similar technique, Riedl et al. (19) noted complete resolution of bladder symptoms in 8/13 patients lasting 1-17 months. Partial or short-term improvement was observed in three patients. Two patients experienced aggravated pain for several days after therapy. A 66% increase in bladder capacity was observed. Upon symptom recurrence, treatments were repeated with equal efficacy in 11 patients.

Transurethral resection (TUR) coagulation and laser. Endourological ablation of bladder tissue aims to eliminate urothelial, mostly Hunner, lesions. In a case report, Kerr (20) has described TUR of a 1-cm ulcer in a woman who experienced symptom resolution for 1 year. Subsequently, Greenberg et al. (21) have reported 77 patients with Hunner ulcers treated over a 40-year period: 42 were managed conservatively, seven underwent fulguration, and 28 were treated by TUR in a non-randomised fashion. Fulguration improved symptoms in 5/7 patients. All patients experienced symptom recurrence in < 1 year and efficacy was not superior to non-surgical treatment.

In another series of 30 BPS type C patients (22), complete TUR of visible lesions resulted in an initial disappearance of pain in all patients and a decrease in frequency in 21. Relapse was noted in one-third of patients after 2-20 months, while the remaining two-thirds were still pain-free after 2-42 months. The same group recently has reported the largest series of patients with BPS type C treated by complete TUR of all visible ulcers (23). A total of 259 TURs were performed on 103 patients. Ninety-two patients experienced amelioration, with symptom relief lasting > 3 years in 40% of patients, and most of the remaining patients responded well to subsequent TUR.

Transurethral application of the (Nd-YAG) laser is suggested as an alternative to TUR for endoscopic treatment in BPS. Shanberg *et al.* (24) have treated five refractory BPS patients, four of whom demonstrated cessation of pain and frequency within several days. Follow-up at 3-15 months revealed no relapse, except for mild recurrent voiding symptoms. This series was extended to 76 patients treated at two institutions (25). Although 21 of 27 patients with Hunner ulcers noted symptom improvement, 12 experienced relapse within 18 months. In the group without ulcers, only 20 of 49 patients improved, of whom 10 required further therapy within 1 year.

In a later study, 24 patients with refractory BPS type C underwent ablative Nd-YAG laser ablation of Hunner's ulcers (26). All patients showed symptom improvement within a few days, without complications. At 23 months, mean pain and urgency scores, nocturia and voiding intervals improved significantly. However, relapse in 11 patients required up to four additional treatments. Controlled studies are still lacking. Endourological resection is not applicable to non-ulcer BPS.

Botulinum toxin A (BTX-A) may have an antinociceptive effect on bladder afferent pathways, producing both symptomatic and urodynamic improvements (27). Thirteen BPS patients were injected with 100-200 IU of BTX-A (abobotulinumtoxin A or onabotulinumtoxin A) into 20-30 sites submucosally in the trigone and floor of the bladder. Overall, nine (69%) patients noted subjective improvement, and ICSI scores improved by 70% ($P < 0.05$). There were significant decreases in daytime frequency, nocturia and pain, and a significant increase in first desire to void and maximal cystometric capacity. However, these results are in contrast with those in another study of BTX-A (onabotulinumtoxin A) in 10 patients with BPS (28). One hundred units were injected suburothelially into 20 sites in five patients, while 100 U were injected into the trigone in the remaining five. None of the patients became symptom-free; two showed only limited improvement in bladder capacity and pain score.

To ascertain effect of repeat injections a total of 13 patients were followed up for 2 years, while 58 injections were administered with a mean of 4.8 ± 0.8 injections per patient. The mean interval between two consecutive injections was 5.25 ± 0.75 months. At 1 and 4 months follow-up, 10 patients reported a subjective improvement. Mean VAS scores, mean daytime and night-time urinary frequency decreased significantly. The three non-responders to the first intravesical treatment session underwent further treatment 3 months later with satisfactory results. At 1 and 2 years follow-up, the beneficial effects persisted in all patients (29).

In an RCT, the difference between hydrodistension and hydrodistension plus intravesical BTX-A (onabotulinumtoxin A) was analysed. Of the 67 patients, 44 were divided in two groups: one received 200 U and the other 100 U, and cystoscopic hydrodistension was performed after 2 weeks. The remaining 23 patients received hydrodistension only. There was symptomatic improvement in all groups. However, in the hydrodistension group, 70% had returned to their previous symptoms after the first month, while in the BTX-A-treated groups, there was improvement of VAS, functional bladder capacity and cystometric bladder capacity at 3 months. At 12 and 24 months, the results in the active group were 55 and 30% versus 26 and 17% in the hydrodistension group (30).

Trigonal-only injection seems effective and long-lasting because 87% of patients (n = 23) reported improvement after a 3-month follow-up period in a study by Pinto *et al.* Over 50% referred continuity of the beneficial effect 9 months after the first treatment. When retreatment was needed, similar results were obtained. The authors concluded that this treatment is safe, effective and can be repeated (31).

Hyperbaric oxygen (HBO). In a prospective pilot study, six patients underwent 30 sessions of 100% HBO inhalation and were followed up for > 15 months. Four patients rated the therapeutic result as excellent or good, while two showed only short-term amelioration (32). In a subsequent double-blind, sham-controlled study (33), 3/14 patients on HBO and no control patients were identified as responders ($P < 0.05$). At 12 months, three patients (21.4%) still reported a treatment response. Hyperbaric oxygenation resulted in a decrease of baseline urgency and pain ($P < 0.05$). ICSI scores decreased from 26 to 20 points in patients on HBO, while sham treatment did not result in any improvement. These results suggest that HBO is a safe and feasible therapeutic approach, with moderate effects on a small subgroup of BPS patients. Disadvantages include high costs, limited availability of treatment sites and time-consuming treatment.

Neuromodulation. In the first prospective, single-blind, crossover trial of sacral nerve stimulation (SNS) versus pudendal nerve stimulation (PNS) for patients with BPS (n = 22), PNS gave an overall 59% improvement in symptoms, whereas SNS gave an overall 44% improvement ($P = 0.05$). Most patients who tested both a sacral and pudendal electrode chose PNS as the better site. Follow-up showed marked improvements in voiding variables and validated BPS symptom questionnaires. Over 90% of patients treated with neuromodulation stated that they would undergo implantation again (34).

Long-term results were verified in a retrospective study of 78 patients treated from 1994 to 2008. Permanent sacral neuromodulation implantation was performed in patients who showed at least 50% improvement in their symptoms with a temporary peripheral nerve evaluation test. Median follow-up was 61.5 ± 27.7 months. Good long-term success of sacral neuromodulation was seen in 72% of the patients. The explantation rate was 28%. The most frequent reason for explantation was poor outcome (54% of the failed patients). The revision rate was 50% (35).

In another observational, retrospective, case-controlled review (January 2002-March 2004), 34 female patients underwent permanent device implants . Mean pre-/postoperative pelvic pain and urgency/frequency scores were 21.61 ± 8.6/9.22 ± 6.6 ($P < 0.01$), and mean pre-/postoperative visual analogue pain scale (VAPS) scores were 6.5 ± 2.9/2.4 ± 1.1 ($P < 0.01$). Mean follow-up was 86 ± 9.8 months. Sacral neuromodulation showed adequate improvement for the symptoms of refractory BPS. Reoperation rate was 25% (36).

3.2.15 ***Treatments of limited efficacy and absence of recent publications***

Cimetidine. The H2-blocker cimetidine has been reported to improve symptoms in BPS (1). Thirty-six patients were enrolled in a double-blind clinical study with oral cimetidine versus placebo for 3 months. Patients receiving cimetidine showed a significant improvement in symptom scores, pain and nocturia, although histologically, the bladder mucosa showed no qualitative changes in either group (2).

Prostaglandins. Misoprostol is a prostaglandin that regulates various immunological cascades. Twenty-five BPS patients received 600 µg/day misoprostol for 3 months, with responders treated for a further 6 months. At 3 months, 14 had significantly improved, with 12 showing a sustained response after a further 6 months. However, the incidence of adverse drug effects was 64% (3).

L-Arginine. Oral treatment with l-arginine, the substrate for NO synthase, has been reported to decrease BPS-related symptoms (4-6). NO has been shown to be elevated in patients with BPS (7). However, others could not demonstrate either symptomatic relief or change in NO production after treatment (8,9).

Anticholinergics. Oxybutynin is an anticholinergic drug used in overactive detrusor dysfunction. Intravesically administered oxybutynin was combined with bladder training in one study, with improvement of functional bladder capacity, volume at first sensation and cystometric bladder capacity (10). However, the effect on pain was not reported.

Duloxetine inhibits both serotonin and noradrenaline reuptake. In an observational study, 48 women were prospectively treated with duloxetine for 2 months following an up-titration protocol to the target dose of 2 40 mg/day duloxetine over 8 weeks (11). Duloxetine did not result in significant improvement of symptoms. Administration was safe, but tolerability was poor due to nausea. Based on these preliminary data, duloxetine cannot be recommended as a therapeutic approach for BPS.

Clorpactin is a detergent of hypochloric acid previously used to treat BPS (12-16). Due to high complication rates (14-17), clorpactin instillations can no longer be recommended.

3.2.16 ***Non-pharmacological treatments***

Behavioural bladder training techniques are attractive for BPS patients with predominant symptoms of frequency/urgency but hardly any pain. Parsons *et al*. (1) included 21 selected BPS patients in a protocol that focused on progressively increasing micturition intervals. Fifteen patients reported a 50% decrease in urgency, frequency and nocturia, and there was a moderate increase in bladder capacity. Chaiken *et al*. (2) retrospectively analysed 42 patients, who had been instructed in diary keeping, timed voiding, controlled fluid intake, and pelvic floor muscle training. After 12 weeks, voiding intervals increased by a mean 93 min and daily micturition was reduced by an average of nine voids. Overall, 88% of the patients reported markedly improved or improved symptoms.

Diet. Dietary restrictions are among the many physical self-care strategies found among BPS patients (3).

In an analysis of the Interstitial Cystitis Data Base (ICDB) cohort study, special diets were among the five most commonly used therapies (4). Bade *et al*. (5) have found that BPS patients consume significantly fewer calories, less fat and coffee, but more fibre. Scientific data on a rationale for such diets are unavailable. The concentration of some metabolites and amino acids appears to be changed in BPS (6).

A study of the metabolism of the arylalkylamines (tryptophan, tyrosine, tyramine and phenylalanine) in 250 patients revealed an inability to synthesise normal amounts of serotonin and MHPG noradrenaline metabolite. In this study, dietary restriction of acid foods and arylalkylamines lessened the symptoms, but did not alter specific abnormalities in dopamine metabolism. In another, non-randomised, prospective study of BPS patients with nutrition-related exacerbations, calcium glycerophosphate was reported to ease food-related flares (7). The observed efficacy seems little better than would be expected with placebo.

Overall, dietary management is a common self-care strategy in BPS and offers a cost-effective therapeutic approach. Comprehensive instructions on how to identify individual trigger foods are given in the IC-Network Patient Handbook (8). However, scientific data are limited and dietary restriction alone does not produce complete symptomatic relief.

Acupuncture. In non-curable and agonising diseases like BPS, desperate patients often try complementary medicines, such as acupuncture. However, scientific evidence for such treatments is often poor, with contradictory results from a few low-evidence reports on acupuncture, with any effects appearing to be limited and temporary. A significant increase in capacity occurred after acupuncture in 52 women with 85% reporting an improvement in frequency, urgency and dysuria and symptoms (9). However, at follow-up at 1 and 3 years, these effects were no longer detectable and the authors concluded that repeated acupuncture was necessary to maintain beneficial effects (10).

In a non-randomised comparison in women with urethral syndrome, 128 treated by acupuncture and traditional Chinese medicine were compared with 52 treated by western medicine as controls. Efficacy rates and urodynamic parameters were significantly better in the acupuncture group (11). In contrast, in a prospective study on the effect of acupuncture in BPS (12), no differences in frequency, voided volumes or symptom scores were noted, and only one patient improved for a short period of time.

Hypnosis is a therapeutic adjunct in the management of cancer, surgical disease and chronic pain. Although used in urological patients (13,14), there are no scientific data on its effect on BPS symptoms.

Physiotherapy. General body exercise may be beneficial in some BPS patients (15). An uncontrolled trial of transvaginal manual therapy of the pelvic floor musculature (Thiele massage) in 21 BPS patients with high-tone dysfunction of the pelvic floor resulted in significant improvement on several assessment scales (16). Langford (17) has prospectively examined the role of specific levator ani trigger point injections in 18 women with CPP. Each trigger point was identified by intravaginal palpation and injected with 5 mL of a mixture of 10 mL 0.25% bupivacaine, 10 mL 2% lidocaine and 1 mL (40 mg) triamcinolone. Thirteen (72%) women improved with the first trigger point injection, with six (33%) women being completely pain-free.

Intravaginal electrical stimulation was applied to 24 women with CPP in the form of 10 30-min applications, two or three times weekly. Stimulation was effective in alleviating pain, as evaluated at the end of treatment and 2 weeks, 4 weeks and 7 months after completion of treatment ($P < 0.05$). There were significantly fewer complaints of dyspareunia following treatment ($P = 0.0005$) (18).

3.2.17 ***Surgical treatment***

When all efforts fail to relieve disabling symptoms, surgical removal of the diseased bladder is the ultimate option (1-4). Three major techniques of bladder resection are common:

- supratrigonal (i.e. trigone-sparing) cystectomy
- subtrigonal cystectomy
- radical cystectomy including excision of the urethra.

All techniques require substitution of the excised bladder tissue, mostly performed with bowel segments.

Techniques without bladder removal. As early as 1967, Turner-Warwick reported that mere bladder augmentation without removal of the diseased tissue was not appropriate (5). Sporadic reports that unresected BPS bladders cease to cause symptoms when excluded from the flow or urine are scarce (6,7).

Supratrigonal cystectomy with subsequent bladder augmentation represents the most favoured continence-preserving surgical technique. Various intestinal segments have been used for trigonal augmentation, including ileum (8-16), ileocaecum (15-22), right colon (8,16,23), and sigmoid (10,12,13,18,22). Substituting gastric segments (24,25) seems to be less helpful because the production of gastric acids may maintain dysuria and persistent pain.

The therapeutic success of supratrigonal cystectomy has been reported in many studies. In 1966, von Garrelts reported excellent results in 8/13 patients with a follow-up of 12-72 months (12). In 1977, Bruce et

al. achieved satisfactory relief of BPS symptoms by ileocystoplasty and colocystoplasty in eight patients (10). Dounis and Gow have reported seven BPS patients whose pain and frequency were considerably improved after supratrigonal cystectomy with ileocaecal augmentation (26).

In 1991, Kontturi et al. used segments of colon and sigmoid colon in 12 cases (22). All five patients augmented with sigmoid colon remained symptom-free over 4.7 years of follow-up. Two of seven cases augmented with colon required secondary cystectomy with formation of an ileal conduit. Nielsen et al. have reported a series of eight patients undergoing supratrigonal cystectomy with ileocaecocystoplasty.

Although symptoms resolved in two patients, treatment failure in another six necessitated secondary cystectomy and ileal conduit formation (17).

Linn *et al*. (27) have followed six BPS patients after supratrigonal cystectomy with ileocaecal augmentation for a period of 30 months, and have reported that all patients were symptom-free and voided spontaneously.

In 2002, Van Ophoven *et al*. (1) reported the long-term results of trigone-preserving cystectomy and consecutive orthotopic substitution enteroplasty in 18 women with BPS, using ileocaecal (n = 10) or ileal (n = 8) segments. At a mean follow-up of nearly 5 years, 14 patients were completely pain-free, 12 voided spontaneously, and 15 had complete resolution of dysuria. Ileocaecal bowel segments showed superior functional results, because in the group augmented with ileum, three patients required self-catheterisation and one a suprapubic catheter. Overall, surgery achieved a significant improvement in diurnal and nocturnal frequencies, functional bladder capacity and symptom scores, with only two treatment failures.

In more recent reports with longer follow-up, the debate on the outcome of BPS patients undergoing cystectomy continues and results vary greatly between different surgeons and patient populations.

Chakravarti (28) presented a retrospective review of 11 patients, who had undergone a trigone-preserving orthotopic substitution caecocystoplasty for intractable BPS Type 3 C and were followed up for a mean period of 9 years. All had symptomatic relief and an increase in bladder capacity to normal. There was no mortality and minimal postoperative morbidity, with two patients requiring intermittent self-catheterisation due to high residual volumes. No significant urinary reflux or metabolic complications were noted. However, two patients required cystectomy after 4 and 6 years, respectively, due to recurrent trigonal disease in one patient and urethrotrigonal hypersensitivity following intermittent self-catheterisation in the other. One patient developed an advanced adenocarcinoma in the caecal segment 7 years after the primary operation.

Blaivas *et al*. (29) have reported less favourable results. Long-term outcomes of augmentation enterocystoplasty or continent urinary diversion were analysed in 76 patients with benign urological disorders, including seven with a clinical diagnosis of BPS. The BPS patients all failed surgical treatment because of persistent pelvic pain and failure to achieve adequate bladder capacity, rather than because of incontinence. The authors currently consider BPS to be a contraindication for enterocystoplasty.

In contrast, Navalon *et al*. (30) have reported a 32-month follow-up of four women with refractory BPS who underwent supratrigonal cystectomy with orthotopic substitution ileocystoplasty. Suprapubic pain disappeared in all cases, as well as lower urinary tract symptoms, with good control of urinary frequency day and night in the immediate postoperative period. All patients reported high satisfaction with the outcome.

Subtrigonal cystectomy. Although less popular, subtrigonal cystectomy has also been reported (27,31-34). Subtrigonal resection has the potential of removing the trigone as a possible disease site, but at the cost of requiring ureteral reimplantation with associated risks of leakage, stricture, and reflux. Nurse *et al*. reported trigonal disease in 50% within their cohort (13/25) and blamed surgical failures on the trigone left in place (35).

In contrast, Linn *et al*. have indicated that the level of resection was not solely responsible for treatment success. While completely curing six patients by supratrigonal resection, there were three failures among 17 subtrigonal resections, and half of the successful subtrigonal resections required self-catheterisation to support voiding of the ileocaecal augmentate (27). A recent report on female sexuality after cystectomy and orthotopic ileal neobladder (36) describes eight patients. Pain was relieved in all eight, but only one regained a normal sexual life postoperatively.

Selecting patients and technique. BPS is benign and does not shorten life, so that operative procedures rank last in the therapeutic algorithm. However, severely refractory patients should not have to tolerate unsuccessful conservative treatments for several years when surgical options are available.

Detailed counselling and informed consent must precede any irreversible type of major surgery, which should only be undertaken by experienced surgeons. The choice of technique is influenced by the experience of the surgeon. The appropriate extent of tissue resection should be based on the endoscopic and histopathological findings. Some surgeons recommend preoperative cystoscopy and bladder capacity as a prognostic parameter for operative success (7). Responders and failures following orthotopic substitution differed in mean preoperative bladder capacity (200 vs. 525 mL, respectively) (17). These findings have been

supported by Peeker *et al*. (37), who found that patients with end-stage BPS Type 3 C had excellent results following ileocystoplasty, whereas patients with non-ulcer disease were not helped. These results have recently been confirmed by another study from the same institution.

A retrospective analysis of 47 patients fulfilling the NIH criteria, who underwent reconstructive surgery using various techniques during 1978-2003 (38), resulted in complete symptom resolution in 32/34 patients with classic Hunner-type disease, but only 3/13 patients with non-ulcer disease.

Cystectomy with formation of an ileal conduit stills ranks first in current US practice trends in surgical BPS therapy (39). For cosmetic reasons, however, techniques of continent diversion are preferred, particularly in younger patients. After orthotopic bladder augmentation, particularly when removing the trigone, voiding may be incomplete and require intermittent self-catheterisation. Patients considering these procedures should be advised and must be considered capable of performing, accepting and tolerating self-catheterisation.

For patients with BPS who develop recurrent pain in the augmented bladder or continent pouch after enterocystoplasty or continent urinary diversion, Elzawahri (40) has recommended retubularisation of a previously used bowel segment to form a urinary conduit.

For younger patients, it may be important to know that pregnancies with subsequent lower-segment Caesarean section after ileocystoplasty have been reported (41). Reconstructive surgery for refractory BPS is an appropriate last resort only for well-selected patients with refractory end-stage disease. The decision to embark on major reconstructive surgery should be preceded by a thorough preoperative evaluation, with an emphasis on assessment to determine the relevant disease location and subtype.

A summary of the treatment options for BPS, including LE and GR is given in the next section. Figure 6 and 7 are algorithms for the diagnosis and therapy of BPS based on the information discussed above.

3.2.18 ***Conclusions and recommendations: treatment of BPS***

Conclusions	**LE**
None of the present existing treatments have effect on all BPS subtypes or phenotypes.	4
Conventional analgesics have little efficacy. Opioids are effective in controlling BPS pain.	2b
Corticosteroids are not recommended as long-term treatment.	3
Hydroxyzine has limited efficacy shown in RCT and is effective in associated non bladder diseases.	1b
Limited data exist on effectiveness of cimetidine in BPS.	2b
Amitriptyline is effective in pain and related symptoms of BPS.	1b
Oral PPS is effective in pain and related symptoms of BPS.	1a
Oral PPS plus subcutaneous heparin is effective in pain and related symptoms of BPS especially in patients initially low responders to PPS alone.	1b
Only limited data exist on the effectiveness of antibiotics in the treatment of BPS.	2b
Insufficient data for the effectiveness of prostaglandins in BPS exist. Adverse effects are frequent.	3
Global response on cyclosporin A was superior to PPS, but associated with more adverse effects.	1b
Duloxetin has shown no effect and tolerability is poor.	2b
Oxybutynin has limited effect in BPS pain, but data are scant.	3
Only insufficient data exist for the effectiveness of gabapentin in BPS.	3
Only insufficient data exist for the effectiveness of suplatast tosilate in BPS.	3
Preliminary data showed effectiveness of quercetin alone and in multimodal uncontrolled studies.	3
Intravesical lidocaine plus sodium bicarbonate is effective in the short term.	1b
Intravesical PPS is effective based on limited data and may enhance effect of oral treatment.	1b
There are limited data on the effectiveness of intravesical heparin.	3
Intravesical hyaluronic acid may have long term effects in BPS patients with positive intravesical modified KCl test.	2b
Intravesical chondroitin sulphate may be effective according to non-randomised studies. Published RCTs are underpowered.	2b
Intravesical DMSO is effective in the treatment of BPS, but side effects have to be considered.	1b
Intravesical submucosal BTX-A injection plus hydrodistension has sustained and significantly improved effect over hydrodistension alone.	1b
Only limited data exist on the effectiveness of BTX-A injection into detrusor or trigone.	3

Data on effectiveness of intravesical vanilloids are contradictory. Largest of RCTs without efficacy.	1b
Intravesical Bacillus Calmette Guérin (BCG) is not effective in BPS.	1b
Intravesical clorpactin has insufficient data to support effectiveness and high complication rates.	3
There is only insufficient data to support effectiveness of bladder distension.	3
Scarce data indicate electromotive drug administration may have a beneficial effect in patient subsets.	3
Transurethral resection (Coagulation and laser) may be effective in BPS type 3 C.	3
Sacral neuromodulation may be effective in BPS.	3
Pudendal nerve stimulation is superior to sacral nerve stimulation for the treatment of BPS.	1b
Bladder training may be effective in patients with predominant urinary symptoms and little pain.	3
Manual and physical therapy may have limited effects.	3
Avoidance of some food and drink avoids pain triggering.	3
Acupuncture: data contradictory.	3
Psychological therapy may be effective in ameliorating coping with disease.	3
No definitive conclusion on the effectiveness of surgical organ removal for BPS can be drawn based on large variability results in reported series.	3

Recommendations	**GR**
Subtype and phenotype-oriented therapy for BPS is recommended.	A
Multimodal behavioural, physical and psychological techniques should always be considered alongside oral or invasive treatments for BPS.	A
Opioids might be used in BPS in disease flare-ups. Long term application solely if all treatments failed.	C
Corticosteroids are not recommended as long-term treatment.	C
Hydroxyzine is recommended for use in BPS.	A
Consider cimetidine as valid oral option before invasive treatments.	B
Amitriptyline is recommended for use in BPS.	A
Oral PPS is recommended for use in BPS.	A
Treatment with oral PPS plus subcutaneous heparin is recommended especially in low responders to PPS alone.	A
Antibiotics can be offered when infection is present or highly suspected.	C
Prostaglandins are not recommended. Insufficient data on BPS, adverse effects considerable.	C
Cyclosporin A might be used in PPS but adverse effects are significant and should be carefully considered.	B
Duloxetin is not recommended for BPS treatment.	C
Oxybutynin might be considered for the treatment of BPS.	C
Gabapentin might be considered in oral treatment of BPS.	C
Consider intravesical lidocain plus sodium bicarbonate prior to more invasive methods.	A
Consider intravesical PPS before more invasive treatment alone or combined with oral PPS.	A
Consider intravesical heparin before more invasive measures alone or in combination treatment.	C
Consider intravesical hyaluronic acid before more invasive measures.	B
Consider intravesical chondroitin sulphate before more invasive measures.	B
Consider intravesical DMSO before more invasive measures.	A
Consider intravesical bladder wall and trigonal injection of BTX-A if intravesical instillation therapies failed.	C
Consider submucosal injection of BTX-A plus hydrodistension if intravesical instillation therapies failed.	A
Intravesical therapy with Bacillus Calmette Guérin is not recommended in BPS.	A
Intravesical therapy with clorpactin is not recommended in BPS.	A
Intravesical therapy with vanilloids is not recommended in BPS.	C
Bladder distension is not recommendedas atreatment of BPS.	C
Electromotive drug administration might be considered before more invasive measures.	C
Consider transurethral resection (or coagulation or laser) of bladder lesions, but in BPS type 3C only	B

Neuromodulation might be considered before more invasive interventions.	B
Consider bladder training in patients with little pain.	B
Consider manual and physical therapy in first approach.	B
Consider in diet avoidance of triggering substances.	C
Accupuncture is not recommended.	C
Consider psychological therapy in multimodal approach.	B
All ablative organ surgery should be last resort for experienced and BPS knowledgeable surgeons only.	A

PPS = pentosanpolysulphate sodium; DMSO = dimethyl sulphoxide; BPS = bladder pain syndrome.

Figure 6: diagnosis and therapy of BPS

Assessment	Treatment	
Urine culture	Grade A recommended	Standard: Hydroxyzine, Amitriptyline, Pentosanpolysulphate
Uroflowmetry		Intravesical: PPS, DMSO, onabotulinum toxin A plus hydrodistension
Cystoscopy with hydrodistension		
Bladder biopsy	Grade B recommended	Oral: Cimetidine, cyclosporin A
Micturition diary		Intravesical: hyaluronic acid, chondroitin sulphate
Pelvic floor muscle testing		Electromotive drug administration for intravesical drugs
Phenotyping		Neuromodulation, bladder training, physical therapy
ICSI score list		Psychological therapy
	Not recommended	Bacillus Calmette Guerin
		Intravesical Chlorpactin
	Other comments	Data on surgical treatment are largely variable
		Coagulation and laser only for Hunner's lesions

3.3 Genital pain syndrome

3.3.1 ***Scrotal pain syndrome***

Scrotal pain syndrome is the occurrence of persistent or recurrent episodic pain localised within the organs of the scrotum, which may be associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven infection or other obvious local pathology. Scrotal pain syndrome is often associated with negative cognitive, behavioural, sexual, or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. Scrotal pain syndrome is a generic term and is used when the site of the pain is not clearly testicular or epididymal. The pain is not in the skin of the scrotum as such, but perceived within its contents, in a similar way to idiopathic chest pain.

3.3.2 ***Pathogenesis***

The pathogenesis of chronic scrotal pain is diverse and in most cases unknown. Pain in the scrotum can be divided into direct pain localised in the scrotum, or referred pain coming from another place or system in the body. The problem is that we cannot always make that division in clinical practice. Direct pain is located in the testes, epididymis, inguinal nerves or the vas deferens.

3.3.2.1 Testicular pain syndrome

Testicular pain syndrome is the occurrence of persistent or recurrent episodic pain perceived in the testes and may be associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven infection or other obvious local pathology. Testicular pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. Previous terms have included orchitis, orchalgia and orchiodynia. These terms are no longer recommended.

3.3.2.2 Epididymal pain syndrome

Epididymal pain syndrome is the occurrence of persistent or recurrent episodic pain perceived in the epididymis, which may be associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven infection or other obvious local pathology. Epididymal pain syndrome is often associated with negative cognitive, behavioural, sexual, or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction.

Structural abnormalities of the epididymis can be visualised using ultrasound. Patients with multiple cysts may have pain caused by the compression that these cysts exert on the epididymis. Another local entity is chronic epididymitis (1). Chronic epididymis may be associated with signs of inflammation: inflammatory or obstructive chronic epididymitis (2).

3.3.2.3 Nerves

The ilioinguinal and genitofemoral nerves are the most prominent afferent nerves for the scrotum (3). The inguinal nerves are especially important. It is generally accepted that pain after inguinal surgery (hernia) is a consequence of damage to the nerves inside the spermatic cord (4). This is based on the anatomical knowledge that all nerves involved in testicular pain merge in the spermatic cord (5). This fact has consequences for the choice of treatment. The pudendal nerve supplies the skin of the perineum and the posterior side of the scrotum. Pain in this area is pathognomic for pudendal neuropathy.

3.3.2.4 Post-vasectomy pain syndrome

Post-vasectomy scrotal pain syndrome is a scrotal pain syndrome that follows vasectomy. Post-vasectomy scrotal pain syndrome is often associated with negative cognitive, behavioural, sexual, or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. Pathogenetically, it is thought that post-vasectomy pain is caused by the fact that the vas deferens is no longer patent. This may lead to congestion in the epididymis which in turn gives rise to pain because of dilatation

of hollow structures (6). Incidence of post-vasectomy pain is 2-20% among all men who have undergone a vasectomy (7). In men with post-vasectomy pain, only 2-6% have a VAS score > 5 (8). In a large cohort study of 625 men, the likelihood of scrotal pain after 6 months was 14.7%. The mean pain severity on a VAS score was 3.4/10. In the pain group, 0.9% had quite severe pain, noticeably affecting their daily life. In this cohort, different techniques were used to perform the vasectomy. The risk of scrotal pain was significantly lower in the no-scalpel vasectomy group, at 11.7% compared with 18.8% in the scalpel group (9).

3.3.2.5 Post-inguinal hernia repair

Chronic pain after inguinal hernia surgery is a well recognised phenomenon. An international working group has set up guidelines for prevention and management of postoperative chronic pain following inguinal hernia surgery. They have stated that the most important way of preventing pain is to identify and preserve all three inguinal nerves (10). Chronic scrotal pain is a complication of hernia repair, but in trials, it is seldom reported or it is put under the term chronic pain (not specified). In studies that have explicitly mentioned scrotal pain, there was a difference in incidence between laparoscopic and open hernia repair. In almost all studies, the frequency of scrotal pain was significantly higher in the laparoscopic than in the open group (4,11-13). In one particular study, there was no difference at 1 year but after 5 years, the open group had far fewer patients with scrotal pain (14).

3.3.2.6 Referred pain

Growing knowledge of pain mechanisms has taught us that pain felt in organ A can be caused by dysfunction of structure B. The best known referred pain is of myofascial origin, especially the trigger points (see Chapter 9). Problems inside the bladder or abdominal cavity can also give rise to pain in the scrotal area. When making a treatment plan for patients with scrotal pain, it is important to remember this phenomenon.

*3.3.3 **Diagnosis***

A physical examination is mandatory in patients with scrotal pain. Gentle palpation of each component of the scrotum is performed to search for masses and painful spots. A rectal examination is done to look for prostate abnormalities and to examine the pelvic floor muscles. Scrotal ultrasound has limited value in finding the cause of the pain. In > 80% of patients, ultrasound does not show abnormalities that have clinical implications (15,16). If physical examination is normal, ultrasound can be performed to reassure the patient that there is no pathology that needs therapy (mainly surgery). Ultrasound can be used to diagnose hydroceles, spermatoceles, cysts and varicoceles. When abnormalities such as cysts are seen, this may play a role in therapeutic decision making. In general practice, it seems that many urologists are performing ultrasound examination in almost all patients. Swiss urologists, for instance, perform it in 93% of cases (17).

*3.3.4 **Treatment***

Treatment of chronic scrotal pain is based on the principles of treating chronic pain syndromes, described throughout these guidelines. It is becoming increasingly clear that advances in the non-surgical management of testicular pain are mainly based on the emergence of pain relief as a specialty. Knowing this, it seems obvious that referring to a multidisciplinary pain team or pain centre should be considered in an early phase of the consultation (18). By doing this, surgery can be postponed or even avoided.

3.3.4.1 Conservative treatment

For conservative treatment, apart from pharmacotherapy, myofascial therapy by specialised physiotherapists should be considered. The pelvic floor muscles should be tested and will often be found overactive, which means that they contract when relaxation is needed. An overactive pelvic floor should be treated by physiotherapy (19-21). More specific myofascial trigger points are found in the pelvic floor, but also in the lower abdominal musculature. Treatment consists of applying pressure to the trigger point and stretching the muscle (22,23) (see Chapter 9).

3.3.4.2 Surgery

In a survey among Swiss urologists, it was found that 74% would do an epididymectomy, 7% an inguinal orchiectomy, and 6% a denervation (17). In the literature, there is consensus on postponing surgery until there is no other option. The only treatment that seems to be effective is microsurgical denervation. Epididymectomy is a choice in selected cases and orchiectomy is the last resort.

3.3.4.1.1 Microsurgical denervation

Considering the fact that all the nerves for the scrotal organs merge into the spermatic cord, it seems reasonable to cut all these nerves in patients with pain. All the studies that have been done were cohort studies but their success rates were high. The size of effect was so remarkable that it is recommended that randomised studies are performed to obtain better proof. The three cohort studies that are found were

consistent in the indication criteria, the diagnostic methods applied, and the surgical approach used. All had a follow-up of at least 20 months. They included patients with chronic scrotal pain who did not respond to conservative treatment. Ultrasound showed no abnormalities and a spermatic cord block showed pain relief of > 50%. The surgical approach is inguinal. The cord is transected in such a way that all identifiable arterial structures, including testicular, cremasteric, deferential arteries and lymphatic vessels are left intact. The surgery is performed under magnification by loupe or microscope. Complete relief of pain is achieved in 71-96% and partial relief in 9-17%. This means that 12-15% had no relief of pain after denervation. The complication of testicular atrophy was seen in 3-7% of the operated patients (24-26). There is no difference in success based on the cause of pain. The laparoscopic route for denervation seems feasible but the results are unclear (27).

3.3.4.1.2 Epididymectomy

There is to date no hard evidence available, but expert opinion is clear that orchiectomy should be reserved for patients who have undergone denervation but still have pain. Epididymectomy shows different results in various groups of patients. Epididymectomy shows the best results in patients with pain after vasectomy, or pain on palpation of the epididymis and when ultrasound shows multiple cysts. Patients with chronic epididymitis show bad results with epididymectomy.

The percentage of patients that are cured ranges from 50 to 92% (1,6,28-30). These results are also from cohort studies but the fact that assessment can help in predicting the chance of success makes further studies worthwhile. One study in our search has yielded different results, namely, that post-vasectomy patients fared worse and that ultrasound did not help in predicting the result of the operation. No reason was found for this result (9).

3.3.4.1.3 Orchiectomy

Orchiectomy is seen as the last resort in patients with intrascrotal pain, who do not respond to any other treatment. There have been no studies than can help in making a rational decision on whether to perform orchiectomy.

3.3.4.1.4 Vaso-vasostomy

In post-vasectomy pain syndrome, a vaso-vasostomy might help to overcome the obstruction and thereby improve the pain. Some studies have shown good results but the quality of these studies was limited. Results are as high as 69-84% (31,32).

*3.3.5 **Conclusions and recommendations: scrotal pain syndrome***

Conclusions	**LE**
The nerves in the spermatic cord play an important role in scrotal pain.	2b
Ultrasound of the scrotal content is not of help in diagnostics nor treatment of scrotal pain.	2b
Post -vasectomy pain is seen in a substantial number of men undergoing vasectomy.	2b
Scrotal pain is more often noticed after laparoscopic then after open inguinal hernia repair.	1b
Microsurgical denervation of the spermatic cord is an effective therapy for scrotal pain syndrome.	2b
Vaso-vasostomy is effective in post-vasectomy pain.	2b
Orchiectomy is the last resort in treating scrotal pain syndrome.	4

Recommendations	**GR**
We recommend to start with general treatment options for chronic pelvic pain (see chapter 10).	A
We recommend informing about the risk of post-vasectomy pain when counselling patients planned for vasectomy.	A
To reduce the risk of scrotal pain, we recommend open instead of laparoscopic inguinal hernia repair.	A
We recommend that during inguinal hernia repair all the nerves in the spermatic cord are identified.	A
For patients who are treated surgically, we recommend microsurgical denervation of the spermatic cord.	A
For patients who do not benefit from denervation we recommend to perform epididymectomy.	B
We recommend that orchiectomy is reserved as last resort when every other treatment has failed.	C

3.4 Urethral pain syndrome

3.4.1 ***Definition***

Urethral pain syndrome is the occurrence of chronic or recurrent episodic pain perceived in the urethra, in the absence of proven infection or other obvious local pathology. Urethral pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. Urethral pain syndrome may occur in men and women.

3.4.2 ***Pathogenesis***

Based on the definition, there is no well-known pathogenetic mechanism responsible for urethral pain syndrome. There are no data available to answer the question: "how common is dysuria in the presence of negative rigorous investigation of the bladder and urethra?" Some suggestions have been proposed. The intimate relation of the urethra with the bladder (both covered with urothelium) makes it plausible that pathology seen in the bladder is also found in the urethra and causes the same symptoms. This is the case in classifying urethral pain syndrome as a form of BPS. It is obvious that what might cause pain in the bladder could be responsible for urethral pain. Mechanisms thought to be basic for BPS also apply to the urethra. This means that the specific testing with potassium is used to support the theory of epithelial leakage (1,2). Urethral syndrome is supposed to be the same as BPS in that the epithelium is leaking, thereby causing pain.

Another possible mechanism is the neuropathic hypersensitivity following urinary tract infection (3). Symptoms recorded in patients with urethral pain syndrome can also be classified as referred pain from other organs or from the myofascial system. Attention to the phenomenon of referred pain is important. See Chapter 9 for more on the myofascial origin of the pain.

The relationship with gynaecological and obstetric aspects is unclear. In a small group of patients with urethral pain, it has been found that grand multiparity and delivery without episiotomy were more often seen in patients with urethral syndrome, using univariate analysis (4).

3.4.3 ***Treatment***

There is no specific treatment that can be advised. Management should be multidisciplinary and multimodal (5). Laser therapy of the trigonal region may be a specific treatment. One trial comparing two forms of laser reported good results, but did not compare with sham treatment (6). The majority of publications on treatment of urethral pain syndrome have come from psychologists. In a 2007 review of treatment, Kaur and Arunkalaivanan have concluded that "treatment at its best" is by "behavioral therapy including biofeedback, meditation, bladder retraining, and hypnosis has been used with some success", but no reference is given, and no trials of these arose from the search. Baldoni *et al*. (7) have reported high rates of anxiety and depression, and worsening of symptoms related to stress in patients with urethral pain syndrome The only treatment trial found was by Baldoni *et al*. The psychological model that he used is not entirely clear: they have described how "in some cases" psychotherapy enables patients to recognise "the emotional implications" of their urinary problem, leading to both physical and psychological improvement. "Emotional implications" could mean either emotional consequences, consistent with a cognitive behavioural model of chronic pain in which those consequences, rather than the pain itself, are targeted to improve QoL, or it could mean implications for - exposure of - emotional conflict or similar psychological disorder, which is presumed to be the aetiology of the urethral pain.

Baldoni *et al*. recruited 36 female patients diagnosed with urethral syndrome in an Italian urology clinic after negative urography, cystoscopy and urine culture, and urodynamic examination. Thirteen women were randomly selected for psychotherapy, but the method was not blind or free of possible bias. Psychotherapy was 12-16 weekly 1-h sessions, with additional fortnightly group discussion, and focused on associations between urinary symptoms and emotion. Four patients were also prescribed low-dose antidepressants. The control group received usual care but no psychological treatment.

Assessment of symptoms at 6 months and four years after the end of treatment (with loss of two patients from each arm) showed substantial improvement in total urinary symptoms and additionally in pelvic pain, with 9/11 psychotherapy patients with normal levels of urinary function at 6 months, and 8/11 with normal levels at 4 years. Control patients were unchanged at both follow-up points. The trial had significant weaknesses; in particular, the non-blind assignment to treatment condition, the non-standardised measures, and, for the purposes of this review, the combination of all urinary symptoms so that treatment effects on pain were obscured. The authors have noted that the lack of any credible intervention with controls makes it difficult to conclude that it was the particular treatment, rather than the general provision of treatment, which brought about recorded improvement. However, the results can be taken as encouraging the trial of psychological methods, using orthodox outcome measures and more rigorous methodology.

3.4.4 ***Conclusions and recommendations: urethral pain syndrome***

Conclusions	**LE**
Urethral pain syndrome may be a part of BPS.	2a
Urethral pain may be neuropathic hypersensitivity following urinary tract infection.	2b
There is no specific treatment for urethral pain syndrome.	4

In patients with significant distress associated with bladder or urethral symptoms, psychological treatment may be worth using to reduce distress and thereby improve function and quality of life.	4

Recommendations	GR
We recommend to start with general treatment options for chronic pelvic pain (see chapter 10).	A
We recommend that patients with urethral pain syndrome are treated in a multidisciplinary and multimodal programme.	B
When patients are distressed, we recommend referring them for pain-relevant psychological treatment to improve function and quality of life.	B

4. GYNAECOLOGICAL ASPECTS OF CHRONIC PELVIC PAIN

4.1 Introduction

Chronis pelvic pain in urological and gynaecological practice is often complex and difficult to treat. The aim is to try and determine a remediable cause and treat it using the most effective available therapy. However, in 30% of cases, no cause is ever determined and this presents a therapeutic challenge to the attendant physician (1).

4.2 Clinical history

Taking a detailed medical history is essential to making a diagnosis. The nature, frequency and site of the pain, and its relationship to precipitating factors and the menstrual cycle, may provide vital clues to the aetiology. A detailed menstrual and sexual history, including any history of sexually transmitted diseases and vaginal discharge is mandatory. Discrete inquiry about previous sexual trauma may be appropriate.

4.3 Clinical examination

Abdominal and pelvic examination will exclude any gross pelvic pathology (tumours, scarring, and reduced uterine mobility), as well as demonstrating the site of tenderness if present. Abnormalities in muscle function should also be sought. Clinical pelvic examination should be a single digit examination if possible, but in most cases a gentle double digit examination is tolerable and sometimes necessary. The usual bimanual examination can generate severe pain so the examiner must proceed with caution. The examination of a woman with CPP can be very difficult, and many authors recommend that it should be directed to the determination of cutaneous allodynia along the dermatomes of the abdomen (T11-L1) and the perineum (S3). The degree of tenderness of the muscles and on the perineum (perineal body, levators and obturator internus) should be determined.

*4.3.1 **Investigations***

Vaginal and endocervical swabs to exclude infection are mandatory and cervical cytology screening is advisable. Pelvic imaging, using ultrasound scanning or magnetic resonance, can provide useful information about pelvic anatomy and pathology. Any areas of tenderness detected can provide information related to the possible presence of current or pre-existing visceral disease (2,3). Laparoscopy is perhaps the most useful invasive investigation to exclude gynaecological pathology (4,5) and to assist in the differential diagnosis of CPP in women (6). Often it is combined with cystoscopy (7,8) and/or proctoscopy to help identify the site of multi-compartment pain.

Psychological considerations around laparoscopy

There have been three diverse studies of laparoscopy. Elcombe et al. have shown, by comparing waiting time for laparoscopy, that there was a distinct and lasting improvement in pain consequent on laparoscopy, which was greater than the gradual improvement without further treatment before or after laparoscopy. Improvement was related to beliefs about pain and its meaning in terms of serious disease, and not to medical variables (9).

In another study, showing women a photograph of their pelvic contents taken during laparoscopy during post-laparoscopy feedback did not improve pain ratings or beliefs about pain more than feedback without a photograph (10).

Peters et al. compared standard clinical care of patients with CPP (where organic causes of pelvic pain were excluded first and diagnostic laparoscopy was routinely performed, before attention being given to other causes such as psychological disturbances) with a second group, where an integrated approach was chosen from the beginning (equal attention was given to somatic, psychological, dietary, environmental, and physiotherapeutic factors and laparoscopy was not routinely performed) (11). Both groups were similar with respect to clinical characteristics of the patients and the severity of their pain as assessed by various pain parameters. Evaluation of the pain 1 year after the institution of treatment revealed that the integrated approach improved pelvic pain significantly more often than the standard approach for three out of four pain parameters. Though laparoscopy played no important role in the treatment of pelvic pain it was found to be an essential tool to rule out any organic cause for the pain. Equal attention to both organic and other causative factors from the beginning of therapy is more likely to result in a reduction of pelvic pain than just using a standard approach (11). Pain and function improved somewhat more in the integrated group, but scoring was not standardised and hard to interpret.

4.4 Pain associated with well-defined conditions

4.4.1 ***Dysmenorrhoea***

Pain in association with menstruation may be primary or secondary. Primary dysmenorrhoea classically begins at the onset of ovulatory menstrual cycles and tends to decrease following childbirth (6). Secondary dysmenorrhoea suggests the development of a pathological process and it is essential to exclude endometriosis (5), adenomyosis (12) and pelvic infection.

Treatment

Reassurance and an explanation of the cause of dysmenorrhoea are usually helpful, together with the use of simple analgesics, followed by non-steroidal anti-inflammatory drugs (NSAIDs) (13), which are particularly helpful if they are started before the onset of each menstrual cycle. NSAIDs are effective in dysmenorrhoea, probably because of their effects on prostaglandin synthetase.

Suppression of ovulation using oral contraceptive tablets (either combined or progesterone only) or the use of a levo-norgestrol intra-uterine device reduces dysmenorrhoea dramatically in most cases and may be used as a therapeutic test. As a result of the chronic nature of the condition, potentially addictive analgesics should be avoided and multidisciplinary pain management strategies, including psychology should be engaged.

4.4.2 ***Infection***

In premenopausal women, a history of pelvic inflammatory disease (PID) must be excluded. Swabs to exclude infections with organisms such as chlamydia and gonorrhoea, as well as vaginal and genital tract pathogens (14), should be taken. Patients' sexual contacts need to be traced in all cases with a positive culture. If there is any doubt about the diagnosis, laparoscopy may be helpful.

Pelvic inflammatory disease can cause the same clinical findings as endometriosis and can lead to a chronic pain state. Although PID often has a bacterial origin, viral infections such as primary herpes simplex infection need to be excluded because they also present with severe pelvic/vaginal/vulvar pain (15). They are usually associated with ulcerating lesions and inflammation, which may lead to urinary retention (16). Hospitalisation and opiates may be needed to achieve adequate analgesia.

Treatment

Treatment of infection depends on the causative organisms. Subclinical chlamydial infection may lead to tubal pathology, which can result in subfertility in the future. Thus, screening for this organism in sexually active young women is essential to prevent this complication. Standard broad-spectrum antibiotics targeting Gram-positive and negative organisms are normally recommended. Chronic PID is no longer common in developed countries, but still poses a significant problem for women in developing countries.

4.4.3 ***Endometriosis and adenomyosis***

The incidence of endometriosis is rising in the developed world. The precise aetiology is still a source of debate, but an association with nulliparity is well known.

A diagnosis is usually made when a history of secondary dysmenorrhoea and often dyspareunia exists. On examination, there is often tenderness in the lateral vaginal fornices, reduced uterine mobility, tenderness in the recto-vaginal septum, and on occasion, adnexal masses. Laparoscopy is the most useful diagnostic tool (17-19).

Endometriotic lesions affecting the urinary bladder or causing ureteric obstructions can occur, as well as lesions affecting the bowel, which may lead to rectal bleeding in association with menstruation.

Adenomyosis is associated with augmented pain during menses. It is diagnosed by an ultrasound scan of the uterus, which often shows cystic dilatation of the myometrium (20).

Treatment

As in primary dysmenorrhoea, analgesics and NSAIDs are helpful in easing pain at the time of menstruation. Hormone treatment with progestogens or the oral contraceptive pill may halt progress of endometriosis, but is not curative. A temporary respite may be obtained by using luteinising hormone releasing hormone analogues to create an artificial menopause, although the resulting oestrogen deficiency does have marked long-term side effects, such as reduced bone density and osteoporosis. Thus, these drugs are normally only used before surgery to improve surgical outcome and reduce surgical complications in patients with endometriosis. Surgery for endometriosis is challenging and the extensive removal of all endometriotic lesions is often thought to be essential. This is still considered to be controversial, as there is at least one RCT showing no benefit in pain relief in the removal of early endometriosis compared to sham surgery (21,22). Nevertheless, he best results are achieved laparoscopically, by highly trained and skilled laparoscopic surgeons, in specialist centres (19,23). A multidisciplinary team is required for the treatment of extensive disease, including a pain management team. The pain associated with endometriosis is often not proportionate to the extent of the condition and, even after

extensive removal of the lesions and suppression of the condition, the pain may continue. In this situation, multidisciplinary pain management strategies, including psychology, should be engaged.
In patients with adenomyosis, there is no curative surgery other than hysterectomy but patients can benefit from hormonal therapy (oral or levo-norgestrol containing intra-uterine devices) and analgesics as outlined above.

*4.4.4 **Gynaecological malignancy***

The spread of gynaecological malignancy of the cervix, uterine body or ovary will cause pelvic pain depending on the site of spread. Treatment is of the primary condition, but all physicians dealing with pelvic pain must be fully aware of the possibility of gynaecological malignancy.

*4.4.5 **Injuries related to childbirth***

Tissue trauma and soft tissue injuries occurring at the time of childbirth may lead to CPP related to the site of injury. Dyspareunia is a common problem leading to long-term difficulties with intercourse and female sexual dysfunction (24). This is often due to transient oestrogen deficiency, commonly seen in the postpartum period and during breastfeeding. Denervation of the pelvic floor with re-innervation may also lead to dysfunction and pain.

Treatment

Treatment with a short course of hormone replacement cream can be therapeutically beneficial. However, often reassurance that the situation will improve on the cessation of breastfeeding is also helpful.

*4.4.6 **Pain associated with pelvic organ prolapse and prolapse surgery***

Pelvic organ prolapse is often an asymptomatic condition, unless it is so marked that it causes back strain, vaginal pain and skin excoriation (25). Prolapse is often a disease of older women, and it is often associated with postmenopausal oestrogen deficiency, which may lead to pain associated with intercourse. Hormone replacement therapy is usually helpful in this circumstance. However, in severe cases associated with a "dragging pain", the only options are specially designed supportive plastic vaginal devices or surgery.
In the past few years, pelvic organ prolapse surgery has gained a new dimension. Most tissue surgery is now augmented by the use of non-absorbable mesh (usually in the form of "mesh kits") (26-28). Although they may have a role in supporting the vagina, they are also associated with several complications including bladder, bowel and vaginal trauma (27). In a subset of these patients, chronic pain may ensue, because mesh insertion may cause nerve and muscle irritation (23,24).

Clinical evaluation

It is essential that patients are fully evaluated clinically. They may also benefit from specialised imaging, using contrast mediums if necessary, to identify problematic areas. Most patients can be treated by mesh-excisional surgery (29,30), if appropriate, or multidisciplinary pain management strategies, including psychology, should surgery not be relevant.

4.5 Vaginal and vulvar pain syndromes

Pain in the vagina or the female external genital organs (the vulva, which includes the labia, clitoris, and entrance to the vagina) is most commonly due to infection or trauma. The latter is usually as a consequence of childbirth or surgery. Pain is usually a precedent to dyspareunia.
When the pain persists for > 6 months, it can be diagnosed as "vulvodynia" or "chronic vaginal/vulvar pain syndrome" with no known cause. It is still a poorly understood condition and often many doctors do not recognise it as a real pain syndrome. Many women feel isolated because it remains a difficult condition to treat.
There are two main subtypes of vulvodynia: generalised vulvodynia, where the pain occurs in different areas of the vulva at different times; and vulvar vestibulitis, where the pain is at the entrance of the vagina. In generalised vulvodynia, the pain may be constant or occur occasionally, but touch or pressure does not initiate it, although it may make the pain worse. In vulvar vestibulitis, the pain is described as a burning sensation that comes on only after touch or pressure, such as during intercourse.
The causes of vulvodynia are many and include:

- History of sexual abuse
- History of chronic antibiotic use
- Hypersensitivity to yeast infections, allergies to chemicals or other substances
- Abnormal inflammatory response (genetic and non-genetic) to infection and trauma,
- Nerve or muscle injury or irritation
- Hormonal changes

Although therapeutic options remain limited and require a multidisciplinary pain management approach, with

psychological and physiotherapy input, they can be treated effectively with physiotherapy, stretching exercises and even botulinum toxin, though in the case of the latter the evidence is variable.

Psychological treatment of chronic vulvar pain

There are few published accounts of psychological treatment for chronic vulvar pain, distinct from provoked vulvar pain (also known as vulvar vestibulitis, provoked vestibulodynia, or dyspareunia).

Three reviews in the past decade, all of provoked as well as chronic vulvar pain, have acknowledged the lack of understanding of aetiology and maintenance of this problem, and emphasise different components of what is known.

Damsted-Peterson et al. have described peripheral and central nervous system changes most consistent with models of chronic pain, as well as local inflammation and pelvic floor tension, and recommend multimodal treatment (31).

Lotery et al. have focused on local factors, and recommend education, support, and counselling, but provide no evidence to support these (32). Nanke & Rief have described interaction of physiological, psychological and interpersonal factors, and recommend biofeedback on the basis of uncontrolled studies (33).

The only RCT found has compared cognitive behavioural therapy (CBT), adapted for vulvar pain from a previously published model, with supportive psychotherapy, for a mixed population of women with provoked and chronic vulvar pain (34). CBT consists of behavioural therapy (for sexual problems, increasing general activity, and pain control), relaxation, and cognitive coping skills. Supportive psychotherapy, also for 10 one hour sessions, involves non-directive talking therapy by an accepting and reflective therapist. Follow-up to 1 year has shown that ~40% of patients with both conditions achieve at least 33% (clinically significant) pain relief, with improvement in sexual and emotional function; CBT shows superiority in some outcomes.

4.6 Summary

Pain in association with urinary and gastrointestinal symptoms must be considered carefully. For example, patients with bladder pain quite often present with dyspareunia due to bladder base tenderness, so though the dyspareunia may be the focus it is the bladder component that is the main problem. Similarly, in those with anal pain it may be the evacuatory dysfunction that is the main culprit. Conditions, such as pelvic congestion has been cited as a cause of pelvic pain of unknown aetiology, but this diagnosis is not universally recognised (15,16).

It is only when all the above conditions have been excluded that the physician may declare that the patient has 'unexplained' pelvic pain. Treating these patients remains a challenge for all physicians but quite clearly the best results are obtained from a multidisciplinary approach that considers all possible causes.

*4.6.1 **Conclusions and recommendations: gynaecological aspects of chronic pelvic pain***

Clinical state		**LE**
Clinical history and examination	Mandatory to making a diagnosis	2a
Investigations	Mandatory to making a diagnosis	2a
	Laparoscopy is well tolerated and does not appear to have negative psychological effects	1b
Pain associated with well-defined conditions	*Dysmenorrhoea: effective therapeutic options*	3
	Infection: effective therapeutic option	3
	Endometriosis: effective therapeutic options including medical and surgical care	1b
	Gynaecological malignancy: effective therapeutic options	3
	Injuries related to childbirth: effective therapeutic options	3
	Pain associated with pelvic organ prolapse: effective therapeutic options	3
Vaginal and vulvar pain syndrome	Diagnosis and therapeutic interventions	3
	Psychological treatment (CBT or supportive psychotherapy) can improve pain and sexual and emotional function	1b
Laparoscopy does not appear to have negative psychological effects		1b

Recommendations	GR
All women with pelvic pain should have a full gynaecological history and evaluation, and including laparoscopy is recommended to rule out a treatable cause (e.g. endometriosis).	A
Provide therapeutic options such as hormonal therapy or surgery in well-defined disease states.	B
Provide a multidisciplinary approach to pain management in persistent disease states.	B
Recommend psychological treatment for refractory chronic vulvar pain.	B
Use alternative therapies in the treatment of chronic gynaecological pelvic pain.	C

5. GASTROINTESTINAL ASPECTS OF CHRONIC PELVIC PAIN

5.1 Introduction

This chapter describes CPP perceived to be associated with the gastrointestinal tract, which is mainly due to functional disorders and cannot be explained by structural or specific well-defined diseases of the pelvis.

Some points to note:

- There may be a considerable overlap of the gastrointestinal with other pelvic pain syndromes.
- Defined gastrointestinal conditions with specific structural defects and diseases may coexist. Behavioural changes such as straining can lead to organic diseases such as rectal prolapse, solitary rectal ulcer syndrome, or pudendal nerve injury with consecutive faecal incontinence.
- Some structural gastrointestinal abnormalities (e.g., postpartum anal sphincter defects, or small rectoceles) are often observed in asymptomatic individuals and may be coincidental with the gastrointestinal pelvic pain syndrome.
- Different diseases can aggravate previously asymptomatic functional disorders which may become symptomatic such as faecal incontinence in patients with diarrhoea of different origins or anal fissure in patients with dyssynergic defecation.
- Finally, we need to consider that all functional disorders such as anorectal pain are defined on the basis of retrospectively evaluated longstanding symptoms, which ideally would have been registered prospectively with symptom diaries (1,2).

5.2 Clinical history

Functional anorectal disorders are diagnosed by symptoms, supplemented by objective findings. The predominant symptoms patients are interviewed about are discomfort or pain in relation to their bowel habits, daily activities, and eating. A precise history of dysfunctional voiding or defecation should be asked, ideally applying symptom questionnaires for urinary and anorectal symptoms (e.g., Rome III questionnaire for anorectal pain). Excessive straining at most defecations, anal digitations in dyssynergic defecation, and a sensation of anal blockage may be found in patients with chronic anal pain. History of anxiety and depression with impaired QoL is often encountered in anorectal functional disorders and should be evaluated.

*5.2.1 **Clinical examination and investigations***

At clinical examination, perianal dermatitis may be found as a sign of faecal incontinence or diarrhoea. Fissures may be easily overlooked and should be searched thoroughly in patients with anal pain. Rectal digital examination findings may show high or low anal sphincter resting pressure, a tender puborectalis muscle in patients with the levator ani syndrome, and occasionally increased perineal descent. The tenderness during posterior traction on the puborectalis muscle differentiates between “highly likely” and “possible” levator ani syndrome and is used in most studies as the main inclusion criterion. Dyssynergic (paradoxical) contraction of the pelvic muscles when instructed to strain during defecation is a frequent finding in patients with pelvic pain. Attention should be paid to anal or rectal prolapse at straining, and ideally during bimanual examination by the gynaecologist to diagnose an enterocele or cystocele.

*5.2.2 **Diagnostic assessment***

The Rome III criteria for diagnosis of functional anorectal diseases include symptoms for each specific functional disorder as listed below. The gastrointestinal diagnostic assessment should be performed in an interdisciplinary manner, preferably at a pelvic floor centre by a dedicated team and appropriate testing. The most frequently performed investigations are flexible rectosigmoidoscopy or colonoscopy, pelvic ultrasound, anorectal endosonography and anorectal manometry combined with anal EMG and balloon expulsion test.

Three-dimensional anorectal ultrasound has become an indispensable readily available tool for the specialised proctologist. Perineal ultrasound offers the advantage of sphincter imaging without insertion of the transducer into the rectum. MRI in conjunction with MR defecography has become the most valuable imaging technique to assess anorectal function dynamically. MRI studies outline simultaneously the anatomy of the pelvic floor and allow us to visualise different structural and functional pathologies, by applying dynamic sequences after filling of the rectum with a viscous contrast medium (e.g., ultrasound gel). The following pathologies can be visualised: pelvic floor descent, an abnormal anorectal angle while squeezing and straining, rectal intussusception, rectocele, enterocele and cystocele. However, limitations of MR defecography are the left lateral position and the limited space for the patient, which may reduce the ability to strain and hereby reduce the sensitivity of the method, underestimating the size of entero-and rectoceles as well as the amount of intussusception. Surgical consultations should be available for all patients, plus referral to an urogynaecologist or urologist when indicated. Biofeedback treatment, botulinum toxin injection, and percutaneous tibial nerve and sacral nerve stimulation should be available as a complementary therapeutic option to medical and surgical treatment.

5.3 Pain associated with well-defined conditions

5.3.1 ***Haemorrhoids***

CPP is rare in haemorrhoidal disease because endoscopic and surgical treatment is mostly effective in acute disease. The most frequent aetiology of pain without significant bleeding is thrombosed external haemorrhoids or an anal fissure. Haemorrhoidal pain on defecation associated with bleeding is usually due to prolapsed or ulceration of internal haemorrhoids. Anaemia from haemorrhoidal bleeding is rare but may arise in patients on anticoagulation therapy, or those with clotting disorders. Different treatments of haemorrhoids have been evaluated by two systematic Cochrane reviews. Excisional haemorrhoidectomy (EH) has been compared to the less-invasive technique of rubber band ligation (RBL), and has been shown to increase pain, with more complications and time off work. However, despite these disadvantages of EH, complete long-term cure of symptoms is increased by surgery, and minor complications are accepted by patients. RBL is the choice of treatment for grade II haemorrhoids, whereas EH should be reserved for grade III haemorrhoids or recurrence after RBL (3). New stapler techniques of haemorrhoidopexy are associated with a higher long-term risk of recurrence and prolapse compared to conventional EH. Further studies are needed (4).

5.3.2 ***Anal fissure***

Anal fissures are tears in the distal anal canal and induce pain during and after defecation. The pain can last for several minutes to hours. Persistence of symptoms beyond 6 weeks or visible transversal anal sphincter fibres define chronicity. Fissures located off the midline are often associated with specific diseases such as Crohn's disease or anal cancer. Internal anal sphincter spasms and ischaemia are associated with chronic fissures. Medical therapy with nitrates and calcium channel blockers resulting in sphincter relaxation is effective (5). Botulinum A toxin injection is indicated for fissures that are refractory to topical nitrates. Surgery with lateral internal sphincterotomy is the most studied procedure but carries the risk of postoperative faecal incontinence, and may be replaced by fissure excision combined with botulinum toxin or anal advancement flap.

5.3.3 ***Proctitis***

Abdominal and pelvic pain in patients with inflammatory bowel disease and proctitis are often difficult to interpret. Faecal calprotectin may help to differentiate between inflammation and functional pain, to spare steroids. Tricyclic antidepressants at low dose can be effective in this situation when acute exacerbation has been ruled out (6,7).

5.3.4 ***Constipation***

Constipation is usually not associated with CPP but is often associated and may induce increased pelvic discomfort and psychological distress. Dyssynergic defecation is the most common aetiology and responsible for 50% of causes of constipation. Dyssynergia describes an overactivity of pelvic floor muscles during defecation and the partial or complete inability to relax voluntarily pelvic floor muscles. Stool diaries and physiological testing followed by biofeedback treatment when indicated have been established as standard care in randomised controlled trials (8).

5.4 Chronic anal pain syndrome

5.4.1 ***Diagnostic criteria for chronic anal pain syndrome (chronic proctalgia) according to the Rome III criteria are as follows and must include all of the following:***

1. Chronic or recurrent rectal pain or aching.
2. Episodes last at least 20 min.
3. Exclusion of other causes of rectal pain such as ischaemia, inflammatory bowel disease, cryptitis,

intramuscular abscess and fissure, haemorrhoids, prostatitis, and coccygodynia.

These criteria should be fulfilled for the past 3 months with symptom onset at least 6 months before diagnosis (2).

The chronic anal pain syndrome includes the above diagnostic criteria and exhibits exquisite tenderness during posterior traction on the puborectalis muscle. This common and debilitating condition is frustrating to treat. Pathophysiology of pain is thought to be due to overactivity of the pelvic floor muscles. Chiarioni et al. have recently published an RCT demonstrating that biofeedback treatment was superior to electrogalvanic stimulation and massage for treatment of the levator ani syndrome. One hundred and fifty-seven patients who had at least weekly rectal pain were investigated, but only patients with tenderness on traction of the pelvic floor showed a significant treatment benefit. Eighty-seven percent of patients with tenderness of the puborectalis muscle (Rome II: Highly likely Levator Ani Syndrome) reported adequate relief after one month of biofeedback versus 45% for electrogalvanic stimulation, and 22% for massage. These results were maintained at 12 months with adequate relief after nine sessions of biofeedback in 58 % of the whole group (Rome II: Highly likely and Possible Levator Ani Syndrome), after galvanic stimulation in 27 % and massage in 21 % of patients. As previously described in dyssynergic defecation, the ability to expel a 50-ml water-filled balloon and to relax pelvic floor muscles after biofeedback treatment were predictive of a favourable therapeutic outcome (9). The pathophysiology of the chronic anal pain syndrome is therefore similar to that of dyssynergic defecation, and this favours the role of the pelvic floor muscles in the pathophysiology of both conditions. Other treatment modalities have been less successful.

*5.4.2 **Botulinum toxin in pelvic pain***

CPP associated with spasm of the levator ani muscles and treatment of the puborectalis and pubococcygeus muscle by botulinum toxin appears to be promising in some women, as shown in a pilot study (n = 12). The inclusion criteria were dependent only on vaginal manometry with overactivity of the pelvic floor muscles, defined as a vaginal resting pressure > 40 cm H_2O. Although dyspareunia and dysmenorrhoea improved, non-menstrual pelvic pain scores were not significantly ameliorated (10). In the following double-blinded, randomised, placebo-controlled trial, the same group defined pelvic floor myalgia according to the two criteria of tenderness on contraction and hypertension (> 40 cm H20) and included 60 women. In this larger study, non-menstrual pelvic pain was significantly improved compared to that treated with placebo (VAS score 51 vs. 22; P = 0.009). It was concluded therefore that botulinum toxin is effective for reducing pelvic-floor-muscle associated pain with acceptable adverse effects such as occasional urinary and faecal stress incontinence (11). However, recently, a small RCT failed to show any benefit of botulinum toxin, and sacral nerve stimulation has been reported to be somewhat beneficial in an uncontrolled study, showing improvement in less than half the patients (12,13).

*5.4.3 **Intermittent chronic anal pain syndrome (proctalgia fugax) consists of all the following diagnostic criteria, which should be fulfilled for 3 months and before 3 months:***

1. Recurrent episodes of pain localised to the anus or lower rectum
2. Episodes last from several seconds to minutes
3. There is no anorectal pain between episodes.

Stressful life events or anxiety may precede the onset of the intermittent chronic anal pain syndrome. The attacks may last from a few seconds to as long as 30 min. The pain may be cramping, aching or stabbing and may become unbearable. However, most patients do not report it to their physicians and pain attacks occur less than five times a year in 51% of patients. Due to the short duration of the episodes, medical treatment and prevention is often not feasible. Inhaled beta-2 adrenergic agonist salbutamol was effective in an RCT in patients with frequent symptoms and shortened pain duration (14). Other treatment options are topic diltiazem and botulinum toxin (15). However, there is still some controversy as regards the duration of pain of intermittent chronic and chronic anal pain syndrome and RCTs do often use different definitions extending the pain duration in order to better evaluate the study-drug action.

5.5 Summary

Chronic pelvic pain is an interdisciplinary entity needing multispecialty and multidisciplinary diagnostic assessment by gastroenterology, urology, gynaecology and pain teams as appropriate, with the input of physicians, psychologists and physiotherapists amongst others. Anorectal pain is investigated best by endoscopic and functional testing to rule out structural disease that can be treated specifically. CPP due to functional disorders remains a therapeutic challenge that may respond to biofeedback therapy, electrogalvanic syndrome and botulinum toxin in the case of levator ani syndrome and defecatory defects associated with pelvic pain.

5.5.1 *Conclusions and recommendations: anorectal pain syndrome*

Conclusions on functional anorectal pain.	**LE**
Tenderness on traction is the main criterion of the chronic anal pain syndrome.	1a
Biofeedback is the preferred treatment for the chronic anal pain syndrome.	1a
Electrogalvanic stimulation is less effective than biofeedback.	1b
Botulinum toxin is efficient in CPP with spasms.	1b
Sacral neurostimulation is effective in pelvic pain.	3
Inhaled salbutamol is effective in intermittent chronic anal pain syndrome.	3

Recommendations for functional anorectal pain	**GR**
Functional testing is recommended in patients with anorectal pain.	A
Biofeedback treatment is recommended in patients with pelvic pain and dyssynergic defecation.	A
Botulinum toxin in women with pelvic pain and electrogalvanic stimulation can be considered in the chronic anal pain syndrome.	B
Sacral neuromodulation is recommended in the chronic anal pain syndrome.	C
Inhaled salbutamol is recommended in the intermittent chronic anal pain syndrome.	C

6. PERIPHERAL NERVE PAIN SYNDROMES

6.1 Neuropathic pain

Much has been written on the subject of peripheral neuropathic pain (1-4) including its diagnosis and treatment. There are some fundamental principles that are worth considering:

1. Nerve injury is associated with changes both within the peripheral nervoussystem (PNS) and the central neural axis including the higher centres. These changes serve to produce an increasing disparity between stimulus and response (Chapter 2).
2. In the PNS, nerve damage may produce a neuroma that can provide a source of ongoing afferent central activity. The neuroma may be discreet and palpable to touch or en-passage and not palpable. Neuromas are sensitive and respond to: compression (e.g., by the surrounding tissue or digital pressure), temperature change and adrenergic stimulation. Sympathetic nerve fibres can grow into neuromas as well as the associated dorsal root ganglia, which may result in sensitivity to body adrenaline changes such as through mood and environment with subsequent changes in pain.
3. Windup is a progressive increase in centrally elicited action potentials per unit peripheral stimulus. A severe acute insult or a chronic repeated stimulus may result in a transient windup phenomenon becoming permanent through immediate gene activation and neurochemical and structural neuronal changes within CNS. These long-term changes in central sensitisation are associated with dysfunction of the afferent sensory nervous system and perception, as well as efferent motor, vasomotor and pseudomotor activity within the pathways of the injured nerve (5).
4. These central changes may result in abnormal afferent processing for nerves other than those originally damaged, so that increased perception (pain, allodynia and hyperaesthesia) from an area greater than the expected pattern may occur. In the case of tissues with innervation that overlaps with an injured nerve, somatic and visceral hypersensitivity (e.g., sensory urge with increased frequency of voiding/evacuation) may be perceived from those tissues.

Essentially, what may be considered a simple nerve injury may be magnified by the CNS so that a whole region may be involved and a non-specific regional pain syndrome may arise. There is also a suggestion that involvement of both the peripheral and central nervous system in the control of the endocrine and immunological system may also become abnormal. Certainly, there is a complex interaction between nerve injury, emotional well being, disability and widespread pain. A proportion of patients go on to develop chronic fatigue syndrome, fibromyalgia and immunological disorders (6-8).

6.2 Anatomy

When considering pelvic pain mechanisms, nerves associated with the pelvis/genitalia are generally divided into thoraco-lumbar and sacral root afferents. The hypogastric plexus is mixed autonomic (sympathetic and parasympathetic) and may contain afferents associated with pain.

6.2.1 The anterior groin nerves

The **iliohypogastric nerve** arises from L1 and its anterior branch supplies the skin above the pubis; its lateral cutaneous branch is distributed to the anterolateral part of the buttock.
The **ilioinguinal** nerve is smaller than the iliohypogastric nerve; it also arises from L1 and is distributed to the skin of the groin and mons pubis.
The **genitofemoral** nerve arises from L1 and L2. It passes through the psoas muscle, then down it to emerge through the deep inguinal ring. Its genital branch supplies the cremaster muscle and a part of the anterior and lateral scrotum. The femoral branch passes close to the external iliac artery, the deep circumflex iliac artery and the femoral artery to be distributed to the upper part of the femoral triangle. The two branches of the femoral branch may separate at any level, therefore, sensory phenomena associated with nerve damage depend upon the level of the lesion and individual variability.
The **lateral cutaneous** nerve of the thigh arises from L2 and L3 and eventually leaves the abdomen behind or through the inguinal ligament at a variable distance medial to the anterior superior iliac spine. In the thigh, it divides into an anterior branch that supplies the anterolateral skin of the thigh, approximately 10 cm down from the inguinal ligament to the knee. The posterior branch supplies the skin more laterally from the greater trochanter, down to the mid-thigh.
The **obturator nerve** arises from L2-L4, descends through the psoas muscle, runs around the pelvis in close proximity to the obturator internus muscle and obturator vessels, and leaves the pelvis via the obturator foramen. This nerve has significant motor innervation, and its cutaneous branch is distributed primarily to the skin on the medial aspect of the knee.

6.2.2 The posterior subgluteal triangle nerves

The posterior triangle area is the area defined superiorly by the upper border of the piriformis, inferiorly by the lower border of quadratus femoris, laterally by the greater trochanter and medially by and lateral border of the sacrum, the lateral borders of the sacrotuberal ligament and ischeal tuberosity. This region contains the sciatic nerve, posterior femoral cutaneous nerve (which branches into the posterior cutaneous perineal branch and the cluneal nerves), the nerve to the obturator internus muscle, and the pudendal nerve. These nerves pass deep to the piriformis muscle and superficial to the superiour gemellus and obturator internus muscles. Injury in this area may damage one or more of these nerves (Figure 13) (9-15).

6.2.3 Branches of the pudendal nerve

The **pudendal nerve** has its origins at the S2-S4 levels. S2 and S3 also contribute to the sciatic nerve and S4 to the coccygeal plexus and the annoccoccygeal nerves.
The pudendal nerve has three main branches: the **inferior anorectal nerve**, the **superficial perineal nerve** (which terminates as cutaneous branches in the perineum and posterior aspect of the scrotum), and the **deep perineal nerve**, which is distributed to the pelvic structures (innervating parts of the bladder, prostate and urethra). This branch terminates as the dorsal nerve of the penis/clitoris, which innervates the glans.
In addition to sensory branches, the pudendal nerve provides motor innervation to anal and urethral sphincters, as well as to the bulbospongiosus and ischiocavernous muscles (involved in the bulbocavernosal response, orgasm and ejaculation). Autonomic fibres also pass with the pudendal nerve and are derived from the presacral parasympathetic as well as sympathetic fibres via the hypogastric plexi.

6.2.4 Anatomical relations of the pudendal nerve (Figure 13)

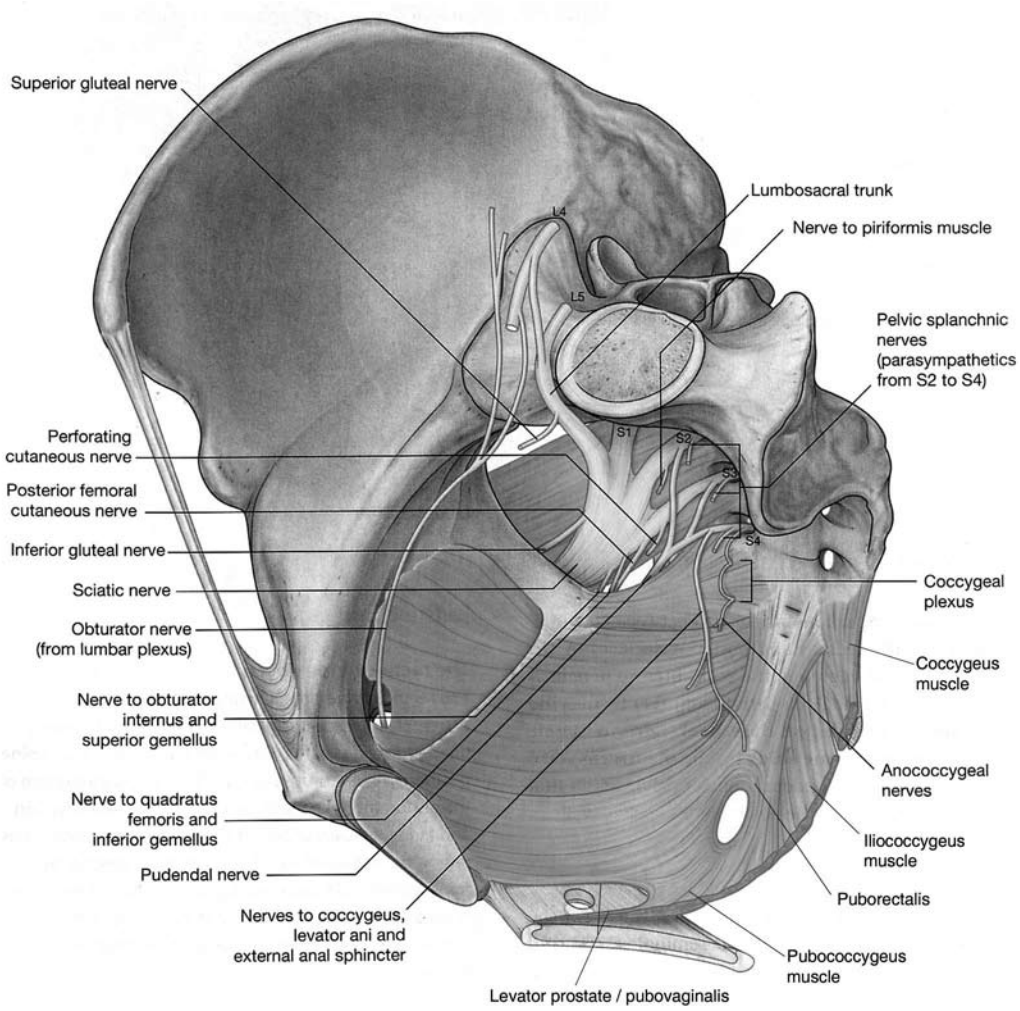
The anatomy may be variable, however, the three roots that form the pudendal nerve usually merge anterior to the sacrum and inferior to the piriformis muscle.
The pudendal nerve leaves the pelvis via the greater sciatic notch to enter the subgluteal region. In the posterior subgluteal triangle (the area bordered by the inferior edge of the piriformis muscle, the sarotuberous ligament medially and the upper border of the rectus femoris muscle inferiorly), the nerve emerges from under the inferior border of the piriformis muscle with its associated pudendal artery and veins; it is medial to the nerve innervating the obturator internus muscle, which is medial to the posterior femoral cutaneous nerve (which divides into its cutaneous branch but also the inferior cluneal nerves and perineal nerves), which is medial to the sciatic nerve. These anatomical relations are important for neurotracing techniques used for nerve blocks and because symptoms in those nerve territories also help with diagnosis (16-20).

The pudendal nerve leaves the subgluteal region as it wraps around the superficial surface of the ischeal spine/sacrospinal ligament to re-enter the pelvis (9,10) via the lesser sciatic notch (between the more ventral sacrospinal ligament and the more dorsal sacrotuberal ligaments). This occurs 15% of the time at the enthesis of the spine and the ligament; 75% of the time, it is more medial, and 10% of the time, it wraps around the spine. The sacrotuberal ligament may have a sharp superior border, be wide, and as a result, close

to the spinosacral ligament, or be divided with the pudendal nerve passing through it. All of these features may predispose to nerve injury.
As the pudendal nerve re-enters the pelvis below the levator muscles, it runs within a fascial canal medial to the internal obturator muscle (Alcock's canal).

The inferior anorectal branch may never be a true branch of the pudendal nerve, and may have its origins directly from sacral the roots. As a consequence, pain associated with pudendal nerve injury may not involve the anorectal area. Similarly, pain may only be perceived in the anorectal area if the main pudendal nerve is not involved. In 11% of cases, the inferior anorectal nerve pierces the sacrospinal ligament, possibly increasing the risk of entrapment. Other variations of the anorectal branch exist with the nerve branching off from the main pudendal nerve at any point in the gluteal region or within the pelvis. In 56% of cases, the pudendal nerve is a single trunk as it re-enters the pelvis. Some people have two or three pudendal nerve trunks.

Figure 13: Anatomical relations of the pudendal nerve



Source: Drake, Vogel, & Mitchell: GRAY's ANATOMY FOR STUDENTS, 2004 Elsevier Inc.

6.2.5 ***Afferent nerves and the genitalia***

- The afferents from the skin of the genitals pass via a complex of multiple sensory nerves and this makes the anatomical diagnosis of nerve injury as a cause of pain difficult.
- The anterolateral part of the scrotum/labia majora has afferents associated with the genitofemoral nerve primarily; there may also be some involvement of the ilioinguinal and iliohypogastric nerves.
- The posterior scrotal/labia branches of the pudendal nerve transmit sensation from the posterior scrotum/labia majora.
- The penis shaft is innervated on its dorsal surface by the genitofemoral, ilioinguinal and iliohypogastric nerves, and the ventral surface by the perineal branches of the posterior femoral cutaneous nerve and cutaneous branches of the pudendal nerve.

- The glans penis/clitoris is associated with the dorsal nerve of the penis/clitoris, the terminal branch of the pudendal nerve.
- All the nerves that are associated with the scrotum may also receive afferents from the testes, although classically, the nerves from the testes are usually associated with the genitofemoral nerve (thoracolumbar as opposed to sacral roots).
- The superficial branches of the pudendal's superficial perineal nerve and the perineal branch of the posterior femoral cutaneous nerve receive afferents from the perineal skin.
- Deeper afferents from the perineum and from some of the pelvic organs pass to the pudendal nerve via its deep perineal branch.

*6.2.6 **Afferents in the autonomic plexus***

The pelvic plexus is associated with both the parasympathetic and sympathetic nerves, and as well as afferents associated with these pathways, afferents may travel back to the sacral and thoracolumbar roots with these autonomic nerves. Sites for injury and possible intervention may thus include: the ganglion impar, superior hypogastric plexus, inferior hypogastric plexus, and lumbar sympathetic trunk, as well as more central spinal root areas.

6.3 Etiology of nerve damage

*6.3.1 **Anterior groin nerves - etiology of nerve damage***

The primary afferents of the anterior groin nerves enter the spinal cord at the thoracolumbar level (T10 to L3). Thoracolumbar spinal pathology and any pathology along the course of the nerve may result in neuropathic pain in the distribution of these nerves. As well as neoplastic disease, infection and trauma, surgical incisions and postoperative scarring may result in nerve injury (21-23).

*6.3.2 **Pudendal neuralgia - etiology of nerve damage***

Anatomical variations

Anatomical variations may predispose the patient to developing pudendal neuralgia over time or with repeated low-grade trauma (such as sitting for prolonged periods of time or cycling) (9,10).

The pudendal nerve may be damaged due to local anatomical variation at the level of:

1. The piriformis muscle. For example, as part of a piriformis syndrome: in some cases, the nerve may pass through the muscle and hence be trapped; or in other cases, muscle hypertrophy or spasm is implicated.
2. The sacrospinal/sacrotuberous ligaments, possibly accounting for 42% of cases.
3. Within Alcock's canal (medial to the obturator internus muscle, within the fascia of the muscle), possibly accounting for 26% of cases.
4. Multiple levels in 17% of cases.

The site of injury determines the site of perceived pain and the nature of associated symptoms (e.g., the more distal the damage, the less likely the anal region will be involved).

*6.3.3 **Surgery***

In orthopaedic hip surgery, pressure from the positioning of the patient, where the perineum is placed hard against the brace, can result in pudendal nerve damage (24,25). The surgery itself may also directly damage the nerve. Pelvic surgery such as sacrospinous colpopexy is clearly associated with pudendal nerve damage in some cases (26,27). In many types of surgery, including colorectal, urological and gynaecological, pudendal nerve injury may be implicated.

*6.3.4 **Trauma***

Fractures of the sacrum or pelvis may result in pudendal nerve/root damage and pain. Falls and trauma to the gluteal region may also produce pudendal nerve damage if associated with significant tissue injury or prolonged pressure.

*6.3.5 **Cancer***

Tumours in the presacral space must be considered. Tumours invading the pudendal nerve may occur and there may also be damage from surgery for pelvic cancer (13).

*6.3.6 **Birth Trauma***

This is more difficult to be certain about (12). The pudendal neuralgia of birth trauma is thought to resolve in most cases over a period of months. However, rarely, it appears to continue as painful neuropathy. Multiple pregnancy and births may predispose to stretch neuropathy in later life.

*6.3.7 **Elderly women***

Child birth (28) and repeated abdominal straining associated with chronic constipation (29) are thought to predispose elderly women to postmenopausal pelvic floor descent and stretching of the pudendal nerve with associated pain. Changes in the hormone status may also be a factor.
In the Urogenital Pain Management Centre, the commonest associations with pudendal neuralgia appear to be: history of pelvic surgery; prolonged sitting (especially young men working with computer technology); and postmenopausal older women. Trauma- and cancer-related pain is less frequent, cycling where as classical appears to be rarely seen.

6.4 Diagnosis for pudendal neuralgia

*6.4.1 **Differential diagnosis of other disorders***

Other forms of neuropathic pain (30,31).
As well as the pudendal nerve, there are several other nerves that may mimic the symptoms of pudendal neuralgia if they are damaged.

Inferior cluneal nerve. This is a branch of the posterior femoral cutaneous nerve. This nerve is prone to injury in the ischial region. Cluneal nerve injury produces a sensation of pain perceived more laterally than that for pudendal neuralgia.
Sacral nerve roots. The S2-S4 nerve roots may be involved. This is an important differential diagnosis as tumours must be excluded.
Cauda equina syndrome. Lumbar spinal pathology involving the cauda equina may result in an intractable neuropathic pain.
Ilioinguinal, iliohypogastric and genitofemoral nerves. Injury to these nerves or their roots may occur from thoracolumbar pathology, abdominal posterior wall conditions, surgery, and entrapment in the groin. The pain may extend into the groin, anterior perineum and scrotum/labia majorum. If the femoral branch of the genitofemoral nerve is involved, pain may extend into the inner thigh.

Referred spinal pain
Pain from thoracolumbar pathology may refer to the groin. Spinal pain may become associated with muscle hyperalgesia and trigger points. The muscle associated pain may spread to involve a range of muscles, including the pelvic floor muscles with resultant pelvic pain.

Musculoskeletal disorders
Trigger points associated with localised tenderness and pain may be detected in the piriformis, obturator internus, levator ani, bulbocavernosal and ischeocavernosal muscles, as well as the gluteal, adductor, rectus abdominus and spinal muscles. All of these may refer the pain to or close to the pelvis.
Pathology of the joints (sacroiliac, pubic symphysis, hip and spinal) may also refer into the pelvis.
Coccyx pain syndrome, a painful coccyx may occur for a number of reasons (Chapter 2).

*6.4.2 **Clinical presentation of pudendal neuralgia***

6.4.2.1 Age

There is a wide age range, as one would expect with a condition that has so many potential causes. There is a suggestion that, the younger the patient, the better the prognosis. Essentially, the sooner the diagnosis is made, as with any compression nerve injury, the better the prognosis, and older patients may have a more protracted problem (32-34).

6.4.2.2 Sex

Six out of ten cases are observed in women.

6.4.2.3 History

A proportion of patients will be able to relate the onset of pain to an acute event such as surgery, sepsis or trauma, and occasionally, cycling for a prolonged period. Chronic injury is more frequent, such as associated with sitting for prolonged periods over time. Many will be idiopathic.

The pain is classically perceived in the perineum from anus to clitoris/penis. However, less-specific pain distribution may occur, and this may be due to anatomical variation, involvement of branches of the nerve rather that the main nerve, CNS central sensitisation, and consequently, the involvement of other organs and systems in a regional pain syndrome. Other nerves in the vicinity may also be involved, for example, inferior cluneal nerve and perineal branches of the posterior femoral cutaneous nerve. The musculoskeletal system may become involved, confusing the pain picture as aches and pains develop in the muscles due to immobility

and disability, possibly magnified by the CNS changes.

Burning is the most predominant adjective used to describe the pain. Crushing and electric may also be used, indicating the two components - a constant pain often associated with acute sharp episodes. Many patients may have the feeling of a swelling or foreign body in the rectum or perineum, often described as a golf or tennis ball. The term pain has different meanings to patients and some would rather use the term discomfort or numbness.

Aggravating factors include any cause of pressure being applied, either directly to the nerve or indirectly to other tissue, resulting in pudendal traction. Allodynia is pain on light touch due to involvement of the CNS, and may make sexual contact and the wearing of clothes difficult. These patients often remain standing, and as a consequence, develop a wide range of other aches and pains. Soft seats are often less well tolerated, whereas sitting on a toilet seat is said to be much better tolerated. If unilateral, sitting on one buttock is common. The pain may be exacerbated by bowel or bladder evacuation.

6.4.2.4 Associated features

Pudendal nerve damage may be associated with a range of sensory phenomena. In the distribution of the nerve itself, as well as unprovoked pain; the patient may have paraesthesia (pins and needles); dysaesthesia (unpleasant sensory perceptions usually but not necessarily secondary to provocation, such as the sensation of running cold water); allodynia (pain on light touch); or hyperalgesia (increased pain perception following a painful stimulus, including hot and cold stimuli). Similar sensory abnormalities may be found outside of the area innervated by the damaged nerve, particularly for the visceral and muscle hyperalgesia.

The cutaneous sensory dysfunction may be associated with superficial dysparunia, but also irritation and pain associated with clothes brushing the skin. There may also be a lack of sensation and pain may occur in the presence of numbness. Visceral hypersensitivity may result in an urge to defecate or urinate. This is usually associated with voiding frequency, with small amounts urine being passed. Pain on visceral filling may occur. Anal pain and loss of motor control may result in poor bowel activity, with constipation and/or incontinence. Ejaculation and orgasm may also be painful or reduced.

Many of those suffering from pudendal neuralgia complain of fatigue and generalised muscle cramps, weakness and pain. Being unable to sit is a major disability, and over time, patients struggle to stand and they often become bedbound. The immobility produces generalised muscle wasting, and minimal activity hurts. As a consequence of the widespread pain and disability, patients often have emotional problems, and in particular, depression. Patients with CPP are also often anxious and have the tendency to catastrophise. Depression, catrostophising and disability are all poor prognostic markers.

Cutaneous colour may change due to changes in innervation but also because of neurogenic oedema. The patient may describe the area as swollen due to this oedema, but also to the lack of afferent perception.

6.4.2.5 Clinical examination

A full clinical examination of the spinal, muscular, nervous and urogenital systems is necessary to aid in diagnosis of pudendal neuralgia, especially to detect signs indicating another pathology. Often there is little to find in pudendal neuralgia and frequently findings are non-specific. The main pathognomonic features are the signs of nerve injury in the appropriate neurological distribution, for example, allodynia or numbness. Tenderness in response to pressure over the pudendal nerve may aid the clinical diagnosis. This may be elicited by per rectal or per vaginal examination and palpation in the region of the ischeal spine and/or Alcock's canal. Muscle tenderness and the presence of trigger points in the muscles may confuse the picture. Trigger points may be present in a range of muscles, both within the pelvis (levator ani and obturator internus muscles) or externally (e.g., the piriformis, adductors, rectus abdominus or paraspinal muscles).

6.4.2.6 Investigations

MRI scans of the pelvis are usually normal although some practitioners claim them to be useful (35,36). However, MRI scans of the pelvis and spine (mid thoracic to coccyx) are considered essential to help with the differential diagnosis of pudendal neuralgia. Electrophysiological studies may reveal signs of perineal denervation, increased pudendal nerve latency, or impaired bulbocavernosal reflex (25,34,37-39). However, for an abnormality to be detected, significant nerve damage is probably necessary. Pain may be associated with limited nerve damage, therefore, these investigations are often normal in patients thought to have pudendal neuralgia.

6.5 Management of pain associated with nerve damage

The approach to managing a patient with pain following nerve damage is similar irrespective of the nerve involved. There is a suggestion that early treatment has a better prognosis. The general principles are covered in chapter 10 of this document.

*6.5.1 **Pudendal neuralgia and injections***

The role of injections may be divided into two. First, an injection of local anaesthetic and steroid at the sight of nerve injury may produce a therapeutic action. The possible reasons for this are related to the fact that steroids may reduce any inflammation and swelling at the site of nerve irritation, but also because steroids may block sodium channels and reduce irritable firing from the nerve. The second possible benefit of local infiltration is diagnostic. We have already indicated that when the pudendal nerve is injured there are several sites where this may occur. Differential block of the pudendal nerve helps to provide information in relation to the site where the nerve may be trapped (16-20,35,40-44) .

Infiltration at the ischeal spine requires the use of a nerve stimulator/locator. Both motor (anal contraction) and sensory endpoints may be noted. The anatomical endpoint may be localised by fluoroscopy, computed tomography (CT) guidance, or the use of ultrasound. Ultrasound avoids any form of radiation, whereas CT guidance involves a significant amount of radiation. Currently, fluoroscopy is probably the imaging technique most frequently used because it is readily available to most anaesthetists that perform the block.

Currently, infiltration of the pudendal nerve within Alcock's canal is primarily undertaken with the use of CT. As well as injecting around the pudendal nerve, specific blocks of other nerves arising from the pelvis may be performed. Similarly, trigger point injections into tender areas within muscles may also be considered. Pulsed radiofrequency stimulation has also been suggested as a treatment (45).

*6.5.2 **Pudendal neuralgia and surgery***

Decompression of an entrapped or injured nerve is a routine approach and probably should apply to the pudendal nerve as it applies to all other nerves. There are several approaches and the approach of choice probably depends upon the nature of the pathology. The most traditional approach is the transgluteal approach; however, a transperineal approach may be an alternative, particularly if the nerve damage is thought to be related to previous pelvic surgery (11,14,33,35,46-48).

Currently, there has been only one prospective randomised study (11). This suggests that, if the patient has had the pain for < 6 years, 66% of patients will see some improvement with surgery (compared to 40% if the pain has been present for > 6 years). Surgery is by no means the answer for all patients. On talking to patients that have undergone surgery, providing the diagnosis was clear-cut, most patients are grateful to have undergone surgery but many still have symptoms that need management.

*6.5.3 **Pudendal neuralgia and neuromodulation***

Pudendal neuralgia represents a peripheral nerve injury and as such should respond to neuromodulation by implanted pulse generators. However, it is important that the stimulation is perceived in the same site as the perceived pain. Spinal cord stimulation (SCS) may be effective for thoraco-lumbar afferents. However, it is difficult to obtain appropriate stimulation from SCS for the sacral nerves including pudendal. There is limited experience with sacral root stimulation and as a result stimulation for pudendal neuralgia should only be undertaken in specialised centres and in centres that can provide multidisciplinarycare (49-51).

6.6 Conclusions and recommendations: pudendal neuralgia

Conclusions	**LE**
Multiple sensory and functional disorders within the region of the pelvis/urogenital system may occur as a result of injury to one or more of many nerves. The anatomy is complex.	2
There is no single aetiology for the nerve damage and the symptoms and signs may be few or multiple.	1
Investigations are often normal.	2
The peripheral nerve pain syndromes are frequently associated with negative cognitive, behavioural, sexual, or emotional consequences.	1
There are multiple treatment options with varying levels of evidence.	1

Recommendations	GR
It is important to rule out confusable diseases.	A
If a Peripheral Nerve Pain Syndrome is suspected, early referral should occur to an expert in the field, working within a multidisciplinary team environment.	B
Imaging and neurophysiology may help with the diagnosis, but the gold standard investigation is an image and nerve locator guided local anaesthetic injection.	B
Neuropathic pain guidelines are well established. Standard approaches to management of neuropathic pain should be utalised.	A

7. SEXOLOGICAL ASPECTS OF CHRONIC PELVIC PAIN

7.1 Introduction

In general human sexuality has three aspects – sexual function, sexual self-concept, and sexual relationships. Pain can affect self-esteem, ones ability to enjoy sex and relationships. Healthy sexuality is a positive and life-affirming part of being human. The capacity to experience optimal comfort and satisfaction in sexual expression also requires basic physical abilities. Essentially, these include intact sensory and motor processes, and the ability to move with ease.

Chronic pain may hinder the ability to move freely, and thus, may limit the positions one can get into to have sex. Second, chronic pain may affect the ability to respond sexually and conversely in CPP the sex act can be associated with pain that can be inhibiting. Research on male sexual dysfunction highlights the importance of considering partners and the impact that male sexual problems have on their partners. Sexual dysfunction occurs in an interpersonal context and has implications for both partners in a relationship. Chronic pain also impacts the sexual and interpersonal functioning of couples; declines in sexual activity and reduced relationship satisfaction have been noted among patients with chronic pain and their partners (1,2).
It is recommended that a biopsychosocial model of CPPS should be incorporated into future research, and that research considers the role that sexual and relationship variables may play in couples' adjustment.
The sexual-response cycle is divided into five phases: desire, arousal (excitement), plateau, orgasm and resolution. They're actually all part of a continuous process of sexual response. There is much variation among individuals, as well as between different sexual events and there are different models to describe the sexual responses (3).

During the sexual response cycle the different phases, are controlled by a different part of the brain and spinal cord. In each of these phases chronic pain and CPP in particular can cause disturbances (4).

- The Desire Phase begins in the "pleasure centers" of the brain and controls a person's sexual appetite or drive. Pain or even the fear of pain can decrease desire, making the person uninterested in sex. In some cases, however, having sex may actually help to relieve pain.
- The Arousal Phase is associated with the swelling of the blood vessels in a man's penis and in a woman's labia, vagina, and clitoris. This swelling causes an erection in the penis and in the clitoris and release of lubricating fluids. If a person experiences pain at the time of becoming excited, the excitement may be reversed, in man the penis will become limp and in woman the lubrication will stop, laeding to dryness.
- The Orgasm Phase describes a genital reflex controlled by the spinal cord, which causes the genital muscles to contract, involuntarily releasing sexual tension and swelling that build up during the excitement phase. In some cases, pain prevents people from reaching this phase.

7.2 General Considerations

Pelvic pain in women (5) and in men (6) is associated with significant sexual dysfunction. While chronic pain impacts all aspects of functioning, including work, family relationships, and social activities, the most frequent complaint cited by patients with CPP (CPP) is sexual dysfunction (7). Factors contributing to sexual dysfunction in patients with chronic pain are multifactorial and contextual (8), and may be related to comorbidity with depression (9,10), use of antidepressant medications (11), and relationship satisfaction (12), among many other factors. There are reports of increased rates of past sexual abuse which may have negative impact on sexual

function (13,14). CPP may have a higher association with sexual dysfunction than other types of chronic pain. CPP specifically involves areas intimately connected to sexuality, which may negatively impact one's body image and sexual self-esteem (15), and also affects both partners in the relationship (16).

7.3 Pelvic floor involvement in sexual function and dysfunction

The pelvic floor of the male appears to have some impact on sexual function, although its exact role is unclear. Erection is a neurovascular event in which the smooth and striated musculature of the corpora cavernosa and pelvic floor play a role in facilitating and maintaining the erection (24). In ejaculation and orgasm the rhythmic contraction of the bulbocavernous and ischiocavernous muscles is perceived as pleasurable. Ejaculation is controlled by the sympathetic nervous system and performed with help of the pelvic floor muscles. Controlling the pelvic floor muscles may delay the onset of ejaculation through an active relaxation of the pelvic floor muscles. This is a learned technique, which may be mastered using pelvic floor biofeedback. Pelvic floor exercise and biofeedback for the treatment of both erectile dysfunction (ED) and premature ejaculation (PE) have been reported on in the literature (25).

Early studies maintained that strong pelvic floor muscles in women, particularly the ischiocavernous muscle that attaches to the clitoral hood, were crucial for adequate genital arousal and attainment of orgasm (26), and that weak muscles may provide insufficient activity necessary for vaginal friction or blood flow, and inhibit orgasmic potential (27). It has also been proposed that sexual pleasure is enhanced for both partners by genital responses provided by contraction of the levator ani (28). It stands to reason, therefore, that better control over pelvic floor muscle contraction and relaxation could improve sexual function.

However, few studies are available to support this notion. In a Scandinavian randomised controlled study pelvic floor muscle training has been demonstrated to improve QoL and sexual function in women with urinary stress incontinence (28). In a Turkish study, improvement in sexual desire, performance during coitus, and achievement of orgasm were reported in women (N=42) who received pelvic floor muscle re-education (29).

The effectiveness of physical therapy in treating sexual pain disorders has been reported upon in the literature as well. Retrospective studies have reported on a success rate of 77% (30,31). Goetsch recently reported her findings that physical therapy may serve as important adjunct to surgery for "vulvar vestibulitis" (vulvar pain syndrome) (32).

7.4 CPP and sexual dysfunction of the male

In the BACH study, Hu et al. found that men who reported having experienced sexual, physical, or emotional abuse had increased odds (1.7 compared to 3.3) for symptoms suggestive of PPS. The authors suggested that clinicians may wish to screen for abuse in men presenting with symptoms suggestive of PPS. Conversely, clinicians may wish to inquire about pelvic pain in patients who have experienced abuse (33).

A key feature of PPS is chronic pain. Chronic pain and its treatment can impair our ability to express sexuality. In a study in England 73% of patients with chronic pain had some degree of sexual problems as result of the pain (8). These problems can occur because of several factors. Psychological factors like decrease in self-esteem, depression and anxiety can contribute to loss of libido. Physiological factors like fatigue, nausea and pain itself can cause sexual dysfunction. Pain medications (opioids, and the selective serotonin reuptake inhibitors, SSRI) can also decrease libido (34) and delay ejaculation.

The evaluation of the effects of PPS on sexual function should take into consideration the adverse effects of drug therapy of PPS on sexuality, as well as the more interesting direct interactions between the PPS symptoms and disorders of libido, erectile function and ejaculation.

The number of studies on the effects of CPP on sexual function is limited. Sexual dysfunction is often ignored because of a lack of standardised measurements. At the present, the most commonly used tool is the international index of erectile function (IIEF) questionnaire (35). Post-ejaculation pain is not mentioned in this questionnaire.

In the 1980s an association between PPS and sexual dysfunction was postulated (36). This study reported a high incidence of decreased libido in patients with PPS, and they also concluded that this syndrome should be viewed as a psychosomatic disorder. Where as psychology may play a role in the genesis of the pain, nowadays we would say there is little evidence to support PPS as being a psychiatric disorder, but rather a biopsychological disorder in certain cases. For more information on this issue see Chapter 3.1.

In 2 reviews the relation between PPS and health status, with influence on sexual activity, were addressed (37,38).

In a Chinese study of men with PPS 1768 males completed the questionnaires. The overall prevalence of sexual dysfunction was 49%. Erectile dysfunction (ED) is the most investigated sexual dysfunction in PPS patients. The reported prevalence of ED ranges from 15.1% to 48%, varying with the evaluation tools and populations (39,40). ED was prevalent in 27.4% of Italian men aged 25-50 (41), 15.2% among Turkish men

(significantly higher than control group) (17) and 43% among Finnish men with PPS (42). The prevalence of ED was found to be higher in young men with PPS than in the general population.

According to other studies men with pelvic pain had higher chance of suffering from ED (43,44). Recently, a significant correlation between "chronic prostatitis", PPS symptoms (measured by NIH-CPSI) and ED (measured by IIEF) was confirmed (45), while other studies using the same questionnaires were not able to confirm such a correlation (35,46). Some studies also report ejaculatory dysfunction, mainly premature ejaculation (6,30,39,40). According to the definition set up by the International Society for Sexual Medicine, PE is "a male sexual dysfunction characterised by ejaculation which always or nearly always occurs prior to or within about one minute of vaginal penetration, and inability to delay ejaculation on all or nearly all vaginal penetrations" (47). The reported prevalence of PE varies widely in PPS patients, but unlike ED the prevalence does not increase with age (40).

A study from Turkey concerning the interaction between PPS and premature ejaculation (PE) according to intravaginal ejaculation latency time showed that 77% of men with PPS suffered from PE (17). Screponi et al. (2001) reported the high incidence of prostatic inflammation symptoms in men with PE (48). PE associated with PPS is hypothesised to be caused by infection or inflammation, thus treatment with antibiotics should reduce PE symptoms. In 2 studies antibiotic treatment has been shown significantly increase in patients IELT (intravaginal ejaculation latency time). Despite these improvements, the mean IELT was still very low and questionable. Before these results can be recommended, further placebo controlled, studies are mandatory (49,50).

Furthermore, there are reports which highlight the appearance of ejaculatory pain in patients with PPS (51), while some studies suggested PPS symptoms improvement by increased ejaculatory frequency and sexual activity (52,53).

The presence of pelvic pain may increase the risk for erectile dysfunction independently of age (44). On the other hand, cross-sectional data suggest no improvement of LUTS by an increased frequency of ejaculation (38). In a study bridging the gap between LUTS and ED, Muller and Mulhall have speculated on the negative impact of PPS on QoL, leading to consecutive impairment of erectile function (54). Although mental distress and impaired QoL related to illness could contribute to sexual dysfunction observed in patients with PPS, the presence of erectile and ejaculatory disorders is more frequently related to symptoms and imaging suggestive of a more severe inflammatory condition (6). These arguments are important for the understanding of the close relationship between CPP symptoms, disturbed sexuality, impact on QoL, and psychological implications including depression (37-40,55).

Sexual dysfunction heightens anger, frustration and depression, all of which place a strain on the relationship and the partner. The female partners of men with sexual dysfunction and depression often present with similar symptoms including pain upon intercourse and depressive symptoms. Men with PPS have reported a high frequency of sexual relationship dissolution and psychological symptoms, such as depression and suicidal thinking (37,54). PPS patients reported greater sexual and relationship problems: 45% reported an increase in pain during or following intercourse, and many reported avoiding sexual relationships for fear of spreading an infection to their partner (56). On the other hand, Smith et al. found that men with PPS did not report significant decrease of sexual satisfaction compared to control. The results of the study suggested that while men with PPS and their partners may experience some sexual difficulties, PPS may not have a large negative impact on patients' intimate relationships (57). Aubin et al. found that men appeared open to the initiation of sex and assumed their partners were sexually satisfied (58).

There is a consensus that therapeutic strategies reducing symptoms, especially against pelvic pain, are of relevance in relation to changes of sexuality. On the other hand, having sex and intimacy can yield positive experiences that will reduce the pain. The central nervous system plays an important role in this mechanism.

7.5 CPP and sexual dysfunction of the female

CPP is a clinical condition that results from the complex interactions of physiological and psychological factors and has a direct impact on the social, marital, and professional lives of women. CPP leads to substantial impairment in QoL and several sexual dysfunctions (58-61).

It seems reasonable to expect that pain, extreme fatigueness , depressive mood and paindrugs will effect womens sexuality. Women with pain may report a variety of sexual problems ranging from decreased pleasure and frequency of intercourse, superficial or deep dyspareunia, and problems in reaching orgasm to a total aversion toward sexual intimacy of any kind. Ter Kuile et al. found in their study that women with CPP reported significantly more pain, depression, and anxiety symptoms and were physically more impaired than women in the control group. In comparison with controls, women with CPP reported significantly more sexual avoidance behavior, non-sensuality, and complaints of "vaginismus" (62).

CPP is more directly associated with sexual dysfunction than chronic pain at other sites. In one study of CPP patients' feelings and beliefs about their pain or illness, 40 out of 64 participants cited sexual

dysfunction as one of the chief problems the illness had caused, making it the most frequent complaint (20). Collett and colleagues (63) also found that patients with CPP reported more sexual problems than women with any other type of chronic pain problem.

The quality of intimate relationships is closely connected with sexual function (64). Satisfaction with the sexual relationship appears to be associated with higher marital functioning (65). In addition to its relationship with marital dissatisfaction, sexual dissatisfaction is related to sexual dysfunction. In cases in which one partner suffers from chronic pain, the ability of both partners to cope with the pain and the extent to which partners are supportive of the chronic pain sufferer have been found to be a predictor of sexual functioning (65).

In community-based studies in the UK (7), New Zealand (59) and Australia (66), a substantially larger proportion of the women with CPP reported dyspareunia (varying between 29% and 42%) than women without CPP (varying between 11% and 14%). Only a few studies have investigated sexual problems within clinical populations (63,67,68). The study of Veritt et al. show that all of the sexual function domains (desire, arousal, lubrication, orgasm, satisfaction, and pain) were significantly lower in women with CPP than in women without CPP (68). In line with the results of the community based studies, patients with CPP reported more sexual problems such as dyspareunia, problems with desire or arousal and lubrication than women without CPP (67-69).

One study of patients enrolled in chronic pain treatment programs in England has reported that 73% had pain-related sexual problems (8). Approximately two-thirds of patients in another study have reported reduced frequency in their sexual relations as a result of CPP (70).

One study demonstrated that CPP patients reported worse sexual function with regard to desire, arousal, lubrication, orgasm, satisfaction, and more frequent and severe pain with vaginal penetration than women without sexual dysfunction (19).

Maruta et al. interviewed 50 chronic pain sufferers and their spouses, of whom 78% of the pain sufferers and 84% of partners described deterioration, including cessation of their sex life (1). In another study, in patients with back pain, half reported decreased frequency of sex since the onset of chronic pain (8)

The female sexual function index (FSFI) has been developed as a brief, multidimensional self-report instrument for assessing the key dimensions of sexual function in women, which includes desire, subjective arousal, lubrication, orgasm, satisfaction, and pain. The study of Veritt FF et al. showed that when FSFI was used women with CPP reported worse sexual function in all subscales and total score than did women without CPP; the largest differences between women with CPP and without CPP were seen for the domains of pain and arousal; the correlations of FSFI corresponded well to each other; the total score and the subscales of the FSFI had high levels of internal consistency and test–retest reliability when assessed in a sample of women with CPP; and finally, that the FSFI showed good ability to discriminate between women with and without CPP (19).

Some studies report a significant association between sexual abuse before the age of 15 years and later CPP (13). It is suggested that there is increased frequency of sexual abuse or trauma history, anxiety and depression in women with CPP (71-75). While the study of Fry et al. with 164 women with CPP show that child sexual abuse did not apparently differ in prevalence from that in the general population, which must throw into question previous assertions about its widespread and general role in CPP.

7.6 Treatment of sexual dysfunctions and CPP

Couples often benefit from early referral for relationship and sexual counseling during their treatment course (76). Specific behavioral strategies for women who have urogenital complaints and female sexual dysfunction often include exploring alternatives to sexual intercourse (manual or oral pleasuring), different coital positions (female superior or side lying), and pacing, such as limiting thrusting to less than that that causes. Planning for the time of intercourse is important, and scheduling a clinic visit after intercourse might be useful to identify specific sites and causes of postcoital flares. Other behavioral changes involve pre- and postcoital voiding, application of ice packs to the genital or suprapubic area (76,77), and use of vaginal dilators before penile penetration. An alternative is to use natural dilators such as different fingers or sex toys. Hypoallergenic nonirritating lubricants can be used to reduce vulvar, urethra, and vaginal friction, and women with signs of vulvovaginal atrophy may benefit from introital application of minimally absorbed locally applied oestrogen cream (78). In patients with an overactive pelvic floor, referral for physical therapy, myofascial release, and internal pelvic floor muscle massage may offer relief (79).

7.7 In summary

Problems with sexual functioning resulting from CPP have to be addressed and assessed by the health-care professional. The attention directed toward these patients must be focused not only on the disease but also on the woman as a whole. As treatment solely of the underlying disease is not acceptable, the care of these suffering women should also address the emotional, sexual, and social problems that the disease causes.

7.8 Conclusions and recommendations: sexological aspects in CPP

Conclusions	LE
Chronic pain can lead to decline in sexual activity and satisfaction and may reduce relationship satisfaction.	2a
Patients who reported having sexual, physical or emotional abuse show a higher rate of reporting symptoms of PPS.	2b
Sexual dysfunctions are prevalent in patient with PPS.	2b
In men with PPS the most prevalent sexual complains are erectile dysfunction and ejaculatory dysfunctions.	3
In females with CPPS all sexual function domains are lower. The most reported dysfunctions are sexual avoidance, dyspareunia and “vaginismus”.	2a
Vulvar Pain Syndrome is associated with BPS.	3
Women with BPS suffer significantly more from fear of pain, dyspareunia and less desire.	2a
Pelvic floor muscle function is involved in the excitement and orgasm phases of sexual response.	3
Chronic pain can cause disturbances in each of the sexual response cycle phases.	2b
Pelvic floor muscle physical therapy may offer relief of pain and reduction in sexual complains.	2b

Recommendations	GR
Clinicians may screen for abuse in patients presenting with symptoms suggestive for prostate pain syndrome without suggesting a causal relation with the pain.	B
The biopsychosocial model should be applied in the evaluation of the effect of prostate pain syndrome on the sexual function of the patient.	B
The biopsychosocial model should be incorporated in research in the role of chronic pelvic pain in sexual dysfunction.	B
Behavioral strategies should be offered to the patient and his/her partner to cope with sexual dysfunctions.	B
We recommend training of the pelvic floor muscles to improve quality of life and sexual function.	B

8. PSYCHOLOGICAL ASPECTS OF CHRONIC PELVIC PAIN

This chapter first addresses general issues concerning the psychological contribution to pelvic pain and its presenting problems, and assessment and treatment, and then it describes the same areas in relation to CPP in women. This is by far the area with the greatest psychological contribution to pelvic and urogenital pain, and exemplifies many of the problems raised in the first part of the chapter.

8.1 Understanding the psychological components of pain

*8.1.1 **Neurophysiology of pain***

Models that integrate the psychological factors consistently found to be relevant in the maintenance of persistent pelvic and urogenital pain with current neurobiological understanding of pain are few but of high quality. Symptom-related anxiety and central pain amplification may be measurably linked, as in IBS (1). Bajaj et al. (2) have demonstrated central sensitisation in symptomatic endometriosis, and this model is more extensively dealt with in Chapter 4. The various mechanisms of facilitation, amplification, and failure of inhibition, mean that there should be no expectation of a simple relationship between physical findings, pain experienced, and resulting distress and restriction of activities. Difficulty disengaging even from expected painful stimuli, undergone voluntarily and within tolerable levels, is characteristic in people struggling with chronic pain (3). However, difficult as it is to relieve chronic pain, the pain system is plastic and treatment attempts are not entirely unsuccessful.

*8.1.2 **Sexual abuse and trauma***

Many studies have reported high rates of childhood sexual abuse in adults with persistent pain, usually in hospital care samples, and particularly by women with pelvic pain (4). However, all these studies are retrospective, and there appears to be a relationship between poor study quality and likelihood of reporting this association (5). The only prospective investigation into the relationship between childhood sexual abuse, physical abuse, or neglect, and “medically unexplained pain”, including pelvic pain, used court records concerning sexual abuse before the age of 11 years to establish a definite history, comparing those with such a history with demographically matched classmates (6). The conclusions of this study were that physically and sexually abused individuals were not at risk for increased pain symptoms, although those individuals with pain problems as adults were more likely to report earlier sexual or physical abuse or neglect; however, this did not correspond with the established early history of abuse.

The correlation between childhood victimisation and pain symptoms is less straightforward than previously thought, and may be more about retrospective explanatory frameworks used by women for pain for which no major pathology is found than about occurrence or extent of abuse. In particular, findings of depression and/or post-traumatic stress disorder in adult women reporting childhood sexual abuse are common, with or without pain. Disentangling the influences and inferences requires prospective studies or careful comparisons rather than, as in many published studies, comparing women with a history of sexual abuse and CPP with women without either (7). No studies have been found about sexual or physical abuse in childhood and pelvic pain in men, although it is evident that they suffer other adverse effects on psychological and physical health (8,9).

*8.1.3 **Interpreting psychological differences***

An important review (7) of CPP in women identifies as problematic the notion that women without physical findings to which pain can be causally attributed differ in psychological characteristics from women with physical findings. They have critically examined the methodologies of studies purporting to show such differences, and the bias introduced by sampling and by unsuitable measures. They argue for better methodology in replication of these studies, particularly those sampling life events, and for greater use of idiographic methods.

In summary, women with pelvic pain often have other ‘medically unexplained’ symptoms, and current or lifetime anxiety and depression disorder; they may have a history of physical or sexual abuse in childhood but the significance of this for pelvic pain is unclear. Studies that invoke ‘medically unexplained’ or ‘psychosomatic’ or ‘somatoform’ disorders do not engage with current understanding of pain, such as viscerovisceral cross sensitisation in relation to multiple pain sites (10), referring instead to a dualistic model in which absence of physical findings is taken to indicate psychological origins of the complaint of pain (11,12). At the extreme, pain is overshadowed by diagnosis as a sexual problem (‘dyspareunia’) when pain is in fact the central problem and not contingent only on sexual activity (13).

8.2 Psychological assessment of pain

The report of anxiety, depression and sexual problems is sufficiently common for these to be important in assessment and in planning treatment. Distress, described in the patient's terms or within a psychodiagnostic framework, is best understood in the context of pain and the meaning of pain to the individual.

Anxiety probably refers to fears of missed pathology as the cause of pain (cancer being foremost among these) and to uncertainties about the possibilities of treatment and the likely prognosis if treated or untreated. A question such as that suggested by Howard (14), "What do you believe or fear is the cause of your pain?" is more suitable than a general anxiety questionnaire.

Depression is also commonly found in men and women with persistent pelvic pain (15). In a study comparing men and women with low back pain, and women with pelvic pain and men with urogenital pain (16), it was found that, when differences in age and pain duration and severity were taken into account, there were no differences in depression according to pain site, and pain site predicted disability.

However, there is a risk when using diagnostic or standard assessment instruments of attributing pain-related problems to neurovegetative signs of depression (17,18). As Stones et al. (19) has cautioned: "Psychological distress may be a consequence and not a cause of persistent pain: while identification of depression is important as part of treatment, caution is required before attribution of causality" (p416).

Pain ratings themselves may be predicted by cognitive and emotional variables (20). Furthermore, target outcomes of pain severity, distress and disability co-vary only partly, and improvement in one does not necessarily imply improvement in the others. Therefore, it is particularly important when the primary outcome is pain to anchor its meaning in a study such as that by Gerlinger et al. (21), who determined clinically important differences in pain in relation to overall satisfaction with treatment.

There are many measures of restricted function, or disability, most suited to musculosketal pain and mobility problems rather than the difficulties of the individual with pelvic or urogenital pain. Some include one or more items related to sexual activity, but there has perhaps been an over-emphasis on the effects of pain on sexual performance, although the overall relationship may be more important (22).

In the Cochrane review of pelvic pain in women (23), the outcomes of pharmacotherapy, surgery and physical therapy trials consist of pain scores (patient-rated and physican-estimated); functional measures such as urinary peak flow rate (for persistent pelvic pain in men); examination findings such as pelvic tenderness (women); and uptake of further treatment following the trial treatment. A few trials have included QoL, but none has measured mood change. This indicates a general but mistaken assumption that improvement in pain leads to resolution of other problems. Furthermore, if all treatments sampled the same domains of pain in their evaluation, comparison across treatments, by medical personnel and patients, would be more easily achieved (24). Suggested instruments for assessment in each of these domains can be found in the consensus paper by Turk et al (25).

8.3 Psychological issues in the treatment of pain

Provision of information that is personalised and responsive to the presenting problem and the concerns of the patient, conveying belief and concern, is a powerful way to allay anxiety (26). It can be helpful to provide additional written information or direct the patient to reliable sources. Many practitioners rely on locally produced material or pharmaceutical products of variable quality, although they endorse the need for independent materials for patients (27).

Ideally, treatment arises from general principles and practice in the field of chronic pain, with specific study of the population of concern and design of appropriate treatment trials (28). The field of pelvic pain shows a curious phenomenon whereby few of the mainstream psychologically based treatments are subjected to trials and published, but instead there are often rather idiosyncratic versions of treatment components, or combinations of interventions, published in single, often underpowered trials. It is hard to conclude anything from these, as is seen in the psychological treatment section of several other chapters.

Psychological interventions may be directed at the pain itself, with the intended outcome of reducing pain and its consequent impact on life, or adjustment to pain, with improved mood and function and reduced health care use, with or without pain reduction. The major psychologically based treatment that improves adjustment, which is aimed more at reducing distress and disability than pain, is cognitive behavioural therapy, for which there has been > 10 systematic reviews (29), although its effects may be small and maintenance in the longer term is uncertain. For less disabled and distressed patients, this can be delivered in part over the internet (30). A systematic review of short-term psychodynamic psychotherapy (31) has reported similar improvements in "somatic disorders", which often includes pelvic pain, although it was not among the trials reviewed. Pain-focused interventions, again with no trials in pelvic pain, have been subjected to systematic review, including hypnotherapy (32) and autogenic training (33).

However, all these systematic reviews suffer from heterogeneity among the trials, shortcomings in trial methodology, and little longer-term follow-up to establish maintenance of treatment gains. The crucial question, of what works best for whom, is unanswered and possibly unanswerable given the complexity of

variables, outcomes, and the difficulties in standardising treatments.

8.4 Female pelvic pain

8.4.1 ***Psychological risk factors in development and maintenance of pelvic pain***

A thorough review from nearly 15 years ago (34) argues against division of aetiology into organic versus psychogenic, and concludes that, given the methodological problems of many studies, the evidence for sexual abuse as a risk factor is uncertain. A large review and meta-analysis of risk factors, including physical pathology, psychological distress, and sexual abuse (35) drew mainly on retrospective studies, which introduced various biases.Pelvic pain and distress may be variously related, each as the consequence of the other, or arising independently.

The only systematic review (5) of risk factors for chronic non-cyclical pelvic pain in women included the following as well as medical variables: sexual or physical abuse (ORs from 1.51 to 3.49); psychological problems such as anxiety (OR: 2.28, 95% CI: 1.41- 3.70) and depression (OR: 2.69, 95% CI: 1.86-3.88); hysteria, i.e., multiple somatic problems (OR: 4.83, 95% CI: 2.50-9.33); and psychosomatic symptoms (OR: 8.01, 95% CI: 5.16-12.44). The terms hysteria and psychosomatic symptoms can best be understood as multiple somatic symptoms not associated with or indicative of any serious disease process, and personality variables are not reliably associated with pelvic pain in women. Although some of these risk factors are doubtless interrelated - history of sexual abuse and depression, for instance - such effects cannot be disentangled from the studies available.

Issues of early trauma such as childhood sexual or physical abuse as a risk factor are addressed in more detail earlier in this chapter, but it is important to say that better quality studies, including one prospective study using court records of childhood abuse (6), have reported a weaker or no relationship, or not one which is specific to pelvic pain (5, 36-38). However, another systematic review (9) has concluded that there is some evidence for a specific relationship between rape and CPP (and also with fibromyalgia and functional gastrointestinal disorders). It is also important to recognise the possible role of recent sexual assault on the presentation of pelvic pain (4,39).

There have been fewer studies of maintenance of or recovery from pelvic pain in relation to psychological factors. Weijenborg et al. (40) have found that, in 25% of women treated surgically, recovery from pelvic pain over a mean 3 years follow-up was not predicted by pain variables at baseline, nor by a general measure of psychological distress or sociodemographic variables, or reports of childhood sexual abuse.

Studies that have described pelvic pain as medically unexplained or psychosomatic, due to the lack of physical findings, have been discarded. This is because such a distinction is unhelpful and is not informed by our understanding of pain mechanisms (11). When diagnostic investigations are used to assign symptoms to physical and mental origins, with no suggested connection between them, and with interest only in the former type of symptoms, explanations are often experienced by women as scepticism about the reality or severity of the pain (41). This can undermine the therapeutic relationship between the patient and the doctor (42). Ehlert et al. (43) have found that women with pelvic pain with and without laparoscopic findings do not differ from one another; only from pain-free controls, as anticipated by Savidge & Slade (7). Distress, described in the patient's terms or within a psychodiagnostic framework, is best understood in the context of pain and the meaning of pain to the individual (7). In a large primary care study, Zondervan et al. (44) have noted the tendency to attribute pelvic pain without obvious pathology to a psychological cause, and that it is increasingly recognised as unhelpful; depression and anxiety are common in any chronic pain, not pelvic pain alone. They have found that restriction by pain does not distinguish between women who do and do not seek healthcare, and that there may be an anxiety-related cause of the pain in both groups.

8.4.2 ***Psychological assessment of pelvic pain***

Anxiety and post-traumatic stress symptoms are common in some women with CPP (44,45), and may account for substantial variance in health status and treatment use. Negative investigative findings do not necessarily resolve women's anxieties about what might be causing pain (26). Depression may be related to pain in various ways, as described above. Until measures are available that are adequately standardised in patients with pain, anxiety and distress may be best assessed by questions about concerns about the cause of pain, its implications, and its consequences for everyday life (46).

Reference to the studies of the IMMPACT group (24) is recommended for guidance on outcome measures suitable for pain trials.

8.4.3 ***Psychological factors in treatment of persistent pelvic pain***

Untreated, there is a significant rate of symptom improvement. In one study, 25% of patients reported recovery (nearly half with total recovery) over a 3-4-year period, and neither pain nor distress at baseline, nor intervention received, was found to be associated with recovery (40). This recovery rate should be borne in mind when

interpreting results of treatment trials.

There is one Cochrane systematic review and meta-analysis of treatments for pelvic pain, excluding that due to endometriosis, IBS, and chronic PID (47). All treatments were included (although the update protocols split surgical from non-surgical (48), and outcomes were mainly pain scores, QoL, and resource use, including healthcare resources. The 14 treatment trials included counselling, psychoeducation, reassurance, and emotional disclosure, as well as a multicomponent pain management programme. The authors concluded in favour of educational counselling combined with ultrasound scanning, which improved pain and mood; and a multidisciplinary rehabilitative approach including surgery, pharmacotherapy, physiotherapy, and psychosocial intervention, which improved function but not pain. Emotional disclosure (a stress reduction method) through writing brought about a small improvement in some pain scores.

Several other reviews make positive comments on psychological involvement (49), and recommend addressing psychological concerns from the outset rather than after other treatment has failed. Psychological interventions may be directed (1) at the pain itself, with the intended outcome of reducing pain and its consequent impact on life, or (2) at adjustment to pain, with improved mood and function and reduced health care use, with or without pain reduction.

In the first category are relaxation and biofeedback methods of controlling and decreasing pain by reducing muscle tension, and this is applied in mainly uncontrolled trials to pelvic floor retraining both in men and women. The only RCT (50) applied a specific type of cognitively enhanced physical therapy to overall muscle tension, but not to the pelvic floor, combined with normal gynaecological treatment compared with gynaecological treatment alone. Pain was reduced by 50% and motor function improved in various aspects by 10 h of physical therapy, with particular attention to tension and relaxation and to the thoughts and emotions that interfere with balanced posture and movement.

In the second category, multicomponent pain management, involving education, physical retraining, behavioural change, and increasing activity, relaxation and cognitive therapy, is often applied to mixed groups of chronic pain patients, including those with pelvic pain. A systematic review and meta-analysis (51) which shows a good outcome for mixed chronic pain or back pain groups across pain experience, mood, coping, and activity, cannot with confidence be extrapolated to women with pelvic pain alone. The only RCTs in CPP used elements of this approach in combination with medroxyprogesterone acetate (MPA) or placebo (52). Combination of MPA and psychological therapy outperformed other treatment methods in the long term, with nearly three quarters of women reporting > 50% pain relief.

Several single treatments with benefits in other chronic pain or chronic health problems have been tried in pelvic pain. Norman et al. (53) have compared emotional disclosure by writing about pain with writing about positive events as a control. The differences were small but in favour of emotional disclosure on one measure of pain appraisal, particularly in women with more distress at baseline. Given the extent of problems associated with pelvic pain, this intervention on its own is unlikely to produce much change, but could be combined with other components described above.

In a different intervention, Fenton et al. (54) have conducted a small RCT of transcranial direct current stimulation compared to sham stimulation. Pain reduction was greater in the treatment group, in the first week only, as was reduction in disability.

8.5 Conclusions and recommendations: psychological aspects of CPP

Conclusions	LE
There is no evidence that distress generates complaints of pelvic pain, or that multiple symptoms suggest unreality of pain.	2b
Current or recent sexual abuse should be assessed as possible contributory factors in pelvic pain.	2a
Psychological intervention in general can produce benefits in pain, mood, and quality of life, depending on its content and focus.	1a
Psychologically informed physical therapy can improve pain and function.	1b
Combined exercise and cognitive behavioural therapy with medroxyprogesterone acetate can reduce pain in a majority of women with pelvic pain.	1b
Transcranial direct current stimulation may reduce pain in the short term.	1b

Recommendations	GR
Psychological distress is common in pelvic pain in women but should be interpreted in the context of pain.	A
We recommend asking the patient what she thinks may be wrong to cause pain, to allow the opportunity to inform and reassure as appropriate.	B
We recommend trying psychological interventions in combination with medical and surgical treatment, or alone.	A

9. PELVIC FLOOR FUNCTION AND CHRONIC PELVIC PAIN

9.1 Introduction

The pelvic floor is made up of muscles and fascia. The muscles usually function as a composite, although the anterior and posterior components may act in isolation. The pelvic floor has three functions: support, contraction and relaxation.

9.2 Function

In its resting state, the pelvic floor supports the bladder and the urethra in the anterior compartment, the uterus and the vagina in the middle compartment, and the rectum and the anus in the posterior compartment. The integrity of the support function depends on the anatomical position of the muscles, on the resting tone and on the integrity of the fascia. When intra-abdominal pressure rises, the pelvic floor muscles must respond with a contraction occurring simultaneously or before the pressure rise. The latter is termed an anticipatory response or feed-forward loop. Contraction of the pelvic floor muscles results in inward movement of the perineum and upward movement of the pelvic organs. In many situations, other muscles such as the abdominal, adductor and gluteal muscles also contract. There are two types of contraction that can be distinguished: a voluntary contraction, resulting from impulses arising in the cerebral cortex, and a reflex contraction. These contractions not only maintain support of the pelvic organs, they close the urethra, anus and vagina, thus avoiding loss of urine or stools. Contractions also form a defence against introduction of foreign objects into the anus or vagina, and in women, they can protect against sexual penetration. Additionally, detrusor muscle inhibition occurs in parallel with pelvic floor muscle contraction. Pelvic floor muscle contractions play an important role in sexual function. During the arousal phase, pelvic floor muscle contractions are used to increase vasocongestion. During the final phase of the sexual response cycle, a series of involuntary contractions is associated with the physical sensations of orgasm. Pelvic floor muscle relaxation results in a decrease or termination of the squeezing of the urethra, vagina and anus. The perineum and the pelvic organs return to their anatomical resting position. Relaxation of the pelvic floor muscles is needed for voiding, defecation and for sexual intercourse. The muscles of the pelvic floor are integrated in the total muscular girdle of the pelvis, yielding the stability needed for bearing the trunk. Instability in its turn leads to compensatory pelvic floor muscle (over) activity.

9.3 Dysfunction

Pelvic floor dysfunction should be classified according to “The standardisation of terminology of pelvic floor muscle function and dysfunction” (1). This is an international multidisciplinary report from the International Continence Society. By palpation of the pelvic floor muscles, the contraction and relaxation are qualified. Voluntary contraction can be absent, weak, normal or strong, and voluntary relaxation can be absent, partial or complete. Involuntary contraction and relaxation is absent or present.
Based on these signs, pelvic floor muscles can be classified as follows:

- non-contracting pelvic floor
- non-relaxing pelvic floor
- non-contracting, non-relaxing pelvic floor.

Based on symptoms and signs, the following conditions are possible:

- normal pelvic floor muscles

- overactive pelvic floor muscles
- underactive pelvic floor muscles
- non-functioning pelvic floor muscles.

Normal pelvic floor muscles relax during urination and contract during coughing. Overactive pelvic floor muscles do not relax during micturition, defecation or during sex and cause dysfunctional voiding, overactive bladder, constipation and dyspareunia (2). Underactive pelvic floor muscles do not contract sufficiently to keep the patient dry. Non-functioning pelvic floor muscles do not show any activity whatsoever and can cause every type of pelvic organ dysfunction.

Overactivity tends to develop over a protracted period, with many causes. A psychological mechanism that is thought to play a role is that contraction of the pelvic floor muscles closes some of the exits of the body (anus and vagina), and helps to keep urine and stool inside. It gives women a defence mechanism against unwanted vaginal penetration of any type. The pelvic floor muscles also help to postpone micturition, which can be of benefit in a social or working environment. In summary, the pelvic floor muscles assist in adaptation to different situations in life.

9.4 Pelvic floor muscles and myofascial pain

Chronic pelvic pain can simply be a form of myalgia, due to misuse of muscles, in this case, the pelvic floor muscles. Studies in the field of chronic prostatitis support the idea that patients with CPP have more muscle spasm and increased muscle tone and pain when palpating the pelvic floor muscles (3). Muscle relaxation can diminish spasm and pain (4). Repeated or chronic muscular overload can activate trigger points in the muscle. A report from the Chronic Prostatitis Cohort Study showed that 51% of patients with prostatitis and only 7% of controls had any muscle tenderness. Tenderness in the pelvic floor muscles was only found in the CPP group (5).

*9.4.1 **Muscular aspects***

The relationship between muscular dysfunction (especially overactivity) and pelvic pain has been found in several studies. Rectal pain treated with pelvic floor muscle therapy is only relieved when patients learn to relax their pelvic floor muscles (6). The vast majority (92.2%) of men visiting a tertiary centre for pelvic pain had dysfunction of the pelvic floor muscles. This finding was true regardless of evidence of inflammation (prostatitis or cystitis) (7). This relationship has been found in chronic prostatitis (8), BPS (9) and vulvar pain (10). Dysfunction of the pelvic floor directly affects function of the pelvic viscera and vice versa. Both systems can act as the primary signal to the spinal cord, with a cascade of reactions ascending to the central nervous system as a result. The muscle itself ends up with a diminished length, leading to restrictions even when it is in a relaxed state.

*9.4.2 **Neurological aspects***

In 1999, the first ideas about the neurological aspects of the pelvic floor muscles in relation to CPP were published. The probability of central nervous system breakdown in the regulation of pelvic floor function was suggested as a mechanism for development of CPP. Of the patients presenting with pelvic pain, 88% had poor to absent pelvic floor function (11). Basic studies on the role of neurogenic inflammation have also elucidated some important phenomena. Irritation of the prostate, bladder and pelvic floor muscles results in expression of C-fos-positive cells in the CNS. There appears to be convergence of afferent information onto central pathways. Once the central changes have become established, they become independent of the peripheral input that initiated them (12).

*9.4.3 **Myofascial trigger points***

Repeated or chronic muscular overload can activate trigger points in the muscle. Trigger points are defined as hyperirritable spots within a taut band. Other criteria for trigger points are: recognition of the pain as ‘familiar’, and pain on stretching the muscle. Apart from pain, trigger points prevent full lengthening of the muscle, thereby restricting the range of movement. Pain as a result of these trigger points is aggravated by specific movements and alleviated by certain positions. Positions and movements in which the shortened muscle is stretched are painful. Patients know which activities and postures influence pain. Trigger points can be located within the pelvic floor muscles and in adjacent muscles such as the abdominal, gluteal and ileopsoas muscles. Pain is aggravated by pressure on the trigger point (e.g., pain related to sexual intercourse). Pain also worsens after sustained or repeated contractions (e.g., pain related to voiding or defecation).

9.5 Diagnostics of pelvic floor muscle function

Diagnosing pelvic floor muscle function in patients with CPP starts by taking a complete functional history of the pelvic organ function. The following items certainly should be addressed: lower urinary tract function,

anorectal function, sexual function, gynaecological items, presence of pain and psycho-social aspects.

9.5.1 ***Physical examination***

After taking a history, physical examination should be done. Special attention must be paid to the abdominal, inguinal and genital areas, but also to the pelvic alignment. The patient should be asked to point at the location of maximal pain and at the secondary pain points. Palpation of the abdomen with special attention to the muscles may yield pain points that are important for making a treatment plan. A vaginal or rectal examination should be performed to assess the function of the pelvic floor muscles, according to the ICS report. This assessment has been tested and shows satisfactory face validity and intra-observer reliability. It can therefore be considered suitable for use in clinical practice (13). Rectal examination is a good way to test the pelvic floor muscle function in men (14).

9.5.2 ***Electromyography and pressure measurement (EMG)***

Additional examination can be done using electromyography. This is preferably done using an intravaginal or intra-anal probe. This measures the electrical activity of the pelvic floor muscles as a group. It does not reveal anything about the efficacy of the contraction or relaxation. There is good correlation between digital palpation and intravaginal surface EMG (15). To measure the effect pelvic floor muscle contraction, a pressure probe can be used. The measurement of anal pressure is reliable (16), Performance of EMG in different positions gives more insight into the properties of the pelvic floor. EMG is one of the most used input methods for biofeedback. Intraluminal pressure can also be used for this purpose.

9.5.3 ***Imaging***

Anatomical imaging of the pelvic floor muscles can be done using MRI. It is still debatable whether MRI can be of help in diagnosing pudendal entrapment. Functional imaging can be done using techniques such as video-urodynamics (pelvic floor muscles in relation to bladder function) or defecography (pelvic floor muscles in relation to defecation). The reason for this is to exclude disease-specific pain. Repeated imaging studies may be detrimental for the patient because they emphasise somatic causes of the pain.

9.5.4 ***Myofascial trigger points***

There is no accepted reference standard for the diagnosis of trigger points. Data on the reliability of physical examination are conflicting. Reliability is relatively good for tenderness and for recognisable referred pain. It is lower for taut band recognition and local twitch response. The reliability improves when examination is done by experts, who are specially trained in diagnosing trigger points. Other techniques are used for diagnosing trigger points but none has become a standard.Among these are imaging techniques and EMG (17).

In a cohort study of 72 men with CPP, the relationship between the locations of the trigger point and the referred pain was examined. Ninety percent of the patients showed tenderness in the puborectalis muscle and 55% in the abdominal wall muscles. Of the patients in whom trigger points were found in the puborectalis, 93% reported pain in the penis and 57% in the suprapubic region. Patients with trigger points in the abdominal muscles reported pain in the penis (74%), perineum (65%) and rectum (46%) (18).

9.6 Treatment of pelvic floor muscle pain

Treating pelvic floor overactivity and myofascial trigger points should be considered in the management of CPP. Treatment should be done by specialised physiotherapists who are trained not only in the musculoskeletal aspects of pain, but also in the psychological mechanisms and the role of the CNS in chronic pain.

9.6.1 ***Pelvic floor muscle exercise***

For patients with CPP and dysfunction of the pelvic floor muscles, it is very helpful to learn how to relax the muscles when the pain starts. By doing this, the circle of pain-spasm-pain can be interrupted. In the case of shortened muscles, relaxation alone is not enough. Stretching of the muscle is mandatory to regain length and function. Studies on physical therapy for pelvic floor pain syndrome have been sparse. A single blinded RCT with myofascial physical therapy and general massage was carried out in patients with prostate or bladder pain. The global response rate to treatment with massage was significantly better in the prostate than in the bladder pain group (57% vs. 21%). In the prostate pain group, there was no difference between the two treatment arms. In the bladder pain group, myofascial treatment did significantly better than the massage. Massage only improved complaints in the prostate pain group. The fact that the prostate pain group consisted of only men is mentioned as a possible confounding factor (19).

9.6.2 ***Biofeedback and electrostimulation***

Biofeedback can be helpful in the treatment of pelvic floor pain in the process of recognising the action of

the muscles. Visualising the action of the pelvic floor muscles by using biofeedback is an eye opener to many patients. Biofeedback should always be used in consultation with the patient. Special care should be taken when there is a history of negative physical or sexual experiences. The numbers of patients in most studies concerning biofeedback have been small but the results are promising. In a cohort study, 31 patients with CPP syndrome participating in a pelvic floor biofeedback re-education programme were followed. The mean chronic prostatitis symptom index decreased from 23.6 to 11.4. They also measured the pelvic floor muscle activity by EMG using an anal probe. The resting amplitude was taken as a parameter for the ability to relax the pelvic floor muscles. This parameter was 4.9 μV at the start and 1.7 μV at the end of the treatment, so the relaxation improved markedly. There was also a correlation between the decline in EMG values and improvement in prostatitis symptom score (20).

In a study among patients with levator ani syndrome, biofeedback was found to be the most effective therapy. Other modalities used were electrostimulation and massage. Adequate relief was reported by 87% in the biofeedback group, 45% for electrostimulation, and 22% for massage (6). A review on biofeedback in pelvic floor dysfunction has shown that biofeedback is better than placebo or sham treatment. An odds ratio of 5.8 favouring biofeedback has been calculated based on three studies (21).

*9.6.3 **Myofascial trigger point release***

The treatment of myofascial trigger points has different options. There are three groups of treatment: (1) manual therapy: pressure and release, compression, spray and stretch; (2) dry needling: putting a solid filiform needle directly in the trigger point, repeatedly and in an up and down pecking motion; and (3) wet needling: injection of lidocaine or botulinum toxin into the trigger point. The evidence for all the different treatments is weak. In most studies, no significant difference between these techniques has been found. One problem is that most of the studies were small and heterogeneous with regard to the patients and methods. This is especially true for comparing any technique with sham or placebo treatment. For manual therapy, central trigger points are treated by stretching the muscle because this inactivates it. Trigger points lying in the attachment of the muscle to the bone are treated using direct manual therapy. Other well-known techniques such as biofeedback and neuromuscular stimulation have been used in the treatment of trigger points. There is no evidence that manual techniques are more effective than no treatment (22). In most studies of dry needling, it has been compared with wet needling. Different systematic reviews have come to the conclusion that, although there is an effect of needling on pain, it is neither supported nor refuted that this effect is better than placebo (23). Other reviews have concluded that the same is true for the difference between dry and wet needling (24,25).

*9.6.4 **Botulinum A toxin***

Botulinum A toxin (BTX-A) is an inhibitor of acetylcholine release at the neuromuscular junction and has a paralysing effect on striated muscles. BTX-A has been injected into trigger points. It is more expensive than lidocaine and has not been proven to be more effective (26). Reviews do not support the injection of BTX-A into trigger points (27).

Pelvic floor muscle overactivity plays a role in CPP. BTX-A, as a muscle relaxant, can be used to reduce the resting pressure in the pelvic floor muscles. In women with high resting pressure in the pelvic floor muscles, it has been found that BTX-A lowers this pressure significantly. The magnitude of reduction was significantly higher than that in the placebo group. On the pain score (VAS), no intergroup differences were found in this relatively small randomised study (28). BTX-A can also be injected at the sphincter level to improve urination or defecation. Relaxation of the urethral sphincter alleviates the bladder problems and secondarily the spasm. In a cohort study of 13 patients with CPP, BTX-A was injected into the external urethral sphincter. Subjectively, 11 patients reported a substantial change in pain symptoms, from 7.2 to 1.6 on a visual analogue scale (29).

*9.6.5 **Pain management***

The physiotherapist is part of the pain management team, together with the pain doctor and the psychologist. The therapeutic options for physiotherapists may not be the same in every country. Physiotherapists can either specifically treat the pathology of the pelvic floor muscles, or more generally treat myofascial pain if it is part of the pelvic pain syndrome.

9.7 Conclusions and recommendations: pelvic floor function

Conclusions	**LE**
The ICS classification is suitable for clinical practice.	2a
Overactivity of the pelvic floor muscles is related to chronic pelvic pain, prostate, bladder and vulvar pain.	2a

The overactivity of the pelvic floor muscles is an input to the central nervous system causing central sensitisation.	2b
There is no accepted standard for diagnosing myofascial trigger points.	2a
There is a relation between the location of trigger point and the region where the pain is perceived.	3
Myofascial treatment is effective in prostate- and bladder pain syndrome.	1b
Biofeedback improves the outcome of myofascial therapy for pelvic floor dysfunction.	1a
Trigger point release is effective in treating muscle and referred pain, but there is no preference from one method over another.	1a

Recommendations	**GR**
We recommend the use of the ICS classification on pelvic floor muscle function and dysfunction.	A
In patients with chronic pelvic pain syndrome we suggest to actively look for the presence of myofascial trigger points.	B
In patients with chronic pelvic pain syndrome we suggest to apply pelvic floor muscle treatment as first line treatment.	B
In patients with an overactive pelvic floor we recommend biofeedback as therapy adjuvant to muscle exercises.	A
When myofascial trigger points are found we recommend treatment by pressure or needling.	A

10. GENERAL TREATMENT OF CHRONIC PELVIC PAIN

10.1 Introduction

Chronic pelvic pain (CPP) is well defined and involves multiple mechanisms as described in previous chapters. The management requires a holistic approach with biological, psychological and social components. This chapter looks solely at general treatments and should be used as part of a management plan including the interventions suggested in the specific chapters above.

Despite the developments in basic science, there has not been the same in pharmacological intervention. It is recognised that there are often central mechanisms involved in CPP. This chapter looks at general treatments for pain (both peripheral and central) and not the specific treatments mentioned in the chapters 2 and 6.

Despite the frequency of CPP, relatively few studies have specifically looked at the medications used in CPP patients (1). As a result, a wider look at the literature has been undertaken, including the agents used for central and neuropathic pain. Further specific research is required in this group of patients.

The agents concerned are divided for ease of description. Combinations often provide a greater benefit than individual agents. They may also allow lower dosages of each agent and thus minimise the side effects.

The aim of using these drugs is to allow patients to improve their QoL. This is best measured by assessing their function as well as pain severity. If the addition of these agents does not allow this, then they should be withdrawn. Unfortunately, the failure of one agent to provide benefit does not mean that there is an alternative. If the benefit is limited by side effects, then the lowest effective dose should be found (by dose titration). In some circumstances, patients can tolerate a higher level of pain and have fewer side effects.

If the use of simple analgesics fails to provide adequate benefit, then one should consider using the neuropathic agents, and if there is no improvement, consider involving a specialist pain management centre with an interest in pelvic pain.

10.2 Simple analgesics

Paracetamol (acetaminophen)

Paracetamol is a well-tolerated analgesic in a class of its own. This is an antipyretic analgesic with a central mechanism of action(2). It is often available over the counter without prescription. There is evidence that paracetamol is beneficial in managing somatic and arthritic pain. (3-5). There is little evidence for its use in CPP but it should be considered if it has not already been tried.

Non-steroidal anti-inflammatory agents (NSAIDs)

This is a group of agents that include salicylic acid. They have had significant publicity over recent years. They are anti-inflammatory, antipyretic analgesics that act by inhibiting the enzyme cyclo-oxygenase (COX). They have a peripheral effect, hence their use in painful conditions involving peripheral or inflammatory mechanisms.

They are commonly used for pelvic pain because many are available over the counter and are usually well

tolerated. The evidence for their benefit is often weak or non-existent. It should be remembered that they do have side effects, which may be significant. There is no good evidence to suggest one NSAID over another for pelvic pain.

For pelvic pain in which inflammatory processes are considered to be involved, such as dysmenorrhoea (6), NSAIDs are more effective than placebo and paracetamol, but with a higher incidence of side effects. For pelvic pain in which central mechanisms may be incriminated, such as endometriosis (7), then the evidence is lacking for NSAIDs despite their common use.

Guidelines for use of NSAIDs and COX-2 selective agents have been developed. They have more side effects than paracetamol, including indigestion, headaches and drowsiness.

At a practical level, NSAIDs could be considered as analgesics for patients with pelvic pain. They should be tried (having regard for the cautions and contraindications for use) and the patient reviewed for improvement in function as well as analgesia. If this is not achieved, or there are side effects, then the NSAID should be stopped.

Neuropathic analgesics
This is a group of agents that are not simple analgesics but are used to modulate neuropathic or centrally mediated pain. There are several classes used with a recognised benefit in pain medicine. They are taken on a regular basis rather than as required. They all have side effects that limit their use in some patients.

In the UK, the National Institute for Health and Clinical Excellence (NICE) has reviewed the pharmacological management of neuropathic pain (8). There is further guidance in progress for the management of neuropathic pain in the non-specialist setting.

Not all the agents have a licence for use in pain management but there is a history and evidence to demonstrate their benefit. The evidence for treatment of CPP is lacking but is present for other painful conditions. For this chapter, most of the evidence is from non-pelvic pain sources.

The general method for using these agents is by titrating the dose against benefit and side effects. The aim is for patients to have an improvement in their QoL, and is often best assessed by alterations in their function. Side effects frequently limit the use of these agents.

It is common to use these agents in combinations but studies comparing different agents against each other or in combination are lacking.

*10.2.1 **Antidepressants***

10.2.1.1 Tricyclic antidepressants

This is a group of drugs with multiple mechanisms of action. They have a long history of use in pain medicine and have been subjected to a Cochrane review (9). This suggests that they are effective for neuropathic pain with numbers needed to treat (NNT) of approximately three.

Amitriptyline is the most commonly used member of this group at doses from 10 to 75 mg/day (sometimes rising to 150 mg/day). This is titrated against benefit or side effects and taken at night (8). Nortriptyline and imipramine are often used as alternatives.

10.2.1.2 Other antidepressants

Venlafaxine is a serotonin and noradrenalin reuptake inhibiter (SNRI). It does not have a license for managing neuropathic pain but there is evidence of its benefit in chronic pain (8). There are cautions particularly in patients with heart disease. This is a drug best used by those familiar with its use.

Duloxetine is a newer SNRI antidepressant. It is used for depression, urinary stress incontinence and neuropathic pain. There is moderately strong evidence for a benefit in diabetic neuropathy and fibromyalgia at a dose of 60 mg/day (10). Side effects are common and may result in its discontinuation.

Selective serotonin reuptake inhibitors (SSRIs) are antidepressants with fewer side effects. They are effective for depression but there have been insufficient studies to demonstrate their benefit in pelvic or neuropathic pain (9,11,12).

10.2.2 ***Anticonvulsants***

This group of drugs are commonly used in the management of neuropathic pain. There have been general studies as well as some looking more particularly at pelvic pain. Individual agents have been systematically reviewed. Their use is suggested in the NICE Neuropathic Guidelines (8).

Carbamazepine has a long history of use in neuropathic pain. Evidence exists for its benefit (13). It should be remembered that the trials have tended to be of short duration, showing only moderate benefit. There are side effects; some of which may be serious. With more recently developed agents becoming available, with fewer serious side effects, carbamazepine is no longer a first-choice agent.
Gabapentin is commonly used for neuropathic pain and has been systematically reviewed (14). It provides good quality relief with NNT of approximately six. This is a more conservative estimate than in previous reports. Side effects are common, notably drowsiness, dizziness and peripheral oedema. These effects do limit compliance but are often tolerated by patients. The doses involved were all greater than 1.2 g/day. For upper dose levels, reference should be made to local formularies, and many clinicians do not routinely exceed 2.4g/day in divided doses (most commonly three times daily).
One study of women with CPP has suggested that gabapentin alone or in combination with amitriptyline provides better analgesia then amitriptyline alone (15).

Pregabalin is another commonly used neuromodulator. There is good evidence for its efficacy in some neuropathic conditions but the NNT varies depending on the condition (16). The dose for benefit is in the range of 300 to 600 mg/day. The same systematic review has found that doses less than 150 mg/day are unlikely to provide benefit. As with gabapentin, side effects are relatively common and may not be tolerated by patients.

Other anticonvulsants are available but not commonly used for managing pain.

10.2.3 ***Other agents***

Other agents can be used in the management of neuropathic pain but are best limited to those that are specialists in the management of pain and familiar with their use. They tend to be considered after the standard options have been exhausted. As with all good pain management, they are used as part of a comprehensive management plan.

Topical capsaicin has been used for neuropathic pain either by repeated low-dose (0.075%) administration or more recently as a single high dose (8%). Topical application (usually to an area of hyperaesthesia or allodynia) is more inconvenient than for other medications, and capsaicin does cause initial heat on application. Skin sensitivity is a limiting factor and may not be well tolerated. A systematic review has suggested there may be benefit in some patients (17). Care should be taken to ensure that unused cream or that washed off the hands following application is not inadvertently transferred to other areas of skin or mucous membranes.

Antipsychotics have been used and despite limited research, a systematic review has suggested that further research should be undertaken on the atypical antipsychotics, which have fewer side effects and are better tolerated than the older antipsychotics (18).

10.3 Opioids

Opioids are used for chronic non-malignant pain and may be beneficial for a small number of patients. Often patients will stop taking oral opioids due to side effects or insufficient analgesia(19).

They should only be used in conjunction with a management plan and with consultation between clinicians experienced in their use. It is suggested that a pain management unit should be involved along with the patient and their primary care physician.

There are well established guidelines for the use of opioids in pain management as well as considering the potential risks (20). There is also information available on line for patients (21,22).

Opioid rotation is used in palliative care and to some extent in non-cancer pain. The evidence is clinical, largely anecdotal, or from small trials and is not convincing (23). The rational is that if a patient has significant side effects and inadequate analgesia to one opioid then swapping to another agent may be better tolerated.

There are several agents available in the group. They can be divided into weak (e.g., codeine, dihydrocodeine and tramadol) or strong opioids (e.g., morphine, oxycodone, fentanyl and hydromorphone).

Oral administration is preferable, but if poorly tolerated, a percutaneous (patch) route may have advantages. More invasive approaches are less commonly used and within the realms of specialist units.
Side effects are common and require active management. This is particularly true of constipation with some interesting developments on methods for managing it.

There is a growing understanding of opioid-induced hyperalgesia (24); a situation in which patients taking opioids, paradoxically, become more sensitive to painful stimuli. This is another reason for these drugs to be used in a controlled fashion for long-term management of non-malignant pain.

*10.4.1 **Recommendations for use of opioids in chronic/non-acute urogenital pain***

Recommendations
All other reasonable treatments must have been tried and failed.
The decision to instigate long-term opioid therapy should be made by an appropriately trained specialist in consultation with another physician (including the patients and their family doctor).
Where there is a history or suspicion of drug abuse, a psychiatrist or psychologist with an interest in pain management and drug addiction should be involved.
The patient should undergo a trial of opioids.
The dose required needs to be calculated by careful titration.
The patient should be made aware (and possibly give written consent): • That opioids are strong drugs and associated with addiction and dependency. • Opioids will normally only be prescribed from one source (preferably the family doctor). • The drugs will be prescribed for fixed periods of time and a new prescription will not be available until the end of that period. • The patient may be subjected to spot urine and possibly blood checks to ensure that the drug is being taken as prescribed, and that non-prescribed drugs are not being taken. • Inappropriate aggressive behaviour associated with demanding the drug will not be accepted. • Hospital specialist review will normally occur at least once a year. • The patient may be requested to attend a psychiatric/psychological review. Failure to comply with the above may result in the patient being referred to a drug dependency agency and the use of therapeutic, analgesic opioids being stopped.
Morphine is the first-line drug, unless there are contraindications to morphine or special indications for another drug. • The drug should be prescribed in a slow-release/modified release form. • Short-acting preparations are undesirable and should be avoided where possible. • Parenteral dosing is undesirable and should be avoided where possible.

*10.4.2 **Morphine***

There is no compelling evidence that one opioid is better than another. Morphine is the traditional gold standard and the opioid with which many physicians are most familiar. The aim is to use a slow or sustained release preparation starting with a low dose and titrating the dose every 3 days to 1 week against improvement in both function and pain. Side effects should also be monitored and managed accordingly. Particular attention should be paid to the management of constipation.

*10.4.3 **Other opioid agents***

There are a variety of agents available and some are mentioned below, giving an idea of the options available.

Transdermal fentanyl may be considered when oral preparations are restricted (e.g., iliostomy). It may also be beneficial when there are intolerable side effects from other opioids.

Methadone has a long record of use as an opioid. There is a theoretical advantage of benefit with its N-methyl-D-aspartate receptor (NMDA) antagonist activity. This may be particularly relevant in neuropathic pain (25).

Oxycodone may have greater efficacy than morphine in some situations, such as hyperalgesic states including visceral pain (26).

Analgesics with a dual mode of action may have a role in the management of chronic pain. Tramadol is an established analgesic with dual effects on opioid receptors and serotonin release. More recently, a new agent,

tapentadol, has been released with opioid action and noradrenalin reuptake inhibition. It is too early to assess its real value in the armamentarium for pain management.

10.5 Nerve blocks

Nerve blocks for pain management are usually carried out by specialists in pain medicine and as part of a broader management plan (27). They may have a diagnostic or therapeutic role.

Textbooks have been written on the subject and practioners using them should be trained in appropriate patient selection, indications, risks and benefits. Many such interventions also require understanding and expertise in using imaging techniques to perform the blocks accurately.

Diagnostic blocks can be difficult to interpret due to the complex nature of the mechanisms underlying the painful condition or syndrome. Sustained but limited benefit may lead to more permanent procedures (e.g., neurolytic block or radiofrequency procedures). Neurolytic blocks in particular should only be considered by practioners experienced in their use and with the full understanding of the patient because complications can be disastrous.

There is a weak evidence base for these interventions for chronic non-malignant pain.

10.6 Transcutaneous electrical nerve stimulation (TENS)

Despite the popularity of TENS and the number of trials undertaken, a systematic review has been unable to provide an evidence base for this technique (28). It is clear that further more rigorous trials should be undertaken to provide some clarity for a commonly used intervention.

10.7 Neuromodulation in pelvic pain syndromes

The role of neuromodulation in the management of pelvic pain should only be considered by specialists in pelvic pain management. These techniques are only used as part of a broader management plan and require regular follow-up.

The research base is developing and the techniques broadening [e.g., spinal cord stimulation (SCS), sacral root stimulation, dorsal root ganglion stimulation or peripheral nerve stimulation]. These are expensive interventions and thus many of the patients involved are refractory to other therapies. It is thus inappropriate to provide a detailed review of these techniques for this publication.

In the UK, guidance has been published for SCS in neuropathic pain (29). This emphasises the comments above. This guidance suggests a trial period of stimulation before full implementation.

Neuromodulation is still finding its role in pelvic pain management. There has been growing evidence in small case series or pilot studies but more detailed research is required (30). Its role in overactive bladder and faecal incontinence is more robust but is limited for pain.

10.8 Summary

CPP is a common complaint that is well defined and involves multiple mechanisms. Some of the conditions have clear management pathways but many do not. In these CPP syndromes, a holistic multidisciplinary team approach is required with active patient involvement.

This chapter focuses on general treatment of CPP, mainly drug therapy, and comments on other more invasive techniques. The latter are used in combination with other modalities. Many are aimed at management of neuropathic pain or conditions in which central mechanisms are implicated.

At this stage in management, the involvement of trained clinicians with expertise in chronic pain management should be considered. Centres with a particular interest in pelvic pain do exist and involve clinicians from several specialties along with other health care professionals (e.g., physiotherapy, psychology, nursing and occupational therapy).

With any of the agents above, the aim is to assess pain relief, improvement in function, and side effects. This should be done regularly while titrating and optimising drug dose. If there is no benefit, then the drug should be withdrawn.

Neuropathic agents are frequently used and often in combination. There is significant inter-patient variability in

effect. Use is often limited by side effects that may be worse than any pain reduction.

Opioid drugs are used in this group of patients. Their role is limited and they should only be started in consultation with all parties involved (including the patient's family practitioner). National guidelines exist and should be followed. There is growing understanding of the limitations of opioid use, and more recently, the paradoxical situation of opioid-induced hyperalgesia.

10.9 Recommendations for the medical treatment of CPP

Agent	Pain Type	LE	GR	Comment
Paracetamol	Somatic pain	1a	A	Evidence based on arthritic pain with good benefit
NSAIDs	Pelvic pain with inflammatory process (e.g. dysmenorrhoea)	1a	A	Good evidence for their use
	Central mechanisms (e.g. endometriosis)	1a	A	No good evidence for their use
Antidepressants including tricyclic antidepressants, venlafaxine and duloxetine	Neuropathic pain	1a	A	Effective. No specific evidence for CPP.
Anticonvulsants gabapentin, pregabalin	Neuropathic pain, fibromyalgia	1a	A	Effective
Gabapentin	Women with CPP	2b	B	Effective
Topical capsaicin	Neuropathic pain	1a	A	Some evidence of benefit
Opioids	Chronic non-malignant pain	1a	A	Beneficial in a small number of patients
Nerve blocks		3	C	Have a role as part of a broad management plan
TENS		1a	A	No good evidence of benefit
Neuromodulation	Pelvic pain	3	C	Role developing with increasing research.

11. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

AMPA	amino-methylene-phosphonic acid
ATP	Adenosinetriphosphate
BCG	Bacillus Calmette Guérin
BDNF	brain-derived neurotrophic factor
BPS	bladder pain syndrome
BTX-A	Botulinum toxin A
CBT	cognitive behavioural therapy
CFS	chronic fatigue syndrome
CHRP	calcitonin gene-related peptide
CI	confidence interval
CNS	central nervous system
CPP	chronic pelvic pain
CPPS	chronic pelvic pain syndrome
CRH	corticotrophin-releasing hormone
CyA	Cyclosporin A
DMSO	Dimethyl sulphoxide
DNIC	diffuse noxious inhibitory control
DRG	dorsal root ganglion
EH	excisional haemorrhoidectomy
ESSIC	European Society for the Study of BPS
FM	fibromyalgia
FSS	functional somatic syndrome
GAG	glycosaminoglycan
HBO	Hyperbaric oxygen
HIF	hypoxia inducible factor
IASP	Association for the Study of Pain
IBS	irritable bowel syndrome
ICDB	Interstitial Cystitis Data Base
ICSI	Interstitial Cystitis Symptom Index
IPPS	International Prostate Symptom Score
ISSVD	Society for the Study of Vulvovaginal Disease
LUTS	lower urinary tract symptoms
MAPP	Multi-disciplinary Approach to the study of chronic Pelvic Pain research
MPA	medroxyprogesterone acetate
MRI	magnetic resonance imaging
NBS	non-bladder syndromes
NGF	nerve growth factor
NIDDK	National Institute of Diabetes and Digestive and Kidney Diseases
NIH	National Institutes of Health
NIH-CPSI	NIH Prostatitis Symptom Index
NMDA	N-methyl-D-aspartate
NO	nitric oxide
PAG	periaqueductal grey
PID	pelvic inflammatory disease
PNS	pudendal nerve stimulation
PNS	peripheral nervous system
PPMT	pre-post-massage test
PPS	prostate pain syndrome
QoL	quality of life
RBL	rubber band ligation
RCT	randomised controlled trial
RTX	Resiniferatoxin
RUR	transurethral resection
TUNA	transurethral needle ablation
VAPS	visual analogue pain scale

Conflict of interest

All members of the Chronic Pelvic Pain Guidelines panel have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on Renal Transplantation

TABLE OF CONTENTS PAGE

1. INTRODUCTION

Most renal transplantation centres in Europe were founded by urologists. However, many of them are becoming part of transplant centres run by general transplant surgeons. This is the main reason why it is important to present current knowledge about renal transplantation in these European Association of Urology (EAU) guidelines.

As renal transplantation is very much an interdisciplinary field, the Guidelines Group contains not only urologists but also an immunologist (Prof. Dr. Süsal) and a nephrologist (Prof. Dr. Budde). Besides medical and technical aspects, the Guidelines Group has also considered ethical, social, and political aspects. This was necessary because of the still-increasing gap between 'supply' and 'demand' for kidney transplants, and the large differences in organ donation rates between European countries, suggesting European countries can learn from each other on how to increase organ donation rates.

Methodology

There are few prospective randomised studies for most sections of the Guidelines, and sometimes none. Thus, the grades of recommendation, which are evidence-based, seldom exceed grade C (see Table 2). Instead, the Guidelines are well supported by a wealth of clinical experience based on several decades of work in renal transplantation, as in, for example, technical aspects of transplantation and explantation.

A level of evidence (LE) and/or grade of recommendation (GR) have been assigned where possible (1). The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given.

Publication:

The EAU Guidelines on Renal Transplantation were first published in 2003, with a partial update in 2004 followed by this full text update in 2009. Additionally, a quick reference guide is available. All texts can be viewed and downloaded for personal use at the society website: http://www.uroweb.org/guidelines/online-guidelines/.

Levels of evidence and grade of guideline recommendations*

Table 1: Level of evidence

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

Table 2: Grade of recommendation

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**modified from Sackett et al. (1)*

2. KIDNEY DONATION

2.1 Ethical issues in transplantation

*2.1.1 **Primary ethical principles***

A number of primary principles are widely accepted as forming the bedrock of medical ethics (1-3). Conflict in an individual case often arises in trying to adhere to all these principles at the same time.

2.1.1.1 Beneficence: doing good, avoiding harm, autonomy, fairness

A central tenet of medical ethics is the obligation to strive at all times to do good for the patient. Although no physical good will accrue to a donor, it is generally accepted that the psychosocial benefits to the living donor justify the risks involved (4).

Making sure that there is an appropriate balance between benefit and harm is an important clinical judgment. A high standard of donor assessment and risk limitation is therefore of paramount importance before living kidney donation can take place (5).

Individuals are said to have 'decision-making capacity' if they can understand relevant information, consider its implications, and come to a communicable decision. A donor's decision to donate should be respected.

The principle of justice is very important in kidney distribution, where demand far outstrips supply. This means there must be a ranking system for allocating organs in an order of priority that can be morally justified. In transplantation, scarce resources usually have to be carefully allocated to recipients chosen from a larger pool of the population.

*2.1.2 **Deceased donor organ donation***

There has been an increase in living-donor organ procurement in recent years. Most organs still come from deceased donors, brain-dead donors, and from the non-heart-beating donor (NHBD) procurement programme, which is now used by several transplant centres. However, this resource base is shrinking. Together with an ever-increasing rise in potential recipients, this causes considerable pressure on the transplantation programme.

2.1.2.1 Deceased organ donor

In most countries, obtaining consent to proceed with organ donation is a major challenge. The process of gaining formal consent from relatives or from the patient during life can be defined as 'opting in' to a donor scheme. Unless consent is expressly given, the presumption is that consent is withheld. In some European countries, the opposite situation applies. Consent is presumed unless the patient has specifically opted out before death. This type of legislation can increase organ donation. For example, in Spain, this approach has produced a national network of medical teams dedicated to obtaining the maximum number of donors and greatly increasing organ transplantation (6).

2.1.2.2 Allocation of deceased donor organs

Who 'owns' deceased donor organs and who makes the decision regarding allocation are both issues needing clarification (7-9). However, there is a general presumption that the State holds the responsibility for allocation or disposal of donated organs, which is then delegated to the appropriate transplant team (10). It is considered unacceptable that deceased donor donation and allocation should depend upon the personal attributes of the recipient, e.g. race, religion or wealth. In kidney transplantation, the European healthcare systems attempt to maximise benefits by distributing kidneys on the basis of HLA matching. Potential recipients are allocated points for waiting time, matchability and sensitisation. Kidney distribution systems should be transparent and regularly audited.

*2.1.3 **Living-organ donors***

The ethical approach to organ donation is guided mainly by those rules that seek to be charitable. Living-donor transplant has been regarded as a regrettable necessity because of the success of living-donor transplant (as judged by graft and patient survival) and the scarcity of deceased donor organs (11). The chronic shortage of deceased donor organs has led to a more general acceptance of living-donor transplants. The physical and psychosocial well-being of the donor are of primary importance. Each donor should have an advocate (i.e. a psychiatrist and nephrologist from the donor evaluation team) to provide unbiased advice on the donation process and there should be separation of the recipient and donor teams.

Kidneys can be accepted from related and unrelated donors, including spouses, friends and acquaintances, or altruistic donors (anonymous donors) or paired kidney donation (see Section 2.3.3.1). The donor must be given a psychosocial evaluation by a mental health professional, who has no relationship with the recipient, to assess

the donor's ability to make the decision. The donor's confidentiality must be protected and the evaluation must be carried out in the absence of the recipient. If a translator is necessary, the translator must be unknown to both the recipient and donor. The donor should be told about the benefits to the recipient's health (physical and mental) and the risks to the donor's health (physical and mental).

The donor's motivation should be assessed. Coercion and secondary gain (monetary or other personal gain) should be excluded. Outcomes should be discussed: psychological benefits after a successful transplantation (increased self-esteem), and resentment or depression after an unsuccessful transplantation.

Recommendations
It is the right of individuals to donate as well as to receive an organ.
Commercially motivated renal transplantation is unacceptable. It has been widely prohibited by law and is strongly opposed by the International Society of Transplantation.
With the increasing success of living-donor transplants, as judged by graft and patient survival, and with the scarcity of deceased donor organs, living-donor transplants should be encouraged. The appeal of using living donors in renal transplantation is partly due to the ongoing shortage of deceased donors.
The altruistic living donor must give informed consent, which can only be obtained if he or she has a proper understanding of the risks involved.
A patient should be treated as an 'end', and not as a 'means'. Respect for dignity, integrity and authenticity of the person are basic human rights.
Living unrelated donors should only be accepted after the local ethical committee has given permission according to the rules of the country in which the donation is taking place.

Because ethical values cannot be measured using the 'scientific' basis of levels of evidence, grades of recommendation are not given.

2.2 Policies to increase the supply and use of deceased donors

Generally, the gap between the supply and demand of kidneys has tended to stabilise in countries with a donation rate greater than 40 kidneys per million population (pmp), but has increased in countries with a lower donation rate. This is in spite of the trend for donation rates to increase (or stabilise) in Europe since 2001. Table 3 lists recent kidney transplant rates in different European countries (1).

Table 3: Kidney transplant rates in 2010 (1)

Country	Deceased donor kidneys (pmp)	Living-donor kidney (pmp)	Total kidneys (pmp)
Austria (ET)*	38.1	6.9	45
Belgium (ET)* (2008)	38.6	4.2	42.8
Bulgaria	5.14	1.71	6.85
Croatia (ET)*	49.8	4.51	54.31
Cyprus (2008)	34	49	83
Czech Republic	31.1	1.6	32.7
Denmark (ST)**	23	18.1	41.1
Estonia	26.1	3	29.1
Finland (ST)**	30.7	2.06	32.76
France (2007)	42.03	3.5	45.8
Georgia (2008)	0	1.5	1.5
Germany (ET)*	27.8	8.1	35.9
Greece (2009)	10.6	3.0	13.0
Hungary	26.4	4.19	30.59
Iceland (ST)**	No data	15.74	15.74
Ireland (2007)	32.6	1.2	33.8
Italy	25.1	3	28.1
Latvia	27.8	0.9	28.7
Lithuania	19.1	2.4	21.5
Luxembourg (ET)*	12.05	No data	12.05
Malta (2009)	15	12.5	27.5
Moldova (2007)	0	0.6	0.6
Netherlands (ET)*	22.7	28.5	51.2
Norway (ST)**	36.9	16.9	53.8
Poland	24.85	1.3	26.15
Portugal	49.1	4.8	53.9
Romania	5.68	4	9.68
Slovak Republic (08)	27.4	3.6	31
Slovenia (ET)*	30.5	0	30.5
Spain (2009)	45.2	5	48.2
Sweden (ST)**	21.6	17.9	39.5
Switzerland	23.1	14.7	37.8
Ukraine (2009)	0.5	1.9	2.4
United Kingdom	23	16.6	39.6

pmp = per million population.
* ET = Country member of the Eurotransplant.
** ST = Country member of the Scandia Transplant.

The data suggest that a donation rate of 40 pmp per year should be achievable by any single country in Europe, especially with so many sociocultural similarities. However, the act of donation is complex, depending on many factors and interactions, few of which have been proven useful individually or are generally applicable throughout the European Union. Although it is relatively easy to set a minimum standard for organ donation, it is more difficult to recommend specific, donor-promoting activities for individual countries and professional organisations. However, a few options are described below.

*2.2.1 **Donor cards***

Some countries such as the UK require donors to ‘opt in’. Others, such as Belgium and Denmark, ‘presume consent‘ and allow individuals who do not want to be donors to ‘opt out’.

Many countries have publicity schemes encouraging the general population to carry donor cards or register their wish to donate (opting-in) on a computerised donor register. This helps to reduce the risk of donation being refused by the family. In the UK, 15.1 million individuals are registered on the ‘opting in’ computer, while 5-10% of the population prefer to carry donor cards (2). However, the efficiency of this ‘opt-in’ system in creating donors is lower than in countries with a presumed consent. Opt-in systems require continuous publicity to increase the number of opted-in donors and transplant centres. Intensive

care physicians and transplant co-ordinators also need to access the register routinely to identify potential deceased donors.

Recommendation	GR
In all countries without presumed consent law, efforts should be increased to recruit donors through an opting-in register or by carrying donor cards.	C

*2.2.2 **Improved organisation and resources***

Services must be better organised and resourced to increase deceased donor donation. The ability to achieve more than 25 donors pmp increases with the number of intensive care beds. High-donating countries with better-resourced intensive care units (e.g. Spain, France, Belgium) have increased the number of staff responsible for donation (transplant coordinators) and given them proper financial support. Successful education programmes, such as European Donor Hospital Education Programme (EDHEP) (3) or institutional audits, such as Donor Action, have increased and maintained the awareness of intensive care physicians for the need for deceased donor donation and supported them in approaching donor families to discuss donation. Transplant coordinators are responsible for liaising with coroners and public relations, particularly avoiding adverse publicity.

Recommendation	GR
Professional organisations within countries should, where necessary, put pressure on government health departments to maintain enough intensive care beds, create a cadre of national transplant coordinators, and fund and deploy educational programmes for intensive care physicians.	C

*2.2.3 **'Opting-out' legislation***

The introduction of opting-out legislation results in increased rates of deceased donor donation. All European countries with more than 30 kidney donors pmp per annum (see Table 3) have opting-out legislation. Adverse publicity results in a 'soft' presumed consent in most countries, which also takes the family's views into account. Countries with informed consent do not usually perform as well, with the USA producing the highest kidney donation rate of 24 donors pmp through the United Network for Organ Sharing/The Organ Procurement and Transplantation Network (UNOS/OPT) (4,5).

Recommendation
A recommendation cannot be made about something as fundamental as changing the law on deceased donor donation. However, presumed consent with an opting-out law is desirable.

*2.2.4 **Non-heart-beating donor (NHBD)***

Non-heart-beating donors provide an important opportunity to decrease the deceased donor shortage of kidneys, even though NHBD kidneys are suboptimal organs due to the increased risk of delayed graft function and primary non-function. However, the long-term viability of NHBD kidneys in strictly selected donors has been improved by the use of a continuous perfusion machine on the cadaver before harvesting (6).

A continuous perfusion machine can be used to assess NBHD kidney viability. Flow measurements and urinary enzyme excretion (7) are predictors of viability. Presumed consent legislation would allow many more NHBD kidneys because rapid intra-arterial cold perfusion of a recently deceased person would normally be allowed before family members arrive at the hospital. However, under informed consent law, perfusion of a cadaver without relatives' permission is an unwarranted assault. In contrast, under presumed consent, a coroner is able to give permission for perfusion without requiring the relatives' consent, so allowing the use of NHBDs to be expanded significantly.

Recommendations	GR
The use of NHBDs should be expanded significantly.	B
Transplant staff should create policies for recently dead admissions to casualty departments to be used as NHBDs.	B
Local coroners should be consulted regarding the legal implications.	B

*2.2.5 **Elderly donors***

The use of kidneys from elderly donors (> 60 years) is increasing. In countries such as Spain, it represents 40% of total kidney transplants. Long-term survival of kidneys is similar to the transplants performed with non-expanded criteria donors (8). After 6 months' post transplant, patients who have been transplanted have a better survival rate than patients remaining on dialysis. Kidney transplants from donors older than 70 years

carry a higher risk of graft loss and mortality, especially when transplanted to recipients under 60 years (9).

Recommendations	GR
The use of carefully selected donors over 60 years of age should be maintained and encouraged as a continuing source of deceased donor kidneys.	B
Donors over 70 should be evaluated on an individual basis, taking into account that better results are obtained when transplanted to patients older than 60 years.	B

2.3 Policies to enhance living donation

Kidney transplants from living donors offer a better graft and patient survival than those from deceased donors (1). Two major recent developments have led to the increased acceptance of living kidney donation:

- Kidney transplant results have improved so that more patients with end stage renal disease (ESRD) have opted for transplant rather than dialysis;
- As the number of deceased donor kidneys has not increased, the number of living donors has increased.

It is also likely that laparoscopic donor nephrectomy (less time off work, shorter hospital stay) has helped recruit living donors.

The USA have greatly improved the supply of kidney transplants by recruiting more than 50% of total donations from consanguineous and non-consanguineous donors (i.e. living unrelated donors, which comprise 40% of transplants from living donors) (2,3). In contrast, in Europe, living-donor transplants comprise only 15% of transplantations. However, there is a clear trend for an increase in the living-donor rate, especially in the Scandinavian countries, The Netherlands, and Cyprus (see Table 3). Living-donor rates can be improved at different stages in the referral process and in more general ways (Table 4).

Table 4: Ways of improving the living donation rate

During referral process
Nephrologists, at non-transplanting as well as transplanting centres, should be encouraged to discuss openly living donation with families of patients suffering from endstage renal disease, preferably before the patient begins dialysis. This results in pre-dialysis transplantation, increased transplant rates and better use of dialysis resources.
Counselling (e.g. by senior nurse practitioners or living-donor co-ordinators) should be available to discuss screening tests, provide information packs, and arrange reimbursement of necessary donor expenses allowed in law.
If legally permitted, living unrelated donors should be encouraged.
More general methods
Medical methods, such as laparoscopic harvesting, paired kidney exchange, transplantation of grafts with anatomical abnormalities (vascular, urinary tract fusion), reversal of a positive cross-match by treatment with plasmapheresis, and intravenous immunoglobulin administration.
Ethical methods, such as showing appreciation for organ donation.
Organisational methods, such as medical leave for organ donation and reimbursement of all costs to the donor.

Recommendations	**GR**
Living donation in Europe should be encouraged. There is a widening gap between donation and demand for kidney transplants, with not enough deceased donors. There is, however, an increase in living donors. In the USA, the number of kidneys from living donors is nearly the number of kidneys from deceased donors.	C
Organ donation should be considered a charitable gift. Society can express gratitude to organ donors for their gift as with charitable contributions, without jeopardising its altruistic basis (e.g. 'Medal of Honor', limited reimbursement, medical leave, priority access to organ for transplant, donor insurance).	C
All nephrologists who care for ESRD patients should explore the living donor option with the family when a patient first presents with ESRD.	

ESRD = endstage renal disease.

*2.3.1 **Medical methods to increase number of living donations***

2.3.1.1 Acceptance of grafts with anatomical anomalies

The use of grafts with anatomical anomalies is considered a relative contraindication by most experienced transplantation centres because of the shortage of living donors. Anatomical anomalies include renal cysts, uretero-pelvic junction obstruction, solitary stones > 1 cm, duplex ureteral system, and multiple arteries and veins. However, retrospective reports have suggested that grafts with multiple renal artery or vein anomalies, such as circumaortic or retroaortic renal vein, do not carry an increased risk of complications in experienced hands (4).

If the donor has a good immunological correspondence with the recipient, but an abnormal kidney, which is the only kidney available, and if the recipient on haemodialysis has a poor status, the abnormal kidney should be transplanted leaving the donor with the best one.

A laparoscopic right kidney donor nephrectomy is as safe as a left nephrectomy. A recent prospective trial showed no differences in complication rates and graft survival between left- and right-sided donor nephrectomy (5).

Recommendations	**GR**
Multiple renal artery or grafts with anatomical anomalies are not absolute contraindications. Decisions should be made on an individual basis.	C
Laparoscopic right kidney nephrectomy is as safe as left kidney nephrectomy in terms of complications and graft survival.	A

2.3.1.2 Laparoscopic living-donor nephrectomy (LLDN)

Laparoscopic living-donor nephrectomy (LLDN) is an alternative surgical method that has increased the rate of living donations. It is becoming the preferred technique for living-donor renal transplantation. In the USA, laparoscopic donor nephrectomies are more common than open surgery donor nephrectomies. In Europe, although the number of nephrectomies are increasing, fewer laparoscopic nephrectomies are performed than open procedures (6).

There is a good evidence base for LLDN, including three systematic reviews, which have compared its safety and efficacy to the 'gold standard' of open donor nephrectomy, at least seven randomised control trials (LE: 1-2), five prospective non-randomised studies (LE: 2) and several retrospective studies (7-9). Compared to open live donor nephrectomy (OLDN), LLDN shows similar rates for graft function, rejection rate, urological complications, and patient and graft survival. However, measures for analgesic requirements, pain, hospital stay, and time to return to work are significantly better for a laparoscopic procedure.

In terms of donor safety, the historical mortality rate is 0.03% with open donor nephrectomy, a rate that remains unchanged by the introduction of LLDN (10,11). The data about potential mortality should be included in all informed consent. In addition, LLDN does not affect the long-term risk of developing ESRD (12). However, the laparoscopic approach takes longer and requires additional resources. Nevertheless, the shorter hospital stay and a more rapid return to work may compensate for the initial higher costs. In addition, the number of live kidney donations has increased by more than 100% in many institutions since the introduction of the laparoscopic approach.

Overall, laparoscopic nephrectomy offers donors less post-operative pain, shorter convalescence and better cosmetic results compared to traditional open donation. In experienced hands, this procedure is accomplished without increased risk to the donor's safety or allograft function. As with OLDN, LLDN should be considered the gold standard of treatment.

Recently introduced, LESS transumbilical nephrectomy allows the surgeon to work through the umbilicus using a multientry port. The same incision is then used for kidney withdrawal. Increasing experience in selected centres suggest that it is a promising technique with better cosmetic results. NOTES-assisted transvaginal nephrectomy is a technique that also allows avoiding the extraction abdominal scar. Both LESS transumbilical nephrectomy and NOTES-assisted transvaginal nephrectomy are experimental and should be used only in highly specialised centres (13).

Table 5: Laparoscopic live donor nephrectomy: advantages and disadvantages

Advantages	**Disadvantages**
Less post-operative pain	Graft loss or damage during 'learning curve'
Minimal surgical scarring	Pneumoperitoneum may compromise renal blood flow
Rapid return to full activities	Longer operative time and work (about 4 weeks)
Shorter hospital stay	
Magnified view of renal vessels	

Recommendations	**GR**
Laparoscopic nephrectomy offers equal urological complications, graft function and graft survival to open nephrectomy, with less post-operative morbidity, shorter convalescence, and better cosmetic results.	A
Laparoscopic nephrectomy increases the number of individuals willing to donate. It should be used only by appropriately trained and experienced surgeons.	C

2.3.1.4 ABO-incompatible donors

ABO incompatibility was once a contraindication for renal transplantation, but this is no longer the case because of new techniques (antibody adsorption columns) (1) and new immunosuppressive tools (e.g. anti-CD20 monoclonal antibody, rituximab) (2). This has increased the opportunities for organ donation. Successful transplantation case studies have been reported in living donors against a blood group barrier, with retrospective studies showing similar outcomes to those of blood-group-compatible transplants (3,4). Limitations of the current reports are the small patient numbers, relatively short follow-up periods and differences in treatment protocols (5,6). Further investigation is ongoing (7-10). Current reports indicate that ABO-incompatible transplantation require a more intense and more costly immunosuppressive therapy (11-13) (LE: 3).

Until more long-term data are available, and key issues of the treatment protocol are solved, this procedure remains experimental and should only be performed as part of a scientific trial. Patients should be counselled on the potential risks (more intense immunosuppression, lack of long-term outcome data) and benefits (immediate availability of a living donor). Other transplantation methods should be considered, such as cross-over transplantation, which allows timely transplantation using standard immunosuppressive protocols (LE: 3).

Recommendations	**GR**
ABO-incompatible transplantation is a promising procedure undergoing clinical evaluation.	C
Due to its experimental nature, it should be performed in experienced centres under scientific documentation.	C
Patients should be counselled about potential risks and alternatives.	C

2.3.1.5 Cross-match-positive living-donor kidney transplants

This was previously thought to be a contraindication. However, several pilot studies (11-14) have reported successful transplantation with acceptable short-term results, using extensive antibody elimination strategies (e.g. plasmapheresis), intravenous application of immunoglobulins, and a more intense immunosuppression with antibody induction and the use of B-cell depleting agents (e.g. anti-CD20 antibody rituximab) (LE: 3).

Due to a lack of standardised treatment protocols and the lack of long-term results from larger

cohorts, this procedure remains experimental and should only be performed as part of a scientific trial. Patients should be counselled adequately on the potential risks. Alternative ways for transplanting highly immunised patients (e.g. Eurotransplant Acceptable Missmatch programme, cross-over transplantation) should be considered to allow a timely transplantation of these patients with standard immunosuppressive protocols (15) (LE: 4).

Recommendation	GR
Transplantation of cross-match positive living donors is an experimental procedure, which should only be performed in scientific trials. Patients should be counselled about risks and potential alternatives.	C

2.3.1.6 Living unrelated kidney donation

In many countries in Europe, altruistic non-consanguineous kidney donation is allowed legally, provided checks are made for altruistic motivation and financial gain excluded (15,16). The results are comparable to related living donation (LE: 3).

Recommendation	GR
Living related and unrelated donation should be encouraged within national laws.	B

2.3.1.7 'Non-directed' living-donor transplantation

'Non-directed' living-donor transplantation between an altruistic donor and a recipient unknown to the donor is being performed in a few centres worldwide (17-19). Although controversial, there seem to be no moral or social reasons to exclude such truly altruistic donors (16,20). However, there are ethical and legal concerns about this type of donation (21), which at the moment make it difficult to recommend in these guidelines.

2.3.1.8 Payment to living donors from a central organisation

Although paying living donors to donate organs from a central organisation would be a potential way of increasing organ availability in an era of organ shortage (22), it is generally agreed that the payment of living donors to donate organs is ethically unjustifiable (23,24). It is strongly recommended that all organ donors have adequate lifelong access to medical care for the prevention of renal failure and potential side effects of organ donation (15,16).

The cornerstone of clinical transplantation has been the altruistic donation of kidneys from living relatives. The gift of a transplant is priceless and societies that support transplantation have generally refused to give a monetary value to a transplantable organ or tissue. In Europe, it is illegal to make a payment for living related organs and The World Health Organization (WHO) has stated that the body and its parts cannot be the subject of commercial transactions, and all giving and receiving of payments should be prohibited (24) (LE: 4).

Recommendations	GR
Legislation in every European country forbids payment for organs.	C
Donation of an organ should remain a gift of live without any financial impetus.	C

*2.3.2 **Ethical ways of showing appreciation for organ donation***

2.3.2.1 Donor 'medal of honour'

Organ procurement organisations could have ceremonies which recognise and honour organ donation. A donor 'medal of honour', given by a top official of a country, would effectively express appreciation and gratitude on behalf of the whole community to the living donors and families of deceased donors (1,2). Policymakers, ethicists and the transplant community cannot agree on whether giving benefits to the families of organ donors would increase organ availability (3) (LE: 4). Because of the lack of evidence, no general recommendation can be made on whether or not to provide incentives for living donors or families of deceased donors.

*2.3.3 **Organisational ways to encourage organ donation***

2.3.3.1 Cross-over transplantation or paired organ exchange

A cross-over renal transplantation or a paired kidney exchange transplant is an exchange between two or more couples, who are prevented by ABO incompatibility or positive cross-match from donating their kidneys to their preferred recipients. The problem may be solved by exchanging the living donor kidneys between pairs of couples to achieve a cross-match negative or ABO-compatible combination.

The inclusion criteria should favour the exchange of equivalent kidneys in size and age. A programme of cross-over kidney transplantation allows an exchange of organs between two living donors (4), or in some countries, from one living donor and one deceased donor (5). By using paired kidney exchange, the recipients are able to benefit from living donation. Paired kidney exchange also reduces the duration of dialysis before transplantation and expands the pool of living donors (6). Graft survival rates of paired kidney exchange are similar to directed, compatible live donor transplants (7) (LE: 3).

Recommendation	**GR**
Paired kidney exchange and cross-over renal transplantation if permitted by national law is a way of increasing the number of kidney transplants.	C

2.3.3.2 Medical leave for organ donation

No-one should have to incur a personal expense for donating an organ (8). Many countries legally provide 30-days' paid medical leave to all employees who donate an organ for transplantation (9). The American Society of Transplantation has recommended living donors should be given leave from employment similar to parental leave granted for a new baby (LE: 3).

Recommendations	**GR**
The health and well-being of living donors should be monitored in a follow-up register to document any long-term medical problems due to donation.	B
There should be a national insurance plan that provides life and disability insurance for all living donors.	B

2.4 Kidney donor selection and refusal criteria

*2.4.1 **Introduction***

A diagnosis of brain death is required in a comatose subject who may potentially be a deceased organ donor. The potential donor must be evaluated for any transmissible pathological condition and the quality of any organ(s) being considered for transplantation.

The short-term results of transplants with kidneys from donors over 65 years old are almost similar to those with younger organs. However, long-term graft survival is lower (1). In addition, the main physiological risk factor in 'older' kidneys is a prolonged cold ischaemia time (2,3). In keeping with these observations, the modern definition of a suitable donor places less emphasis on age and more on the physical condition of the donor, especially of the organ to be donated. The aim is to reduce the possibility of discarding usable organs. Thus, there are now no absolute age limits to donation. However, a short ischaemia time is mandatory, as well as careful donor selection, particularly because older donors have more co-morbidity. There is a similar trend towards extending the upper age donation limit in living donors to over 55 years old (4).

*2.4.2 **Infections***

The potential donor must be checked for infectious diseases (Table 6):

Table 6: Infections to be checked for in potential donor

Human immunodeficiency virus-1, -2 (HIV-1, HIV-2)
Hepatis C (HCV)
Hepatitis B surface antigen (HBsAg), anti-HBc; acute hepatitis (liver enzymes)
Cytomegalovirus (CMV)
Epstein-Barr virus (EBV), only in paediatric recipients
Active syphilis
Viral infection, sepsis, tuberculosis, infections of unknown aetiology
Family history of (or clinical signs that may be caused by) Creutzfeldt-Jacob disease

There is a high risk of HIV transmission from potential donors with suspected intravenous drug abuse. In addition, serology tests during the incubation period of HIV (2 months) or hepatitis (up to 6 months) may be negative, while large amounts of fluids administered during a resuscitation attempt can result in a normal serology due to dilution effects (5). Serological tests must therefore be repeated and additional tests done (e.g. polymerase chain reaction) to rule out infection.

*2.4.3 **Special exceptions for infections***

Different circumstances apply when an organ recipient is already infected with HIV or hepatitis (Table 7).

Table 7: Exceptions for organ recipients who already have infections

HCV-positive donor
In an HCV-positive recipient, transplant is allowed following informed consent.
In an HCV-negative recipient, there is a high risk of disease transmission. However, transplant may be possible in emergency situations following informed consent.
HBsAg-positive donor

In an HBsAg-positive recipient (if HDV antigen is negative), transplant is allowed after informed consent.
In an HBsAg-negative recipient with high anti-HBs antibody titre and HBc positivity, transplant is allowed after informed consent.
In an HBsAg-negative recipient with intermediate/high anti-HBs antibody titre alone (Hbc-antibody negative), transplantation may carry a higher risk but is allowed after informed consent.
In an HBsAg-negative recipient with undetectable anti-Hbs antibody, transplant is allowed only in a life-saving situation, when HDV antigen is negative and following informed consent.
HBc-antibody-positive donor
In liver transplantation, there is a high risk (50%) of transmitting hepatitis B from an anti-HBc antibody-positive donor to the recipient. In this situation, liver transplantation is allowed after informed consent. Kidneys, heart and lungs carry a low, but not absent, risk of hepatitis B transmission, so kidney transplant is allowed in an HBsAg-positive recipient, or an HBsAg-negative recipient with anti-HBs antibody titre ≥10 mIU/mL, following informed consent.
In an HBsAg-negative recipient with no anti-HBsAg antibody, only life-saving transplants are allowed, after informed consent.

*2.4.4 **Malignant tumours***

A previous history of malignancy is not usually a contraindication for organ donation. However, there are some absolute contraindications that make a donor unsuitable for transplant. These are active cancer or a history of metastatic cancer (with a few exceptions, such as testicular cancer) and cancers with high recurrence rates, such as advanced breast carcinoma, melanoma, leukaemia, or lymphoma. In addition, when a potential donor has experienced a brain haemorrhage of unknown aetiology, metastasis must be excluded as a cause of intracranial bleeding. For example, the serum level of human chorionic gonadotropin (hCG) must be measured to exclude chorioncarcinoma in female donors.

With other cancers, if less than 10 years has elapsed since completion of treatment, a careful risk-benefit assessment must be done of the risk of disease transmission versus mortality on the waiting list. The donor shortage has led to many transplant programmes accepting donors after only 5 years' absence of recurrent malignancy. So far, only a low incidence of donor-transmitted malignancies has been observed (6). Successful renal transplants have been performed with kidneys affected by small, low-grade renal carcinomas that were completely excised. Recipients of organs from donors with a history of malignancy must be informed and carefully monitored (7).

*2.4.5 **Special exceptions for malignant tumours***

For special exceptions in malignant tumours, see Section 8.1.

*2.4.6 **Vascular conditions and renal function***

Important risk factors for organ failure are a prolonged history of diabetes mellitus or serious hypertension with retinal vascular damage. Factors for excluding potential donors or for considering a donor as a single- rather than a multi-organ donor include:

- previous myocardial infarction;
- coronary bypass and angina;
- severe systemic vascular disease;;
- events of long-lasting hypotension;
- oliguria;
- long-lasting intensive care stay.

A donor's renal function should be evaluated at admission using creatinine clearance (Cockcroft-Gault formula), which corrects the serum creatinine value for age, body weight, and sex (8). The urinary tract can also be assessed by 24-h proteinuria and ultrasound kidney imaging, particularly in elderly donors. In many transplant centres, a calculated creatinine clearance level of 50 mL/min is at the lower range for kidneys usable for two recipients, independent of the histology of the organ, but according to the history of the donor, while other centres evaluate glomerular sclerosis and arteriolar sclerosis from renal biopsy (9).

Acute renal failure is not itself a contraindication. The kidneys may be used after careful assessment (LE: 3).

*2.4.7 **Marginal donors***

The following criteria need to be considered in a marginal organ (10) (LE: 3):

- Age over 70 years without other risk factors.
- Age between 60 and 70 years, with a history of diabetes mellitus, hypertension, clinical proteinuria up

to 1 g/24 h, or retinal vascular changes.

- Calculated creatinine clearance of 50 mL/min – the organs are still valuable for a single graft.
- Calculated creatinine clearance < 50 mL/min – the organs should be used as dual graft or discarded if histologically abnormal.
- Approximately 5-20% of glomerulosclerosis at biopsy with at least 25 glomeruli taken from both kidneys – the organs are still valuable for a single or double graft.
- More than 20% glomerulosclerosis – an individual decision has to be made based on renal function.

The true clinical meaning of each criterion is unknown because none of them have been rigorously validated and opinions differ over their individual value, as for example with pre-transplant renal biopsy (11,12).

*2.4.8 **One graft or two grafts per recipient***

The rationale for dual marginal kidney transplantation is based on two conflicting concepts. Firstly, kidneys with a small nephron mass undergo hyperfiltration and glomerular hypertension, which causes progressive glomerulosclerosis (13). A single marginal kidney has a reduced renal mass and a suboptimal number of nephrons, which are further reduced by cold ischaemia time, transplant trauma, and the potential nephrotoxicity of immunosuppressive therapy. Simultaneous transplantation of both kidneys to the same recipient may increase nephron mass and prevent kidney damage.

Secondly, marginal kidneys have a functional reserve only verifiable after transplantation. In addition, the glomerular filtration rate of a transplanted kidney often increases post transplant (14-16). Dual transplantation is redundant because it shortens the organ pool.

These two opposing concepts would seem to suggest that kidneys judged unsuitable based on function or histology should either both be transplanted into a single recipient or both be discarded (17). However, a prospective multicentre study (18) concluded that double-kidney transplants are safe, well tolerated, and result in no more surgical complications than single-graft operations.

To date, the surgical technique for dual renal grafting has not been standardised (19,20) (LE: 3).

Recommendations	**GR**
Any brain death comatose subject should be considered a potential organ donor, without age limits.	C
Consensus for organ harvesting should be obtained from relatives or significant others according to local law and policies. Authorisation for explantation by the donor's close relatives is always recommended, even if local legislation on organ donation presumes consent: - Contact between relatives and a well-trained, sensitive professional is very important in establishing favourable public opinion on organ donation. - Individuals who objected to donation during life must always be excluded.	
Any donor organ affected by a potentially transmittable pathology (infections, neoplasias) must be carefully evaluated considering the risk-benefit ratio for the recipient.	B
A good-quality organ must be guaranteed to the recipient and every transplant centre must establish its own guidelines on organ acceptability. Organs from marginal donors can only be used after thorough assessment. The recipients need to be informed and must confirm their acceptance.	C

2.5 Explantation technique

*2.5.1 **Technique of deceased donor organ recovery***

Each solid organ should be procured as quickly as possible to minimise ischaemic injury. Removal of the heart, lungs, liver, and pancreas (Table 8) usually takes place before kidney retrieval (Table 9) (1-10) (LE: 3). Continuous machine perfusion reduces injuries due to ischaemia or reperfusion and improves the immediate post-operative graft outcome (8-10) (LE: 3).

Table 8: Important considerations during removal of heart, lungs, liver, and pancreas

Infuse 3L of University of Wisconsin (UW) solution into the aorta before organ recovery.
Open Gerota's fascia to expose the kidneys for surface cooling. While the heart is being removed and the cold perfusate is being infused, place ice slush into the abdominal cavity to provide surface cooling for the liver, kidneys, and pancreas.
After the heart is removed and the liver is to be retrieved, careful attention should be given to ensure the following: • Do not extend the aortic cannula beyond the ostia of the renal arteries. This will avoid the risk of inadequate flushing of the kidneys, leading to unnecessary and harmful warm ischaemia. • If the superior mesenteric artery is not being taken along the coeliac artery for the liver, the upper portion of the remaining aorta can be reclamped to allow continued perfusion of the kidneys and cooling during removal of the liver. • If the superior mesenteric artery is taken with the liver and removed, it may not be possible to place a curved forceps in a tangential manner on the remaining segment of aorta. Although this would allow continued flushing of the kidneys, there is a risk of occluding the renal artery orifices, especially on the right side.
During transection of the vena cava between the liver and the kidneys, take care to avoid injury to the right renal vein. The right renal vein can often extend superiorly before entering the vena cava and may be accidentally transected. Because a segment of infrahepatic vena cava is needed in liver transplantation, the kidney retrieval team must be instructed to leave an optimal amount of venal caval cuff to go with the liver to prevent injury to the right renal vein.
The pancreas, if being retrieved, should be removed before the kidney. Again, injury to the left renal artery or vein can occur while the pancreas is dissected. Often the pancreas, and occasionally the kidneys, are recovered en bloc with the liver and then separated on the back table.
It is unnecessary to perform extensive kidney mobilisation prior to kidney removal, especially in multiple organ recovery. Such retroperitoneal dissection may cause accidental injury to aberrant renal arteries, so causing incomplete perfusion and warm ischaemia of the kidneys (2-4) (LE: 2a).

Table 9: Important considerations in kidney retrieval

Dissection is carried cephalad and kept as far posterior as possible; the line of dissection is maintained at the level of the paraspinal muscles. Gerota's fascia is kept attached to the kidneys. At the superior poles of the kidneys, the adrenal glands are left intact attached to the kidneys. The kidneys are removed en bloc without identification of the hilar structures.
On the back table, care must be taken to identify aberrant renal arteries, which may originate from the iliac arteries or distal or superior aorta. The aortic segment is left intact. The ureters are examined for length, numbers, and size.
It is useful to rewash each kidney until the effluent is free of blood before packaging.
If the liver is not to be recovered, a double balloon perfusion cannula can be placed in the aorta for selective renal perfusion and a venting catheter is inserted into the lower vena cava to allow venous blood to be washed out.
Dissection of the kidneys can then proceed with mobilisation of the right colon, exposing the right kidney, the inferior vena cava, and lower aorta. Identification and ligation of the inferior mesenteric artery and vein are performed, and the splanchnic nerves are divided, allowing mobilisation of the left mesocolon and exposure of the left kidney. The coeliac axis is identified, ligated and divided.
Mass clamping of the hepatoduodenal ligament can be performed to minimise flushing of the liver. In a donor < 3-4 years, the surgeon must make sure the aortic cannula does not occlude the renal artery orifices.

Improvements in techniques for harvesting organs from non-heart-beating donors (NBHDs) has allowed the use of organs that would otherwise not have been considered for transplantation. Reports of the satisfactory function of organs retrieved in this manner have been followed by the development of adequate methods of aortic infusion techniques (11-13). Non-heart-beating donors accounted for 11,06% in EUROTRANSPLANT and for 6,5% in USA (12-18).

With the development of multiple organ recovery techniques (19), good co-ordination and co-operation between the various surgical teams involved are essential for the successful retrieval of

transplantable organs (2,19-21). Logistics and programming of organ explantation should routinely be done by the local transplant coordinator.

Recommendations	GR
Kidneys are the last organs to be recovered in multiple organ recovery. Appropriate placement of the aortic cannula for the cold 'in-situ' flush is essential.	C
After retrieval of the thoracic organs and liver, and if the pancreas is to be removed, the liver and pancreas should be recovered en bloc and separated on the back table.	B
In multiple organ recovery, it is essential there is good co-ordination and co-operation between the surgical teams.	C

*2.5.2 **The living donor***

At present, 20% in EUROTRANSPLANT and 40% in USA of all kidney transplants are performed with living donors (14,16) (LE: 2a). In countries with low deceased donor rates, over 75% of kidney transplants are with living donors (22).

Most living donors are family members, but there is an increasing number of genetically unrelated donors, who are 'emotionally related', such as spouses or friends. In 2005, in EUROTRANSPLANT, nearly 50% of living donors were not genetically related (42.2%). In the USA, 37.2% were unrelated living donors (14,16) (LE: 2a).

Ethical guidelines mandate that the living donors have not been coerced and not been paid for their donation. Living donation should be considered a gift of extraordinary value and should be facilitated wherever a suitable donor is available (Table 10) (23-26) (LE: 2b).

Table 10: Advantages of living donation

Better results (both long- and short-term) compared to deceased donor grafts
Consistent early function and easier management
Avoidance of long waiting time for transplantation
Less aggressive immunosuppressive regimens
Emotional gain to donor
Global increase of the kidney transplant rate

2.5.2.1 Evaluation

Evaluation of a potential donor may be performed by an independent physician and consists of a complete history and physical examination, routine laboratory testing, and serological evaluation for EBV, herpes virus, CMV, HIV, HCV, and hepatitis B virus (HBV). Routine evaluation should also include urinalysis and culture, together with 24-h urine collection for creatinine clearance and protein excretion. A borderline hypertensive blood pressure should be measured on at least three, and as many as 10, separate occasions.
Renal angiography is indicated only if spiral computed tomography (CT) scan with three-dimensional reconstruction or magnetic resonance imaging (MRI) angiography with reconstruction are not available.

Donors are unsuitable for a variety of reasons (Table 11). Potential donors for siblings with diabetes should routinely undergo a 5-h glucose tolerance test and the 24-h urine specimen must be free of proteinuria. Unexplained microscopic haematuria may indicate underlying renal disease. A history of thromboembolism or thrombophlebitis places a potential donor at increased risk of pulmonary embolism and contraindicates donation, as does advanced heart disease or a history of malignant neoplasia. Obesity is a relative contraindication for any potential donor > 30% above ideal body weight.

Table 11: Exclusion criteria for living donors

Absolute contraindications
Age < 18 years
Uncontrolled hypertension
Diabetes mellitus
Proteinuria (> 300 mg/24 h)
Abnormal GFR for age

Microscopic haematuria
High risk of thromboembolism
Medically significant illness (chronic lung disease, recent malignant tumour, heart disease)
History of bilateral kidney stones
HIV positive
Relative contraindications
Active chronic infection (e.g. tuberculosis, hepatitis B/C, parasites)
Obesity
Psychiatric disorders

GFR = glomerular filtration rate; HIV = human immunodeficiency virus.

Patients with psychiatric disorders should be fully evaluated by a psychiatrist to establish that the donor understands and agrees to the procedure.

2.5.2.2 Choice of kidney

If examination of the donor's vascular supply and drainage system reveals an abnormality, it must be decided whether the risks imposed on the donor or the recipient are too great. When one kidney is smaller or has a minor abnormality, the donor should always be left with the 'better' kidney.

2.5.2.3 Pre-operative management

Pre-operative assessment by the anaesthesiologist and the pain management team is mandatory.

2.5.2.4 Surgical alternatives in live-donor nephrectomy

There are several ways of harvesting kidneys from living donors (Table 12) (11-13,21,27-35). The method chosen will depend on the surgeon's experience and preferred choice of operation.

Table 12: Approaches for harvesting kidneys from living donors

Approach	Description
Classic transperitoneal	Through a midline or through a left or right subcostal incision.
Sub- or supra-costal extraperitoneal	Can be either left- or right-sided.
Dorsal lumbar	Perform incision either underneath the 12th rib, resecting the 12th rib, or above the 12th rib (extraperitoneal, extrapleural).
Laparoscopic	Can be transperitoneal or retroperitoneoscopic. The transperitoneal approach is more common in the USA and Scandinavia.

The operative stages are similar to those in transperitoneal nephrectomy performed for malignant or benign conditions of the kidney. In 2.3% of cases, concomitant splenectomy is needed (11-13,21,28-35), due to injuries of the spleen that occur during colon dissection. In addition, the transperitoneal approach is accompanied by a significantly higher rate of intestinal complications, such as ileus (functional or even obstructive).

Removal of the left kidney from a living donor is recommended because of the longer length of the left renal vein (36-38).

Before starting the incision, the donor's diuresis is increased, usually by giving mannitol, 25 g. Arterial spasm may be prevented with externally applied papaverine (39).

Laparoscopic kidney removal (Table 13) is a less traumatic technique, entails less pain, a shorter hospital stay and may encourage more people to consider donation.

Table 13: Special considerations during a laparoscopic procedure

Patient's preparation	During organ harvesting, especially during dissection of the renal pedicle, the patient requires appropriate fluids and a mannitol infusion to maximise renal function during surgery and after transplantation (15-17,40,41).
Patient's position on the operative table	Place the patient on the operative table in a left or right position with the kidney bridge. The left kidney is preferred for laparoscopic removal because it has a longer renal vein. On the right side, the liver may make dissection difficult in a transperitoneal approach.

Transperitoneal laparoscopic approach	The transperitoneal approach offers more working space. The kidney is approached by dissecting the colon and peritoneum on different lengths. The approach to the renal artery is more complicated due to its position behind the renal vein. However, after detachment from vascular connections, the kidney can be more easily extracted through a lower umbilical incision.
Retroperitoneoscopic approach	The retroperitoneal approach allows an easy, initial identification of the renal artery and a direct approach to the branches of renal vein. Its main drawback is the limited space for manoeuvre, which also makes it difficult to use endobags for a quick kidney extraction.

2.5.2.5 Post-operative care

Adequate post-operative analgesia is crucial in preventing post-operative complications, such as atelectasis and pneumonia (20,21). Antibiotic prophylaxis should also be given. Subcutaneous heparin, the continuous use of leg stockings and sequential compression devices should be prescribed to prevent deep venous thrombosis of the lower limbs. Most patients tolerate oral feeding by post-operative day 2 or 3, and the donor can be discharged between post-operative days 2 to 6. Renal function should be assessed periodically after operation. Although donors experience a 25% increase in serum creatinine level, the creatinine level should return to near baseline within 3 months.

There are no convincing data to suggest that living donors are at increased long-term risk because of kidney donation. Nevertheless, ongoing periodic long-term follow-up evaluation is recommended for donors. This can be performed by the donor's personal physician (14-17,40-43) (LE: 2a).

Recommendations	**GR**
The use of living donors has been associated with higher success rates than seen with deceased donor donation. Living donation allows some patients to avoid long waiting times and even dialysis.	B
An independent assessment of the donor's renal function by a nephrologist or a specialised team is mandatory in all cases.	B
It is advisable to obtain a psychiatric or independent medical evaluation of the donor's motivation, fitness, and their ability to understand the risks of the operation.	B
It is the surgeon's responsibility to ensure that the donor is medically, as well as psychologically, suitable for the procedure; the donated organ is healthy; and the expectation of success in the recipient is reasonable.	B
The donor should always be left with the 'better' kidney. Kidney removal through a transperitoneal approach has a higher number of splenic and intestinal complications compared with other surgical alternatives.	B
Open-donor nephrectomy should be performed by an extraperitoneal approach through a subcostal or dorsal lumbotomy incision.	B
Laparoscopic donor nephrectomy (either trans- or retro-peritoneal) should only be performed by those trained in the procedure.	B
Hand-assisted laparoscopic donor nephrectomy minimises warm ischaemia time compared to classic laparoscopic procedures.	B

2.6 Organ preservation

2.6.1 Kidney storage solutions

There is no agreement on which of the mechanisms listed in Table 14 is most important for post-ischaemic renal graft function (1-6). No storage solution combines all mechanisms. Previously, Euro-Collins was widely used, but is no longer recommended. Today, Celsior-solution, UW-, and HTK- (histidine-tryptophane-ketoglutarate) solution are equally effective and are standard for multi-organ or single kidney harvesting procedures (7-10) (LE: 1b). For living donors, in whom a long cold ischaemia time is not expected, perfusion with crystalloid solution (e.g. Ringer-lactate) is sufficient.

Table 14: Aims of modern kidney storage solutions*

Control of cell-swelling during hypothermic ischaemia
Maintenance of intra- and extra-cellular electrolyte gradient during ischaemia
Buffering acidosis
Providing energy reserve
Minimising oxidative reperfusion injury

**From references 1-6.*

2.6.2 Methods of kidney preservation

There are two methods of kidney preservation:

- Initial flushing with cold preservation solution followed by ice storage.
- Continuous pulsatile hypothermic machine-perfusion (clinical relevance for non heart-beating donors and marginal donors).

2.6.3 Duration of organ preservation

The duration of cold ischaemia should be as short as possible. Kidneys from the elderly (> 55 years) and marginal donors are more sensitive to ischaemia than young kidneys (LE: 1b). Organ preservation relies mainly on hypothermia, which lowers the metabolic rate, conserves stores of adenosine triphosphate, and prevents formation of oxygen-free radicals during the reperfusion phase.

Recommendations	GR
UW-solution and HTK-solution are standard storage solutions and equally effective for both multiorgan-donors and kidney-only donors.	A
Celsior-solution seems to be equally effective.	B
Keep cold and warm ischaemia times as short as possible for any renal transplant.	A

3. KIDNEY RECIPIENT

Kidney transplantation prolongs life, reduces morbidity, improves quality of life, enables social and medical rehabilitation, and reduces the costs associated with the medical care of patients with ESRD.
Kidney transplantation is a surgical procedure, with inherent risks due to anaesthesia and the surgical procedure itself. In addition, the need for continuous immunosuppressive therapy may lead to immunosuppression-related side-effects.

The pre-transplant evaluation evaluates potential contraindications and risk factors for transplantation (e.g. malignancy, ongoing infection) (LE: 2b).

Recommendation	GR
Careful pre-operative work-up of all transplant candidates is mandatory to improve organ and patient survival in the post-transplant period. The work-up should be repeated regularly.	B

3.1 Pre-transplant therapy

3.1.1 ***Abnormal urogenital tract***

In patients, whose ESRD is caused by either a congenital (i.e. posterior urethral valve, spina bifida, prune belly syndrome, vesico-renal reflux, bladder exstrophy, VATER syndrome) or an acquired malformation (shrunken or neurogenic bladder) of the lower urinary tract, the abnormality should be corrected before transplantation (1-4).

Avoid ureteral implantation in a fibrotic, thickened bladder wall (e.g. following an urethral valve) because of the high risk of surgical complications and/or graft loss (1). In low-compliance bladders, pharmacological therapy (e.g. parasympathicolysis), with or without intermittent self-catheterisation, is necessary. If these methods fail, bladder augmentation is recommended. If catheterisation is not possible, supravesical urinary diversion is crucial.

Anatomical or functional urological disorders do not seem to change the outcome of renal transplantation (LE: 3).

3.1.2 ***Urinary diversion***

In patients with sphincter insufficiency (e.g. neurogenic bladder) or absent bladder, supravesical urinary diversions must be performed, such as conduits or continent catheterisable pouches. Artificial sphincters may be an alternative. In low-compliance bladders with intact sphincters, both bladder augmentation and continent pouches are successful alternatives (4-9).

Most urologists prefer to perform a supravesical urinary diversion at least 10-12 weeks before transplantation (6, 8). Bladder augmentation or conduit is possible following transplantation (6). Patients with conduits, augmented or abnormal bladders have an increased risk of urinary infection (1,4-6).

Results can be similar to those in the general population (7,9-12) (LE: 3).

3.1.3 Indications for pre-transplant nephrectomy

Depending on the indication (Table 15), nephrectomy can be done by either an open or laparoscopic approach (LE: 3-4).

Table 15: Indications for pre-transplant nephrectomy

Autosomal-dominant polycystic kidney disease (ADPKD)
Unilateral or bilateral nephrectomy is necessary if there is not enough space for the transplant kidney, or if there are complications, such as cyst infection, cyst rupture with/without haematuria, pain, or abdominal girth
Nephrectomy can be done before transplantation or simultaneously with similar complication rates and outcomes (2,13,14)
Medically refractory hypertension
Bilateral nephrectomy usually results in less antihypertensive medications (15). It has become rare due to improved control of hypertension with better dialysis and drugs
Chronically infected kidneys
Suspected renal or urothelial cancer
Urolithiasis
No strong evidence for removal of native kidneys in urolithiasis
Nephrectomy is necessary if there is a possible risk of infection due to stones

Recommendations	**GR**
In abnormal urogenital tract, meticulous pre-transplant work-up is necessary, with urodynamics being the key investigation.	B/C
If pharmacological therapy or intermittent catheterisation fails or is not possible, urinary diversion is necessary using catheterisable pouches, conduits or cystoplasties.	B/C
ADPKD with insufficient space or complications, chronic infections, or kidneys with suspected tumour growth have to be removed either pre-operatively or concomitant with transplantation.	B/C

ADPKD = autosomal dominant polycystic kidney disease

3.2 Selection and refusal criteria

3.2.1 ***Contraindications***

3.2.1.1 Malignancy

Active malignancy is a contraindication for transplantation because immunosuppressive therapy may aggravate underlying malignancy, jeopardising the patient's life and long-term success of the transplant (1-3). Patients with a history of malignancy should be cured (see Chapter 8 - Malignancy).

3.2.1.2 Infection

Infections can be a major cause of morbidity and mortality in transplanted patients, especially under intense immunosuppressive therapy. As part of the pre-transplant work-up, carry out screening for infections to exclude any active infections, which might jeopardise the immediate outcome post transplant (1-3). In contrast, chronic infection does not cause an immediate post-operative risk. If chronic infection is detected, counsel the patient and treat it before transplantation or take prophylactic measures after transplantation. Screening for infections also documents the recipient's infectious status in case of disease transmission from the donor. In cases of previous negative serology for CMV, HBV, HCV, and HIV recipients, serology should be repeated at the time of transplantation. A record of the viral status before transplantation enables graft transmission of disease to be firmly excluded. Finally, the recipient's infectious status may have implications for the allocation of organs (LE: 3).

If the patient's history or physical examination suggests an underlying infection, a thorough examination should be instituted, which may involve physicians from other subspecialties, such as an ear, nose, and throat specialist; dentist; dermatologist; urologist; and gynaecologist, to firmly rule out infectious foci (1-3) (LE: 3).

Important infections screened prior to transplantation are HBV, HCV, HIV, tuberculosis (TB), CMV, and Treponema pallidum (1-3). Testing of HBV and HCV serology is particularly important, because viral hepatitis is the major cause of liver disease after renal transplantation and contributes to post-transplant morbidity and mortality (4-6) (LE: 3). A liver biopsy may be needed to assess disease status in patients positive for HBV or HCV before transplantation. Consider antiviral therapy before transplantation according to current guidelines (7-9) (LE: 3).

The serological CMV status of all recipients should be determined (1-3) (LE: 3). Current immunosuppressive regimens are associated with a high incidence of potentially life-threatening CMV disease (4,10) that is, however, preventable with the appropriate prophylactic strategy (LE: 1a).

Human immunodeficiency virus screening is recommended because active HIV disease is a contraindication for transplantation (1-3). However, retrospective studies show that renal transplantation can be successful in well-controlled (no detectable viral load) and treated HIV-positive recipients (3) (LE: 3).

A history of TB is important because adequate preventive measures (e.g. isoniasid prophylaxis; 11,12) will avoid reactivation of TB under heavy post-transplant immunosuppression (LE: 1a). Screening for TB requires a careful history and chest x-ray (1-3) (LE: 3).

Screening for T. pallidum has been previously recommended (1,2). However, due to the low

incidence of disease, it is not strongly recommended for all potential transplant candidates. A Treponema haemaglutination (TPHA)-test may be performed in populations with a higher risk for disease (LE: 3).

Screening for Epstein-Barr virus (EBV) has been suggested in children and young adults (13), because of their higher risk for the development of EBV-related lymphoproliferative disease. General EBV screening is not recommended (LE: 3).

Recommendations	GR
Active infection, which may exacerbate after transplantation causing life-threatening infection, is a contraindication to transplantation.	B
Carry out screening for viral and bacterial diseases in all transplant candidates. Screen all patients for HBV, HCV, HIV, CMV, and TB (history and chest x-ray).	B
Routine screening examination of all patients in all subspecialties is not necessary.	B

3.2.1.3 Other contraindications for transplantation

Transplantation should be offered to patients with potential for long-term survival of the graft because of the scarcity of organs, the complexity of the transplant procedure, and increased mortality associated with the transplant procedure itself.

A short life expectancy and conditions that interfere with compliance (e.g. severe psychiatric disease) are not acceptable risks for long-term success of transplantation. If there is non-compliance, a careful psychological examination should try to identify the underlying cause (14) and if possible institute an adequate treatment (15). Non-compliance is not a lifelong determinant of a personality and re-evaluation may be needed.

Recommendation	GR
In severe co-morbidity or non-compliance, a thorough and individual assessment should be performed.	C

3.2.2 ***Co-morbidity***

Due to the inherent risks of the surgical procedure, anaesthesia, and post transplant immunosuppressive therapy, a careful evaluation of potential transplant recipients is very important, particularly a cardiovascular work-up to reduce early graft failure due to technical problems and to improve patient survival in the post-transplant period (1-3).

3.2.2.1 Cardiac disease

Death with a functioning kidney allograft occurs frequently in kidney-transplanted patients, with cardiac death being the most important cause (16). Nevertheless, uraemic patients with cardiovascular disease are more likely to survive with a renal transplant compared to dialysis (17,18). However, patients with cardiac disease have a higher peri-operative risk (19,20). All candidates should therefore be given a careful history and physical examination for cardiac disease, including an electrocardiogram and chest x-ray (21) (LE: 3).

An additional, extensive cardiac work-up is recommended for patients with a history of coronary heart disease, severe peripheral artery disease, or a history of stroke or severe occlusive cerebrovascular disease, and a long history of renal insufficiency/dialysis (22,23), as well as for elderly and/or diabetic patients (22,24,25) (LE: 3).

The work-up includes (22,23):

- Echocardiography to detect valvular disease, cardiomyopathy, and systolic and/or diastolic left ventricular dysfunction (26).
- Exercise electrocardiogram and/or exercise thallium scintigraphy or stress echocardiography in patients with a low exercise capacity (22,23).
- Coronary angiography in every suspicious case, especially in dialysis patients who are elderly and/or diabetic, or in patients with a long history of renal disease (27).

Revascularisation, either surgical or by coronary angioplasty, should be performed in every suitable transplant candidate (18,24) before transplantation (LE: 3).

Recommendations	GR
Pre-transplant work-up should focus on the presence of cardiac disease.	B
In patients with a high risk of cardiac disease, an extensive work-up is strongly recommended to firmly rule out coronary artery disease.	B
Perform any revascularisation before transplantation.	B

3.2.2.2 Peripheral artery disease, cerebral occlusive vascular disease

Peripheral artery disease is common in uraemic patients (28). In potential kidney transplant recipients, very severe pelvic vessel disease may prohibit transplantation, be a significant cause of technical graft failure, and may enhance the risk of amputation. Cerebral vascular occlusion may lead to post-operative morbidity and mortality (29,30).

Evaluate the patient carefully for signs and symptoms of vascular occlusive disease. Pelvic radiography should be done routinely before transplantation (31,32). If there is vascular calcification, signs and symptoms or risk factors (e.g. age, diabetes, length of time on dialysis) of vascular occlusive disease, perform a thorough work-up, including duplex ultrasonography of the peripheral and cerebral arteries (33), and/or non-contrast enhanced abdominal-pelvic CT scan. In selected patients, angiography and pre-transplant arterial repair can be indicated. Avoid contrast-enhanced MRI because of the risk of nephrogenic systemic fibrosis (34) (LE: 3).

Recommendation	GR
During pre-transplant work-up, special attention should be paid to iliacal, peripheral, and cerebrovascular disease. Appropriate diagnostic and therapeutic measures are recommended.	C

3.2.2.3 Diabetes mellitus

Patients with diabetes mellitus have an increased mortality and reduced long-term graft outcome compared to non-diabetic patients following kidney transplantation (35). Nevertheless, diabetes mellitus itself is not a contraindication for kidney transplant (1-3). Furthermore, a kidney-only transplant or a combined kidney-pancreas transplant will reduce the long-term morbidity and mortality of uraemic diabetic patients compared to dialysis (36,37) (LE: 3).

Thus, kidney transplantation should be considered in every diabetic uraemic patient who has no other severe contraindication, especially cardiovascular disease. In patients with diabetes type I, a combined kidney-pancreas transplant is preferred because it improves blood glucose control and slows progression of cardiovascular disease (38,39) (LE: 3).

Because there is an exceptionally high incidence of cardiovascular disease in diabetic dialysis patients (21-23), it is usually necessary to exclude patients with a high vascular risk using peripheral angiography or non-invasive imaging procedures (e.g. CT scan) (27). Bladder neuropathy is a common complication in diabetic patients (40) and a urological clinical work-up should be performed. In selected patients, an urodynamic examination is needed (LE: 3).

Recommendation	GR
Patients with diabetes mellitus should be transplanted. They require an extensive pre-transplant work-up.	B

3.2.2.4 Obesity

Overweight patients have a higher incidence of surgical and non-surgical complications (41,42). Weight is a traditional risk factor for diabetes, hypertension, and cardiovascular disease. However, renal transplantation provides a better survival and better quality of life in overweight dialysis patients (43,44) (LE: 3). There is not enough evidence to recommend exclusion based on body mass index (BMI).

Recommendation	GR
Obesity itself is not a contraindication for transplantation. However, a thorough pre-transplant evaluation and attempt to reduce weight are recommended.	C

3.2.2.5 Coagulopathies

Coagulation disorders have a negative impact on post-transplant graft survival, leading to early graft thrombosis or post-transplant thrombotic complications (45,46). Early post-transplant anticoagulation may

prevent thrombosis and early graft loss (47,48). As a consequence, a pre-transplant work-up should include the diagnosis of coagulopathies, especially in patients with recurrent shunt thrombosis or with a history of thrombotic events. In these patients, a careful pre-transplant assessment is mandatory, including ATIII, protein C, activated protein C resistance (Factor V Leiden), protein S, and anti-phospholipid antibodies (LE: 3).

Patients on anticoagulant treatment, e.g. warfarin, acetylsalicylic acid, clopidogrel, are not excluded from transplantation. During surgery, special precautions for anticoagulant use are needed.

Recommendation	GR
A careful examination of coagulopathies in patients at risk in order to prevent early post-transplant thrombotic events is recommended.	C

3.2.2.6 Other diseases with potential influence on post-transplant outcome

Some conditions or diseases may follow an aggravated clinical course after transplantation due to immunosuppressive therapy and/or may place the transplanted kidney at a higher risk for complications (1-3). Important examples are diverticulosis, with or without previous episodes of diverticulitis, cholecystolithiasis, and hyperparathyroidism. Decisions for pre-transplant treatment should be made by a multidisciplinary team on an individual basis with appropriate patient counselling (LE: 4).

Mental retardation and psychiatric diseases are not necessarily contraindications for transplantation (1-3). If the patient is able to understand the procedure and can adhere to the procedures and medication required, such patients are eligible for transplantation (LE: 4).

Recommendation	GR
Diseases that might influence post-transplant course should be identified during pre-transplant work-up and if possible treated before transplantation.	C

*3.2.3 **Age***

Although there is no controversy about the fact that a kidney transplant offers improved survival and quality of life in younger patients with ESRD, an ongoing debate exists about kidney transplants in the elderly.

Reduced mortality in patients over 65 years of age has been shown in transplanted patients compared to patients on the waiting list (35,36) and reasonable outcomes have been reported for elderly transplant recipients (49,50) (LE: 3). However, a prolonged waiting time in this patient subgroup significantly decreases the beneficial clinical outcome and socio-economic advantages of transplantation (51,52). Every effort should be taken to reduce waiting times in the elderly (> 65 years). Elderly transplant patients should be enrolled in special programmes such as the Eurotransplant (ET) Senior programme (50), as well as applying for living-donor transplantation (LE: 3).

In elderly dialysis patients selected for kidney transplantation, special attention must be paid to concomitant cardiovascular disease and possible pre-existing cancer (53). Patients should be informed about the potential hazards of transplantation, including a high fatality rate in the first year after transplantation (and infection during the first year post-transplant (49,50,53-56) (LE: 3). If there are any signs of age-related dementia, a psychological evaluation should be instituted.

Recommendation	GR
Although age itself is not a contraindication for transplantation, a thorough pre-transplant evaluation is needed. A careful risk-benefit evaluation must be performed and the patient should be counselled on the increased risks associated with age.	B

*3.2.4 **Recurrence risk (original renal disease)***

An histological recurrence of original renal disease is common in a transplanted kidney. Despite high recurrence rates in some diseases, overall graft loss due to recurrence is less than 10% after 10 years (57,58). Higher recurrence rates have occurred in living related donors and living donation should therefore be critically discussed, especially in diseases with early and very high recurrence rates (LE: 3).

Some rare renal diseases with a high recurrence rate, which can lead to an immediate graft loss, are contraindications for transplant. They include light-chain deposit disease (LCDD), primary oxalosis, and anti-glomerular basement (anti-GBM) antibodies (1-3). However, transplants may still be possible in some circumstances:

- Patients with anti-GBM disease can be given a transplant after disappearance of anti-GBM antibodies (1-3) (LE: 3).

- In patients with primary oxalosis, combined liver-kidney transplantation is recommended (1-3) (LE: 3).
- In patients with amyloidosis or LCDD, no treatment guidelines exist. In this very rare group of patients, case reports and small case series describe successful chemotherapy or autologous stem cell transplantation, with or without kidney transplantation (59-61) (LE: 3).

In patients with systemic diseases (e.g. lupus, vasculitis, haemolytic uraemic syndrome), the underlying disease should be treated and the patient should be in remission before transplantation (1-3) (LE: 3).
For most patients with glomerulonephritis, no special precautions are recommended (1-3). Focal and segmental glomerulosclerosis (FSGS) may recur early after transplantation (62,63) and may be treated with plasmapheresis and/or with anti-CD20 antibody (rituximab) (64,65). When a previous graft has been lost because of recurrent glomerulonephritis, especially FSGS, the patient must be counselled on the higher risk of graft failure in a second transplant. However, successful long-term outcomes have occurred in these patients (62,63) (LE: 3).

Recommendations	**GR**
Recurrence of the original disease is common, but graft loss due to recurrence is infrequent.	C
Only a few rare diseases with a high recurrence rate leading to early graft loss are a contraindication for renal transplant.	C
Patients with the risk of recurrent diseases should be counselled before transplantation, especially before living related kidney transplant.	C

*3.2.5 **Patients with a previous transplant***

Assess patients with a previous graft loss carefully for malignancy, cardiovascular disease (1-3), and for increased immunological risk because of the development of antibodies against the first graft (66). Gradually discontinue immunosuppression following graft failure, as continuous immunosuppressive therapy has a higher risk of complications under renal replacement therapy (67,68) (LE: 3). If the graft becomes symptomatic, perform graft nephrectomy immediately (69). Graft embolisation (70) may be an alternative. However, prophylactic transplantectomy does not seem to be beneficial (71-73). Take appropriate measures to avoid repeated alloantigen mismatches (LE: 3).

Patients with a previous non-renal organ transplant, who develop ESRD (74,75), also benefit from renal transplantation, as there is a high risk of severe complications with a combination of ESRD and continuous immunosuppressive therapy (76) (LE: 3). Work-up should pay special attention to malignancy, cardiovascular disease, potential immunisation, and potential graft dysfunction of the previously transplanted organ, which may therefore require a combined transplant procedure (LE: 3).

Recommendation
Pre-transplant work-up for patients with retransplantation or previous non-renal transplantation should focus on the immunological risk, including a thorough analysis for the presence of anti-HLA antibodies.

3.3 Transplantation in pregnancy

*3.3.1 **Planning pregnancy***

Chronic renal failure is often associated with sexual dysfunction and infertility. After kidney transplantation, sex life and fertility are improved (1). Both male and female patients should be counselled about the possibility of pregnancy. Ideally, pregnancy should be planned at a time of good general and graft health, usually not earlier or later than 1-2 years after transplant (2). In pregnancy occurring some years after transplantation, there is a risk that some chronic rejection and/or some deterioration of renal function may have developed.

If graft function and immunosuppressive therapy are stable, and there is no sign of rejection,

hypertension, proteinuria, hydronephrosis, or chronic infection, there is no significant difference in outcome between early, recommended, or late pregnancies (3) (LE: 2a). Hydronephrosis makes pregnancy riskier because of the increased possibility of infection and lithiasis, which may also worsen in the last trimester. Early detection of pregnancy is important so that monitoring and adjustment of immunosuppressive therapy can begin as soon as possible.

Recommendations	GR
Pregnancy should be planned at a time of good general and graft health, when renal function and immunosuppressive therapy are stable and there is no sign of rejection, hypertension, proteinuria, hydronephrosis, or chronic infection.	B
The second post-transplant year is the ideal period.	B

*3.3.2 **Graft survival***

Recently, the pregnancy rate in the kidney-transplanted population has increased from 2% to 5%. Successful gestations are common in female organ transplant recipients (4) (Table 16).

Table 16: Factors that may affect a kidney graft during pregnancy

Haemodynamic changes
Hypertension
Impairment of renal function (5-10) (LE: 2a)
Rejection (11)
Urinary tract infections

Pregnancies in transplanted women are often unproblematic, but these patients should always be considered high risk and require shared care by an obstetrician, nephrologist, and a urologist.

Recommendations	GR
After kidney transplantation pregnancy is possible and well tolerated for most patients with normal graft function.	B
However, pregnant transplanted women always must be considered at high risk and their care requires the co-operation of the obstetrician, nephrologist, and urologist.	B

*3.3.3 **Care during pregnancy***

The care of a pregnant transplanted patient should focus on the risk factors mentioned in Table 16. This includes checking for bacterial urinary tract infection with monthly urine cultures and always treating bacteriuria, whether symptomatic or asymptomatic. Antibiotics agents should be chosen from the penicillin and cephalosporine families to avoid fetal and renal toxicity. Every urological endoscopy requires antibiotic protection. Viral infections may be transmitted to offspring. If this is CMV, the baby may be mentally retarded. Amniotic culture will reveal any fetal infections (12).

Recommendation	GR
Care during pregnancy should focus on control of proteinuria, hypertension (pre-eclampsia affects 30% of patients), renal function, rejection, and infection.	B

*3.3.4 **Immunosuppressive treatment***

The common immunosuppressive treatment used during pregnancy is cyclosporine, with or without azathioprine and prednisone (6,13). These drugs pass the placental barrier but apparently do not increase the risk of teratogenicity. Blood cyclosporine levels may change, and usually decrease, especially during the third trimester because of increased volume distribution and pharmacokinetic changes. Its dosage should usually be augmented. Recent papers suggest that the new drug tacrolimus (14,15) (LE: 3, 2b) used in kidney, heart, and liver transplantation might also be safe. There are only sporadic reports on the effects of mycophenolate mofetil (MMF), which, like sirolimus, is contraindicated due to teratogenicity (16).

Recommendations	GR
Cyclosporine and tacrolimus do not seem to increase the risk of teratogenicity and they are currently used with or without steroids and azathioprine.	B
Treatment with mycophenolate (mycophenolate mofetil or mycophenolate sodium) or m-TOR inhibitors (sirolimus or everolimus) is not recommended.	B

3.3.5 ***Follow-up***

Rates of spontaneous (14%) or therapeutic (20%) abortions in transplanted women are similar to those in the general population. Although a vaginal delivery is not mechanically impaired by an abdominal graft, pre-term delivery and a high rate (50%) of Caesarean sections are observed, due to a high incidence of prematurity (uncontrolled hypertension, fetal distress, rupture of membranes weakened by steroid use). About 20% of babies have a low birthweight (mean birthweight 2.5 kg ± 0.67 vs normal birthweight 3.5 kg ± 0.53) (17,18), but congenital abnormalities are no higher than in the general population. Breastfeeding is not suggested because of the baby's risk of ingesting immunosuppressive agents. A close follow-up of the mother in the first three post-partum months is recommended, including weekly renal function tests. Delay vaccinations until the infant is 6 months old.

There are few data on the growth, long-term outcome, or adult life of children born from kidney-transplanted mothers. Offspring are often born prematurely and have a reduced birthweight. Long-term studies on fetal exposure to immunosuppressive therapy have only recently begun. No other important data exist at present. Children of fathers in immunosuppressive treatment following kidney transplantation are clinically not different from those of the general population. They are aborted less often than foetuses of kidney-transplanted mothers. However, if the father is affected by hereditary disease, there is a higher risk of transmission.

Recommendations	GR
If there is no premature condition or fetal distress, vaginal delivery can be considered.	B
Breastfeeding is not recommended because of the potential risk of ingesting immunosuppressive agents.	B

4. TRANSPLANTATION TECHNIQUES

4.1 Transplant preparation and transplant techniques in adults

Transplant preparation is a crucial step in the transplantation process and should not be neglected. Key points of transplant preparation are listed in Table 17. The transplant procedure in adults, with special considerations, is detailed in Table 18.

Table 17: Transplant preparation

Kidney
Place the kidney on a sterile iced bed
Check for the absence of renal tumours
Tie all that is cut near the hilus (lymphostasis)
Vein
The right kidney should be removed, together with the infra renal vena cava for lengthening the renal vein on
the back table (1)
Artery
Preserve the aortic patch and check the intima of the renal ostium
In severe atheroma in the ostium, remove the aortic patch
In multiple arteries, back table reconstruction could be necessary (2,3)
Ureter
Preserve peri-pyelic and proximal peri-ureteral fat in the ‘golden triangle’
Check for double ureter

Transplant biopsies
Systematic in some centres because it can be very important to follow the long-term histological modifications of the transplant

Table 18: Transplant technique

Transplant technique in adults
Approach
Extra peritoneal approach of one iliac fossa
Transplantation is possible either into the contralateral or ipsilateral iliac fossa
Lymphostasis with clips or ligatures to avoid lymphocele is mandatory
Total mobilisation of the external iliac vein may avoid traction on the venous anastomosis (sometimes ligation of the internal iliac vein is necessary particularly for right transplant with a short vein)
Minimal dissection of the iliac artery
Vascular anastomosis
Generally external iliac vessels are used; avoid atheromatous plaques
Choose the sites of vascular anastomosis according to the length of each vessel to avoid plication or traction
Both anastomoses are performed with two halves of running non-absorbable monofil 6x0 or 5x0 sutures
Internal iliac artery should not be used except in specific situations
An orthotopic kidney transplant is possible to both the left and right iliac fossa (4)
Ureteral anastomosis
Extravesical implantation at the antero-lateral surface of the bladder is the method of choice. Suture the ureter to the bladder mucosa using two halves of running absorbable 6x0 or 5x0 sutures. This technique gives better results than open implantation to the bladder (5,6)
A double-J stent may be placed to protect the anastomosis, particularly in cases of tricky anastomoses.
Prophylactic double-J stenting prevents major urinary complications (7,8) ((LE; 1a)
The uretero-ureteral anastomosis is an alternative to a very short or poorly vascularised transplant ureter. It is also used for a third transplant or in children (9). A JJ-stent is absolutely necessary in these cases (LE: 3).
Intravesical implantation is an alternative in experienced hands (low rate ureteral complications). There is no data discussing placement of a double-J stent in intravescial implantation
Special considerations
Kidneys taken from children weighing < 15 kg
In adults, en-bloc transplantation should be performed, including the aorta and the inferior vena cava
The two ureters are anastomosed in double pant using the extra-vesical technique
Vascular problems in the recipient
If the iliac arteries do not allow clamping, endarterectomy or a simultaneous vascular prosthesis has to be performed (10)
If a prosthetic replacement has been previously carried out, implant the renal artery into the prosthesis using a punch perforator (11)
If iliac vein and/or vena cava are thrombosed, native renal vein or superior mesenteric vein can be used. However, in most cases, transplantation must be stopped
Postoperative heparinisation is not routinely indicated in non-risky live-donor renal transplantation (12) (LE; 1b)
Paediatric recipient
Large kidneys must be placed in a higher position towards the lumbar fossa, using the aorta or the right common iliac artery and the inferior vena cava
Iliac fossa is an option for young recipients (13,14) (LE: 3)

Recommendations	GR
It is essential not to neglect transplant preparation. This is a crucial step in the transplantation process.	C
Take care with lymphostasis into the recipient and during the graft preparation.	C

Vascular anastomosis sites should take into account the differences in vessel length.	C
JJ-stent may be used routinely.	C
Check the arterial and venous status before transplant.	C
Iliac fossa may be an alternative in children less than 20 kg provided the graft is small enough.	C

4.2 Early complications

*4.2.1 **General complications***

4.2.1.1 Wall abscesses (5%)

These are more common when the recipients are obese or old. Risk factors include diabetes, haematoma, urine lake posttransplant, obesity, rejection, or over-immunosuppression (15,16). Abscesses can be prevented by minimising electrocoagulation and using subcutaneous aspirational drainage in obese patients. A superficial abscess can be treated with a simple opening of the wound, while a deep abscess requires surgical drainage. It is important to look for urinary fistulae (LE; 3)

4.2.1.2 Haemorrhage

Risk factors include acetylsalicylic acid, poorly prepared transplant hilus, multiple renal arteries, renal biopsies and hyper-acute rejection (HAR) (17-19). A large haematoma or active bleeding requires surgical drainage. Following drainage, the uretero-vesical anastomosis must be checked and a JJ-stent may be inserted.

4.2.1.3 Haematuria

After transplant biopsy, look for arterio-venous fistula (AVF) (20). Selective percutaneous embolisation is necessary for large AVF and for recurring haematuria. Clotting may cause ureteral obstruction, increasing the risk of haematuria. Dialysis may be necessary if ureteral stenting or percutaneous nephrostomy are ineffective.

4.2.1.4 Incisional hernia (3-5%)

Risk factors include age, obesity, diabetes, haematoma, rejection, reoperation through transplant incision and finally m-TOR inhibitors (LE; 3). Treat in a similar way to a 'classical' incisional hernia with or without synthetic mesh (15,16,21,22).

*4.2.2 **Urinary fistulae***

Urinary fistulae are the most common early complication. They occur in 3-5% of cases in which a double J-stent has not been used (24-25). They can occur on the ureter, bladder, or parenchyma. The most frequent cause is ischaemic necrosis of the ureter (24,26).

4.2.2.1 Management

If it is possible to localise the fistula, it is worth trying nephrostomy and/or a vesical catheter and double J-stent. Stented re-implantation is possible if necrosis is very distal and the ureter is long enough. Otherwise, uretero-ureteral anastomosis is performed using the patient's original ureter (27). Vesical fistulae can be treated by suprapubic or transurethral catheter. Calyceal fistulae may be treated by JJ-stent and vesical catheter. In most cases, polar nephrectomy and omental plasty are necessary (28).

Recommendations	**GR**
Use a short ureter and keep the peri-ureteral fat around the hilus (29).	C
Avoid ligature of polar artery because of the risk of parenchymal and ureteral necrosis.	C
Prophylactic use of JJ-stent prevents major urinary complications (8).	A

*4.2.3 **Arterial thrombosis***

The incidence of arterial thrombosis is 0.5% in the first post-operative week. Risk factors include atherosclerosis, unidentified intimal rupture, poor suture technique, kinking if the artery is longer than the vein or the anastomosis is incorrectly sited, multiple arteries (30), and paediatric transplants (31-33). It should be suspected if there is primary non-function or sudden anuria. It is diagnosed by Doppler or technetium scan and confirmed by CT scan.

4.2.3.1 Treatment

Surgery is always necessary. A radiological endovascular may be carried out successfully within the first 12 h. However, tolerance to warm ischaemia is poor and most transplants have to be removed.

Recommendations	GR
Importance of procurement technique quality.	C
Preserve when possible the aortic patch; otherwise, use a punch perforator to create a large arterial opening.	C
Look for a possible intimal rupture before performing anastomosis.	C
Avoid plication of the artery.	C
Sudden anuria should lead to Doppler,	C

*4.2.4 **Venous thrombosis***

Venous thrombosis is rare, occurring in 0.5% of kidney transplants in adults and in 2.5% in paediatric patients (33,34). It is suspected by primary non-function, haematuria, or anuria and is diagnosed by Doppler or technetium scan. Salvage thrombectomy has a very poor success rate and transplantectomy is often necessary.

Recommendations	GR
Lengthen the right renal vein with the infra renal vena cava.	C
Carry out a large venous anastomosis.	C
Avoid post-operative drop in blood pressure.	C
If there is a history of thrombosis., check for hypercoagulation or Leiden factor V mutation.	C
Sudden anuria should lead to Doppler.	C

4.3 Late complications

*4.3.1 **Ureteral stenosis***

The renal calyces and pelvis are dilated and there is often an elevated creatinine level. These stenoses occur in 5% (range, 2-7.5%) of transplants (35-37). They can present late between 1 and 10 years' post transplant (38). There are three causes of ureteral dilatation:

- vesical high pressure with thickened bladder wall or urinary retention, which is treated by bladder drainage;
- vesicorenal reflux, which is not an obstruction;
- ureterovesical stenosis due to scar formation and/or poor surgical technique. These comprise 80% of ureteral stenoses. Most occur during the first year post transplant, although the risk of occurrence increases with time to 9% of transplant patients at 10 years.

Risk factors include multiple arteries, donor's age, cold ischemia time, delayed graft function, and CMV infection (35).
Initial treatment involves percutaneous drainage and checking renal function to see if it has improved. Imaging should then be done to determine the level of stenosis, degree, and length. Further treatment depends on the level of stenosis, degree, and delay of occurrence. This can be endoscopic, either transurethral or percutaneous. The outcome of dilatation is better when the stenosis is early, distal, and short (39-43). Treatment can also be with open surgery using a uretero-ureteral anastomosis to the patient's ureter or a vesicopyelostomy.

Recommendations
Use a short and well-vascularised ureter, surrounded by peri-ureteral fat.
Preserve peri-pyelic and proximal peri-ureteral fat in the 'golden triangle'.
Do not narrow the anastomosis and the antireflux tunnel.
Yearly routine echography.

*4.3.2 **Reflux and acute pyelonephritis***

Acute pyelonephritis is a rare complication (44,45). Reflux in the renal cavity is more common (46). Reflux is found in up to 30% of cases after Leadbetter and in 80% after Lich-Gregoire if the submucosal tunnel is short and in 10% if the tunnel is long. In lower urinary tract infections, the risk of acute pyelonephritis is 80% with reflux and 10% without reflux. Every reflux complicated by acute pyelonephritis should be treated with an endoscopic injection. This has a success rate of 30-78% (47,48). If this fails, try using a uretero-ureteral anastomosis if the native ureter is not refluxive, or a ureterovesical re-implantation with a long tunnel if the original ureter is refluxive or non-usable.

Recommendations
The anti-reflux tunnel for the uretero-vesical anastomosis should be 3-4 cm long.
Avoid lower urinary tract infections.
Endoscopic treatment might be the first option for the treatment of symptomatic reflux.

*4.3.3 **Kidney stones***

Kidney stones may be transplanted with the kidney or may be acquired. The incidence is less than 1% of transplants (49,50). The stones manifest themselves by haematuria, infection, or obstruction. Diagnosis may require non-injected CT scan. Some stones are eliminated spontaneously, but if stones do need to be removed, there are several options (51):

- The first step should be to try a JJ-catheter or echo-guided percutaneous nephrostomy.
- Calyceal and smaller renal stones should be treated by extracorporeal shock wave lithotripsy (ESWL).
- Larger stones should be removed by percutaneous (52) or open nephrolithotomy.
- Ureterolithiasis should be treated by ESWL (53) or by ureteroscopy (54).

Recommendations
Treat hyperparathyroidism in the recipient.
Use absorbable threads for the urinary anastomosis.
Treat urinary obstructions and infections.
Check calciuria.

*4.3.4 **Transplant Renal Artery Stenosis***

Transplant Renal Artery Stenosis (TRAS) has an incidence of 10% (range, 1-23%). TRAS risk factors are donor and recipient age, expanded criteria donor, delayed graft function, ischemic heart disease and induction immunosuppression (55). It is suspected when existing arterial hypertension becomes refractory to medical treatment and/or there is an increase in serum creatinine without hydronephrosis (56,57). It is diagnosed by Doppler sonography showing high velocity > 2m/s.

Treatment options include medical treatment and renal function follow-up, with interventional treatment indicated if the stenosis is > 70% (58). Transluminal dilatations, with or without stenting, give poorer results (70%) than surgery, but their simplicity makes them the first-line treatment for aligned and distal stenosis (34,59).

Open surgery is reserved for plication or anastomotic stenosis, failure of percutaneous dilatation, and involves resection with direct implantation. Repair with the saphenous vein must be avoided.

Recommendations
Use aortic patch from the donor.
Examine the artery intima, fix it or re-cut the artery when necessary.
Keep a long left renal vein, and lengthen the right one with the vena cava.
Avoid too tight anastomoses.

*4.3.5 **Arteriovenous fistulae and pseudo aneurysms after renal biopsy***

Arteriovenous fistulae are seen in 10% (range, 7-17%) of cases and are suggested by repeated haematuria (60,61). Diagnosis is by Doppler ultrasound and is confirmed by MRI or by angiography. Angiography is also the first step in treatment. Fistulae may regress spontaneously (20), but when persistent haematuria or when diameter > 15 mm, selective embolisation should be used. Pseudo aneurysms are often due to mycotic infection (62) and can be fatal.

Recommendation	GR
Avoid very deep biopsy reaching the renal hilum.	C

*4.3.6 **Lymphocele***

Lymphocele comprises 1-20% of complications. It occurs secondary to insufficient lymphostasis of the iliac vessels and/or of the transplant kidney. Obesity and the use of some immunosuppressant agents such as m-TOR inhibitors are associated with a higher risk of lymphocele (63-65). Generally, it is asymptomatic, but there may be pain caused by ureter compression or infection. No treatment is necessary for mild lymphocele or if there is no compression of the iliac vessels or the transplant ureter. Otherwise, laparoscopic marsupialisation

is the treatment of choice. Open surgery is indicated when laparoscopy (66) is not available or dangerous (67).

Recommendation	GR
Strict lymphostasis should be maintained by clips or ligatures of the lymphatic vessels of the transplant and during dissection of the iliac vessels.	C

4.5 Kidney transplantation in abnormal urogenital tract

The following points should be considered when performing kidney transplantation in the abnormal urogenital tract:

- The technique used to implant transplant ureters in augmentations or conduits is the same as the method used with a patient's own ureter, e.g. following cystectomy for bladder cancer (Bricker, Wallace) patients.
- In patient with ileal conduits, kidney transplant may be placed upside down to avoid ureter loops
- In bladder augmentations or continent pouches, ureters are implanted by tunnel technique (Goodwin-Hohenfellner), or extravesically (favoured in most patients), e.g. using Lich Gregoir or Leadbetter methods (1-3).
- In ureterocystoplasty, it is feasible to perform uretero-ureterostomy with one of the patient's own ureters (1,4).
- In patients with continent ileocoecal pouches with umbilical stoma or ileocystoplasties/ileal neobladders, transplant kidneys must be placed on the contralateral left side with the transplant ureters, crossing the abdomen subsigmoidally (2,3,5) (LE: 3-4).

5. MATCHING OF DONORS AND RECIPIENTS

Recommendations	GR
The ABO blood group and the HLA-A, -B, and -DR phenotypes should be determined for all candidates awaiting kidney transplantation.	B
To avoid hyper-acute rejection, a lymphocyte cross-match test must be performed before each kidney and combined kidney/pancreas transplantation.	B

5.1 Histocompatibility (HLA) matching

Histocompatibility (HLA) matching is still very important in kidney transplantation because transplant outcome correlates with the number of HLA mismatches (1,2). HLA incompatibility can result in proliferation and activation of the recipient's CD4+ and CD8+ T-cells with concomitant activation of B-cell allo-antibody production. This leads to cellular and humoral graft rejection.

Histocompatibility antigens show remarkable polymorphism. Matching should concentrate on HLA antigens, which impact on rejection rates. The HLA-A, HLA-B, and HLA-DR phenotypes should be determined in all potential recipients and donors. Kidneys from deceased donors should preferentially be allocated to potential recipients with the lowest number of HLA mismatches. This is also true for living-donor transplantation, although HLA-compatibility is less important in living- than in deceased-donor kidney transplantation (3). In living-donor transplantation, other risk factors for graft rejection, e.g. cold ischaemia time, brain death, and donor's age, can be minimised.

5.1.1 ***Practical aspects of HLA-testing***

Laboratories that provide HLA-testing and cross-matching for a transplant centre must have a valid accreditation to ensure accuracy and reliability. They must follow the standards of national and international organisations, such as the European Federation for Immunogenetics. Other practical considerations include (4,5):

- Obtain cells for HLA-typing from the recipient's peripheral blood using an appropriate anticoagulant, e.g. ammonium heparin, ethylene diamine tetra-acetic acid (EDTA) or acid-citrate-dextrose (ACD). Most HLA laboratories use 20 mL heparinised peripheral blood for serological HLA typing and 10 mL EDTA peripheral blood for molecular typing.
- Type donors using lymphocytes from lymph nodes, spleen, or peripheral blood.
- Use a comprehensive set of reagents capable of detecting all commonly occurring HLA antigens in the relevant ethnic group.
- For HLA-A and HLA-B specificities, serological or molecular typing is accepted. For HLA-DR, only molecular typing is accepted. For reporting HLA antigens, the latest WHO nomenclature should be used (6).
- Use family typing or DNA typing to detect possible homozygosity if the phenotype of a potential recipient shows fewer than six HLA-A, -B, -DR antigens.

5.2 Cross-matching

To avoid hper-acute rejection (HAR), a cross-match test must be performed before each kidney and combined kidney/pancreas transplantation. Patients at risk are those who have HLA-specific allo-antibodies or have had an allo-immunising event, such as pregnancy, blood transfusion, or a previous transplantation.

The cross-match test detects preformed allo-antibodies in the recipient's serum directed against lymphocytes of the potential donor. Routinely, a complement-dependent lymphocytotoxicity (CDC) assay is used. Cross-matches must be carried out using unseparated lymphocytes or T-enriched lymphocytes of the potential donor. B-cell cross-matches must be performed if required by the relevant transplantation programmes. T-lymphocytes express only HLA class I antigens. As B-lymphocytes express, besides HLA class I antigens also HLA class II antigens on their surface, a B-cell cross-match is considered to be more sensitive than a cross-match with T-lymphocytes. Spleen contains more B-lymphocytes than peripheral blood. A cross-match with unseparated lymphocytes from spleen is therefore more sensitive than a cross-match with unseparated lymphocytes from peripheral blood. A positive T-cell cross-match is generally a contraindication to transplantation. A positive B-cell cross-match result can occur for different reasons, including anti-HLA class I/II antibodies or allo-antibodies, immune complexes, therapy with anti-B-cell agents (rituximab, alemtuzumab), and non-HLA allo-antibodies (not shown yet). For a positive B-cell cross-match, individual decisions should be made based on the recipient's antibody status and immunological history. Sera obtained 14 days after a potentially sensitising event should be included in a final cross-match.

Be aware of false-positive cross-match results, especially in autoimmune diseases, which often exhibit clinically irrelevant IgM auto-antibodies. Inactivation of IgM antibodies by serum treatment with dithiothreitol (DTT) can minimise false-positive cross-match results. However, be aware that IgM-anti-HLA allo-antibodies are also DTT-sensitive. Anti-HLA allo-antibodies of the IgM isotype are rare and a positive cross-match result due to IgM-anti-HLA is currently considered as potentially relevant.

Flow cytometry cross-match may be used in presensitised recipients at high risk of antibody-mediated graft rejection. However, the great sensitivity of flow cytometric cross-match may exclude unnecessarily a high number of patients from transplantation (1,7). An enzyme-linked immunosorbent assay (enzyme-linked immunosorbent assay, ELISA) cross-match test, which uses solid-phase technology to detect donor-specific anti-HLA antibodies, is being evaluated.

5.3 Pre-existing HLA-specific antibodies

Sera from potential organ recipients should be screened for HLA-specific antibodies every 3 months or as stipulated by the national and/or international organ exchange organisations.
Screening for HLA-specific antibodies should be carried out at 2 and 4 weeks after every immunising event, e.g. blood transfusion, transplantation, pregnancy, and graft explantation.

The results of HLA-antibody testing in a recipient's serum are expressed as the percentage of panel reactive antibodies (%PRA) and as the HLA specificity against which these antibodies react. To detect antibodies to HLA class II antigens, a technique must be used that distinguishes them from antibodies to HLA class I antigens. In the standard CDC assay, the panel of lymphocytes used cover most of the common HLA-alleles in the donor population and should optimally contain at least 50 different HLA-typed cells.

As the assay is not sufficiently sensitive, clinically relevant anti-HLA class I and class II antibodies may go undetected in the traditional microlymphocytotoxicity assay (8). Non-complement fixing antibodies are not detected at all. More specific and sensitive solid-phase techniques have been developed, such as flow cytometry and ELISA, which use solubilised or recombinant HLA molecules instead of lymphocytes. Preformed non-HLA allo-antibodies may also influence graft outcome (9). Solid-phase assays are strictly HLA-specific and cannot detect non-HLA antibodies. It is not clear whether clinically relevant non-HLA antibodies are expressed on B-lymphocytes and can therefore be recognised by lymphocytotoxicity testing. No antibody screening methods can reliably detect all clinically relevant allo-antibodies, and a combination or alternate use of lymphocytotoxic and solid-phase antibody screening methods is therefore recommended (6).

Presensitised patients with high PRA have two major disadvantages:

- Due to an often positive cross-match, they generally wait longer for an organ than non-sensitised patients;
- Overlooked antibodies or higher alloreactivity in the cross-match may adversely affect the graft outcome.

*5.3.1 **Eurotransplant Acceptable Mismatch (AM) programme***

Special efforts, such as the acceptable mismatch (AM) programme of Eurotransplant, have achieved successful transplantation in highly sensitised patients (PRA ≥ 85%) (10). A careful analysis of HLA antibody specificities is carried out to avoid unacceptable HLA antigens and to determine acceptable HLA antigens in potential donors, who are expected to give a negative cross-match result. Patients accepted for the AM programme of

Eurotransplant are given high priority during organ allocation if the donor cross-match test is negative.

5.4 ABO compatibility

Compatibility for ABO blood group antigens is of critical importance in kidney transplantation. Since blood group antigens can behave as strong transplant antigens (i.e. expression on renal vascular endothelium), incompatibility in the ABO antigen system between donor and recipient can cause early HAR and must be avoided. However, with the introduction of antibody elimination methods and anti-B cell agents, increasing numbers of centres are performing successful ABO-incompatible transplantations, even without splenectomy (11).

Despite an elevated risk of post-transplant haemolytic disease due to resting donor B-cells in the graft, the kidneys of potential donors with blood group O can theoretically be transplanted in A, B, or AB recipients. To avoid an increasing imbalance between demand and supply in deceased-donor kidney transplantation in O recipients, ABO identity is demanded by several organ allocation organisations with a few exceptions, e.g. as in zero HLA-A+B+DR-mismatch kidneys. In living-donor transplantation, ABO compatibility is as acceptable as ABO identity.

6. IMMUNOSUPPRESSION AFTER KIDNEY TRANSPLANTATION

6.1 Introduction

The principle underlying successful immunosuppression is ‘the balance of survival’. Practitioners must prescribe a dosage of drug high enough to suppress rejection without endangering the recipient’s health. Increased understanding of immune rejection has led to the development of safe modern immunosuppressives

(1), which suppress sensitised lymphocyte activity against a transplant. Immunosuppression is particularly important during the initial post-transplant period when there is a high incidence of early post-transplant rejection.

In later post-operative stages, 'graft adaptation' occurs, resulting in the very low rejection rates seen in maintenance patients. Rejection prophylaxis should therefore be reduced over time by steroid tapering and gradual lowering of calcineurin inhibitor (CNI) (2,3) (LE: 1b).

Non-specific side-effects of immunosuppression include a higher risk of malignancy and infection, particularly opportunistic infections (1-3). All immunosuppressants also have dose-dependant specific side-effects. Current immunosuppressive protocols aim to reduce drug-specific side-effects using a synergistic regimen (4). A truly synergistic regimen allows profound dose reductions of immunosuppressive drugs, so reducing side-effects, while still maintaining efficacy due to the synergistic effects of the immunosuppressants (LE: 1b).

Current standard initial immunosuppression provides excellent efficacy with good tolerability (5,6). It is given to most patients and consists of:

- CNIs (cyclosporine or tacrolimus);
- Mycophenolate (MMF or enteric-coated mycophenolate sodium, EC-MPS);
- Steroids (prednisolone or methylprednisolone);
- With or without induction therapy.

This multidrug regimen reflects today the standard of care for the majority of transplant recipients worldwide (5,6) (LE: 1b).

This standard regimen is likely to change as new immunosuppressive drugs and new treatment regimens are developed (7). In addition, any initial drug regimen will need to be tailored to the individual needs of a patient as suggested by the appearance of side-effects, lack of efficacy or protocol-driven requirements (3,4,6).

6.2 Primary immunosuppressive prophylaxis

*6.2.1 **Calcineurin inhibitors (CNIs)***

Both cyclosporine and tacrolimus have significant side-effects that are hazardous to the graft and patient (1-3) (8,9). Most importantly, both are nephrotoxic (10,11) (LE: 1a), and long-term use is a major cause of chronic allograft dysfunction, eventually leading to graft loss or severe chronic kidney disease in recipients of non-renal organs (12).

6.2.1.1 Cyclosporine A

Cyclosporine A micro-emulsion (CsA-ME; Neoral) has a better pharmacokinetic profile and appears to be more acceptable to patients compared to the previous formulation (Sandimmune) (1,6,13,14). More importantly, the area under the absorption curve is higher with CsA-ME than with Sandimmune, enabling a reduction in the dosage of cyclosporine without affecting efficacy (8). CsA-ME treatment is also associated with a reduced rejection rate 1 year post transplant (8) (LE: 1b).

Although CsA-ME has proven efficacy and safety, it is a 'critical-dose' drug, so that any deviations from exposure can lead to severe toxicity or failure of efficacy (13,14). The demonstration of bioequivalence in healthy volunteers according to standard criteria is not sufficient evidence to support treatment of all renal allograft recipients with generic formulations of cyclosporine. Until more data are available, the patient and physician prescibing generic cyclosporine formulations must be aware of potential differences in exposure, maximal drug concentration, variability and food effects (15,16). Precautions (e.g. close surveillance and determination of drug levels) should be instituted after conversion from one cyclosporine formulation to another (13,14) (LE: 2a).

Pharmaceutical companies and researchers are asked to provide sufficient data on key pharmacokinetic parameters in target populations, including de-novo transplanted patients. Drug agencies should institute more stringent criteria for 'critical dose' drugs requesting approval (LE: 4).

Cyclosporine causes hypercholesterolaemia, hypertension, gum hypertrophy, constipation, hirsutism, and acne (1-3,8,10) (LE: 1a). Therapeutic drug monitoring is mandatory (17,18) (LE: 3) because of its narrow therapeutic window and the potential for drug-to-drug interaction. The drug level at 2 hours after intake (C2) may correlate better with exposure with retrospective studies suggesting a better correlation for C2 levels with outcome parameters (17,18) (LE: 3). However, no prospective comparative studies have been undertaken, and C2 levels alone may not adequately reflect cyclosporine exposure in the early post-transplant period (17,18) (LE: 2b). Furthermore, the determination of C2 levels may cause logistical problems. Most importantly, similar overall outcomes were achieved with conventional monitoring strategies. In summary, both cyclosporine-monitoring strategies are useful for assessing cyclosporine exposure. The additional measurement of a trough

level in C2-monitored patients or of a C2 level in trough-level monitored patients may provide a more accurate assessment of drug exposure (18) (LE: 4).

6.2.1.2 Tacrolimus

Tacrolimus is a more powerful immunosuppressive than cyclosporine, as indicated by its more potent prophylaxis of transplant rejection. However, its use is associated with diabetes, neurological side-effects (tremor, headache), hair loss, gastrointestinal side-effects (e.g. diarrhoea, nausea, vomiting), and hypomagnesemia (1-3,8,10) (LE: 1a). In combination with a mycophenolate, it may also more often cause over-immunosuppression, namely polyoma nephritis (19) (LE: 1b).

A new modified-release formulation (Advagraf), which allows once-daily dosing of tacrolimus (20,21), has been approved in Europe, though not yet in the USA. Advagraf fulfils standard bioequivalence criteria, although it results in slightly lower exposure, lower peak levels and lower trough levels, which therefore require a higher dosage to maintain exposure (20-23) (LE: 1b). Too low a level of exposure may be critical, especially early after transplantation.

Both tacrolimus formulations provide effective rejection prophylaxis and overall similar outcomes compared to cyclosporine (22) (LE: 1b). Because of its narrow therapeutic window and the potential for drug-to-drug interaction, tacrolimus should be monitored using trough levels, which provide a reasonable estimate for exposure (20,21) (LE: 3).

6.2.1.3 Summary

Meta-analysis of tacrolimus and cyclosporine has demonstrated similar outcomes with respect to overall patient and graft survival (8) (LE: 1a). Some analyses have shown that tacrolimus provided better rejection prophylaxis and was associated with slightly better graft survival, when censored for death in some analyses. Renal function was favourable for tacrolimus-treated patients, but did not reach statistical significance in most analyses. Several more recent trials have confirmed that rejection prophylaxis is better with tacrolimus (22,24,25), but failed to show any benefit with respect to patient and graft survival. Thus, in summary, both Calcineurin-inhibitors (CNIs) can be used for the effective prevention of acute rejection (LE: 1a).

In case of specific side effects of a CNI (e.g. hirsutism, alopecia, gingival hyperplasia, diabetes, polyoma nephropathy) conversion to the other CNI can be a successful strategy to reduce side effects (26,27) (LE: 1b). Due to differences in the efficacy and safety profile, the choice of CNI should include the individual risks and benefits for each patient (LE: 4).

Despite their side-effects, CNIs have been a cornerstone of modern immunosuppresive regimens for more than 20 years because they have resulted in an exemplary improvement in kidney graft survival. This has led to success in pancreas, heart, liver, and lung transplantation (1) (LE: 1a). Future protocols aim to minimise or even eliminate CNIs. However, until such strategies provide superior outcomes, CNIs remain the standard of care in the initial post-operative period (2,3) (LE: 1b). For severe CNI-related side-effects, CNI withdrawal, replacement, or profound reduction may be needed (10) (LE: 2b). Special attention should be paid to maintenance patients, which may need less CNIs than previously thought (26,28) (LE: 1b).

Recommendations	**GR**
Rejection prophylaxis with Calcineurin-inhibitors represents current best practice pending publication of long-term results using newer agents.	A
The choice of Calcineurin-inhibitors depends on the immunological risk, recipient characteristics, concomitant immunosuppression, and socio-economic factors.	A
Blood-level monitoring of both cyclosporine and tacrolimus is mandatory to prevent under-immunosuppression (enhanced risk of rejection) and excessively high blood levels (resulting in a high risk of chronic side-effects, particularly nephrotoxicity).	A

*6.2.2 **Mycophenolates***

The mycophenolates, MMF and EC-MPS, are based on mycophenalic acid (MPA), which inhibits inosine monophosphate dehydrogenase. This is the rate-limiting step for the synthesis of guanosine monophosphate in the de-novo purine pathway. As the function and proliferation of lymphocytes is more dependent on de-novo purine nucleotide synthesis compared to other cell types, inosine monophosphate dehydrogenase (IMPDH) inhibitors may provide a more specific lymphocyte-targeted immunosuppression (1). Mycophenolic acid is not nephrotoxic; however, it inhibits bone marrow function and may cause gastrointestinal side-effects particularly diarrhoea (29,30). Both MPA formulations are equally effective with an almost identical safety profile (29) (LE: 1b), though some prospective studies suggest a better gastrointestinal side-effect profile for EC-MPS in patients who have suffered from MMF-related gastrointestinal complaints, although firm evidence from prospective randomised studies is lacking (31,32) (LE: 2a).

The co-administration of mycophenolate with prednisolone and CNI has resulted in a profound reduction of biopsy-proven rejections (33) (LE: 1b). A retrospective study Mycophenolate mofetil decreased the relative rate for chronic allograft rejection by 27% versus azathioprine, an effect independent of the reduction of acute cellular rejection in patients receiving MMF (33) (LE: 3). Recent retrospective studies have suggested that MPA dose reductions are associated with inferior outcomes (31) (LE: 3).

Other side-effects include the potential for over-immunosuppression, especially a higher incidence of CMV infections and severe CMV disease, and a higher incidence of polyoma nephropathy, especially when mycophenolate is combined with tacrolimus (1-3) (LE: 1b). Standard doses in combination with cyclosporine are MMF 1 g bid or EC-MPS 720 mg bid (LE: 1b), although higher initial doses have been suggested, recently (34,35) (LE: 2b). MPA is not formally approved for use with tacrolimus, though this is the most frequently used drug combination in many countries worldwide (5). Despite its frequent use with tacrolimus, there is insufficient evidence to support the optimal dosage for this combination (34,35). Tacrolimus has no influence on MPA exposure and leads to approximately 30% higher MPA exposure compared to cyclosporine (34,35) (LE: 2a). Most transplant centres use the same starting dose compared to cyclosporine-treated patients (35) (LE: 2b), however dose reductions are frequent, especially because of gastrointestinal side-effects (35). After 6-12 months, most patients are treated with a daily dose of MMF, 1000-1500 mg, or EC-MPS, 720-1080 mg (22,24,25). Due to the high incidence of side effects, some centers perform a protocol-driven MPA dose reduction in tacrolimus treated patients (34,35) (LE: 3).

Regular monitoring for polyoma is recommended in patients given MPA combined with tacrolimus (36,37) (LE: 3).

Due to a higher incidence of CMV disease with MPA, either CMV prophylaxis or a pre-emptive strategy with regular screening for CMV viraemia should be instituted (37-40) (LE: 1a). CMV prophylaxis with antiviral medications (e.g. valganciclovir) should be used routinely in CMV positive recipients and in CMV negative recipients of CMV positive organ transplants, because prophylaxis recently has been shown to reduce CMV disease, CMV-associated mortality in solid organ transplant recipients (40), and leads to better long-term graft survival in kidney allograft recipients (38) (LE: 1a).

The benefit for MPA drug monitoring is uncertain and currently not recommended for the majority of patients (34,35,41-44) (LE: 1b).

In maintenance patients, the potency of MPA can be used for successful steroid withdrawal in most patients (45,46) (LE: 1a) or for substantial dose reductions of nephrotoxic CNIs, which may lead to better renal function (2,3,28,47) (LE: 1b). Although there have been several studies of the potential for CNI-free protocols with MPA and steroids, complete CNI avoidance or withdrawal over the first 3 years has been associated with a substantially increased rejection risk and even worse outcomes in prospective randomised studies (47-49) (LE: 1b). In contrast, CNI withdrawal under MPA and steroids appeared to be safe in long-term maintenance patients beyond 5 years' post-transplant and resulted in improved renal function (50,51) (LE: 1b). It is under investigation whether or not early CNI withdrawal under combination therapy of MPA, steroids and m-TOR inhibitors is safe and efficacious.

Recommendations	**GR**
Mycophenolates are the current standard of care. The standard dose of MMF combined with cyclosporine is 1 g bid or EC-MPS 720 mg bid.	A
Combination therapy of mycophenolates with tacrolimus is not formally approved. Optimal mycophenolate dosing is not yet clear, as tacrolimus-treated patients develop higher MPA exposure compared to cyclosporine-treated patients. The standard starting dose of MMF combined with tacrolimus is MMF 1 g bid or EC-MPS 720 mg bid. This dosage, which is applied in most centres, is often reduced resulting in 30-50% lower doses at 1 year.	A
Mycophenolate drug monitoring cannot be recommended for all patients due to limited evidence supporting its benefit.	A

6.2.3 ***Azathioprine***

Mycophenolate is now routinely used as a primary therapy in place of azathioprine in most units worldwide. In comparison to azathioprione, MPA reduced rejection rates significantly in prospective randomised trials (1,5,6,28,29) (LE: 1b). Although a recent, large, prospective study found that azathioprine may give acceptable results in a low-risk population (52) (LE: 1b), azathioprine is usually reserved for patients who cannot tolerate MPA (5,6). When added to dual therapy with cyclosporine and steroids, a meta-analysis found no significant benefit for azathioprine with respect to major outcome parameters (53) (LE: 1a).

Recommendations	GR
Azathioprine may be used in a low-risk population as initial immunosuppression, especially for those intolerant to MPA formulations.	A
There is no firm evidence for the efficacy of azathiprine in combination therapy with CNIs and steroids.	A

*6.2.4 **Steroids***

Steroids have a large number of side-effects (1-3,45,54), especially with long-term use. Most practitioners still consider prednisolone to be a fundamental adjunct to primary immunosuppression (5), even though successful prednisolone withdrawal has been achieved in the vast majority of patients in many prospective, randomised trials (45,46,55,56) (LE: 1a). These trials suggest the risk of steroid withdrawal depends on the use of concomitant immunosuppressive medication, immunological risk, ethnicity, and time after transplantation. Although the risk of rejection diminishes over time, potential benefits may be less prominent after a prolonged steroid treatment peroid. (1-3,45,54,57) (LE: 3).

Recommendations	GR
Initial steroid therapy remains the standard in perioperative and early posttransplant period.	A
There is increasing evidence that steroids may be safely stopped in most patients after 3-12 months on combination therapy with Calcineurin-inhibitors and myco phenalic acid.	A
Steroid-free long-term therapy is inherently associated with a reduction of steroid-induced side effects.	A

*6.2.5 **Inhibitors of the mammalian target of rapamycin (m-TOR)***

The immunosuppressants, sirolimus and everolimus, inhibit the mammalian target of rapamycin (m-TOR) and suppress lymphocyte proliferation and differentiation. They inhibit both calcium-dependent and calcium-independent pathways and block cytokine signals for T-cell proliferation. Similar effects are seen on B-cells, endothelial cells, fibroblasts, and tumour cells (1-3,57-60). m-TOR inhibitors are as effective as MPA when combined with CNIs in preventing rejection (57-60) (LE: 1b).

6.2.5.1 Side-effects

m-TOR inhibitors exhibit dose-dependent bone marrow toxicity. Other potential side-effects include hyperlipidaemia, oedema, development of lymphoceles, wound-healing problems, pneumonitis, proteinuria, and impaired fertility (57-60) (LE: 1b). When combined with CNIs, pneumocystis prophylaxis is mandated, e.g. low-dose cotrimoxazole (57-60) (LE: 3). Most importantly, combination therapy with CNIs aggravate CNI-induced nephrotoxicity, although m-TOR inhibitors themself are non-nephrotoxic (57-60) (LE: 1b). Several studies suggest less favourable outcomes for this combination, especially if CNIs are maintained at standard dosages (57-61) (LE: 3). Calcineurin-inhibitors dosage should therefore be substantially reduced in combination therapy with m-TOR inhibitors, which seems to have no impact on effcacy, due to the highly synergisitic potential of this combination therapy (57-60) (LE: 1b).

6.2.5.2 Comparison of pharmacokinetics and licensed use

To date, no prospective comparative studies have been carried out on sirolimus and everolimus. Both m-TOR inhibitors have an almost identical side-effect profile and mainly differ in their pharmacokinetic properties (57-60). Sirolimus has a half-life of about 60 h, is given once a day and is licensed for prophylaxis of kidney recipients only. Everolimus has a half-life of about 24 h, is licensed for kidney and heart recipients and is given twice a day. Everolimus is licenced for use with cyclosporine (57-60) (LE: 1b) and can be given simultaneously with cyclosporine, while sirolimus should be given 4 h after cyclosporine (57-60). Sirolimus is also licensed in combination therapy with steroids for cyclosporine withdrawal from combination therapy with cyclosporine (57-60) (LE: 1b).

Therapeutic monitoring of trough levels is recommended because of the narrow therapeutic window and the risk of drug-to-drug interactions (57-60) (LE: 3).

6.2.5.3 Conversion from CNIs to m-TOR inhibitors

Despite an encouraging earlier metaanalysis (60), recent studies suggest m-TOR inhibitors cannot replace CNIs in the initial phase after transplantation due to lower efficacy and a less favourable side-effect profile, particularly wound healing problems and lymphoceles (2,3,24,57-60) (LE: 1a). Other research suggests that m-TOR inhibitors can safely replace CNI at later stages, e.g. 3 months after transplantation, with improvements in renal function (2,3,57-60,62) (LE: 1a). However, especially early after transplantation, there is a slightly

increased risk of rejection, which may be offset by the benefit of the non-nephrotoxic immunosuppression. Despite higher rejection rates, one study showed better long-term survival, better renal function and fewer malignancies under dual therapy with sirolimus and steroids compared to the more nephrotoxic therapy with cyclosporine, steroids and sirolimus. (2,3,57-60,62) (LE: 1b).

Proteinuria and poor renal function are associated with inferior outcomes. Conversion from CNI is not advisable in patients with proteinuria > 800 mg/day (57-60,63-65) (LE: 1b). A cautious and individual approach should be followed in patients with GFR < 30 mL/min (57-60,63-65) (LE: 3).

Due to an antiproliferative effect and a lower incidence of malignancy in sirolimus-treated patients, conversion from CNIs to m-TOR inhibitors may be beneficial for patients, who develop malignancy after transplantation, or who are at a high risk for the development of post-transplant malignancy (57-60,66) (LE: 3). However, no controlled trials have reported better outcomes after conversion. To date, only a few data on long-term follow-up of m-TOR-treated patients have been reported. Emerging side-effects including proteinuria (66,67) and infertility (68) warrant an individual and cautious approach (LE: 3).

Recommendations	GR
Acute rejection can be effectively prevented by m-TOR inhibitors, such as sirolimus and everolimus, in combination with CNIs. This combination regimen is associated with enhanced nephrotoxicity and inferior outcomes. CNI dosage must be significantly reduced to prevent aggravated nephrotoxicity.	A
Initial CNI-free combination therapy of m-TOR inhibitors with MPA and steroids is not sufficient to effectively prevent acute rejection compared to a standard regimen.	A
Use of m-TOR inhibitors is associated with impaired wound healing. Prophylactic surgical measures must be implemented if patients receive m-TOR inhibitors during the peri-operative period.	A
m-TOR inhibitors can safely replace CNIs beyond the early post-transplant period. They are a valid alternative to CNIs when there are severe CNI related side-effects, e.g. nephrotoxicity.	A
Blood levels of both sirolimus and everolimus must be measured at regular intervals.	A

CNI = Calcineurin-inhibitors

*6.2.6 **T-cell depleting induction therapy***

Prophylactic immunosuppression in many countries, particularly the USA, featured the emergence of 'induction' treatments, using biological T-cell depleting agents. These include anti-thymocyte globulin (ATG), OKT3 and more recently an anti-CD52 antibody (Campath1-H) after renal transplantation (1,5).
Some centres use these agents to provide effective rejection prophylaxis while initiating CNIs after recovery of the graft from ischaemic injury, although evidence supporting this hypothesis is lacking (69,70) (LE: 1b). Graft rejection rates are initially lower with induction treatment (69-71); however, some studies suggest an increased rejection rate after cessation of lymphocyte depletion (70,72). There is no evidence of better long-term graft survival in patients receiving induction therapy versus those who have not (70,73-75) (LE: 3). In contrast, it is well documented that induction therapies with T-cell depleting agents carry an increased risk of post-operative opportunistic infections and cancer, especially post-transplant lymphoproliferative disease (70,73-75) (LE: 3).

Recommendations	GR
Potential life-threatening side-effects of T-cell depleting biological induction therapy include a higher incidence of severe opportunistic infections and malignancy, particularly post-transplant lymphoproliferative disease.	B
Use of T-cell depleting antibodies has not been associated with improved outcomes in the overall population.	B
T-cell depleting antibodies should not be routinely used in a low-risk first-transplant recipient.	B
If such induction therapy is used, the increased risks of infection and cancer must be explained to the patient before staring therapy.	B

*6.2.7 **Interleukin-2 receptor antibodies***

Two high-affinity anti-interleukin-2 (IL-2) receptor monoclonal antibodies (daclizumab and basiliximab) are approved for rejection prophylaxis following organ transplantation (1,70,76-78). These agents are given in a short course during the post-transplantation period, are safe, and have been shown in randomised controlled trials to reduce the prevalence of acute cellular rejection by approximately 40% (70,78) (LE: 1a). Both antibodies appear to be equally efficacious, though no formal comparative study was performed.

A meta-analysis has confirmed the efficacy, although no positive effect on patient or graft survival could be demonstrated (78) (LE: 1a) although large retrospective cohort studies and a recent large prospective

study suggest such a benefit (24,70,73,75). The effect of these antibodies in combination with tacrolimus and/or mycophenolate was not investigated in the meta-analysis. Several recently published large controlled trials support the efficacy and safety of quadruple therapy with these agents (6,22,24,25,49,55,56,70) (LE: 1b). Interleukin-2 receptor antibodies may allow early steroid withdrawal (55,56) (LE: 1b), although higher rejection rates were described. Most importantly, IL-2 receptor antibodies allow a substantial reduction in CNIs, while maintaining excellent efficacy and renal function. (2,3,6,24,47) (LE: 1b).

Recommendations	GR
Use of IL-2R antibodies for preventing rejection is efficacious and safe, and effectively reduces the rate of acute rejection, enabling CNI- and steroid sparing regimens.	A
Formal evidence for improved patient and graft outcome is lacking, although recent large clinical trials suggest such a benefit.	A

7. IMMUNOLOGICAL COMPLICATIONS

7.1 Introduction

Immunological rejection is a common cause of early and late transplant dysfunction (1,2). There is great variation in the timing and severity of rejection episodes and how they respond to treatment (Table 19). There are several main types of immunological reaction (Table 20).

Table 19: Determining factors in rejection episodes and response to treatment (1-5)

Degree of sensitisation to HLA, measured by the panel-reactive antibody (PRA) and specific anti-HLA antibodies
Degree of HLA-mismatch, particularly in sensitised recipients (1)

History of previous rejection episodes
Previous transplantations, especially when graft loss has occurred due to acute rejection
Non-compliance with immunosuppressive treatment
Some virus infections, e.g. CMV

CMV = cytomegalovirus.

Table 20: Main types of rejection (1-7)

Hyper-acute rejection (HAR)
Antibody-mediated rejection is caused by pre-formed anti-HLA or anti-AB (blood group) antibodies
Now rare due to donor-recipient ABO matching and routine pre-transplant cross-matching between donor cells and recipient serum
Acute cellular rejection (ACR)
Much more common than HAR, occurring in 10-40% of transplants
Usually occurs from 5 days' post transplant
Most likely within the first 3 months, though may occur after this time
Usually responds well to steroid bolus treatment
Acute humoral rejection (AHR)
Much less frequent than ACR, occurring in 5-20% of transplants
Most likely within the first 3 months' post transplant
Presence of certain histological features and/or positive C4d immunostaining and/or anti-HLA antibodies
Worse prognosis than ACR because more difficult to treat
Chronic allograft rejection (CAR)
Rare, slowly progressive, immunological process
Certain non-specific histological features and/or anti-HLA antibodies
Requires clear strong evidence for a solely chronic immunological process

The gold standard for the diagnosis of ACR, AHR and CAR is transplant biopsy (1,2) (*see below*), which may demonstrate a mixed histological picture in many cases. The Banff criteria (6,7) are uniform criteria applied to biopsy, which are updated regularly and are the basis for deciding prognosis and treatment (8) (LE: 3).

The term 'IF/TA' replaces the previously used terms 'chronic allograft nephropathy'. This term was used to refer to chronic destruction of the graft associated with fibrosis and arteriosclerosis in renal biopsy and of uncertain aetiology. IF/TA is the common histological manifestation of some damage to the graft, where it is not possible to make a specific diagnosis of the underlying cause (6-9). IF/TA is probably the commonest histological feature in failed grafts and is present to some degree in the vast majority of grafts up to 10 years' post transplant (9).

'Chronic allograft dysfunction' is the term used to refer to the chronic deterioration of graft function without histological evidence (LE: 4).

7.2 Hyper-acute rejection (HAR)

Hyper-acute rejection (HAR) is the most dramatic and destructive immunological attack on the graft (1-5). It results from circulating, complement-fixing IgG antibody, specifically reactive against incompatible donor antigen, which engages with and destroys the vascular endothelium. It occurs in most ABO-incompatible grafts due to the presence of pre-existing IgM iso-antibodies against blood group antigens. In ABO-matched grafts, HAR is mediated by anti-donor HLA IgG antibodies (1-5) (LE: 3).

With the development of the cross-match test, HAR has become an extremely uncommon complication. The complement-dependent cytotoxicity test (CDC) is now universally employed in all transplant centres. Recently, newer techniques have been developed, allowing a more sensitive detection of specific anti-HLA antibodies (4,5) (see Chapter 5). However, validation of these techniques is ongoing. If such diagnostic tests demonstrate the possibility of specific anti-HLA antibodies in the presence of a negative CDC cross-match, an individual decision has to be made whether to transplant or not (LE: 4).

Hyper-acute rejection is a rare complication usually seen at the time of surgery. Within minutes or hours of vascularisation, the kidney becomes mottled and then dark and flabby. Histology reveals generalised infarction of the graft (4). Delayed HAR may occur within a week of the transplant, and may be recognised by

acute anuria, fever, and a swollen graft. Hyper-acute rejection is treated by graft nephrectomy.

*7.2.1 **Prevention***

Hyper-acute rejection can be prevented by the avoidance of an ABO-incompatible renal transplant and by performing a regular CDC cross-match before transplantation (LE: 3). All patients registered for renal transplantation should have their serum screened for anti-HLA antibodies, which are particularly common after pregnancy, previous transplant, transplant rejection, and blood transfusions (4,5,10) (LE: 3). Highly sensitised patients (> 50% PRA) should be considered for prioritisation in a points-based matching algorithm (10) (LE: 3).

In a national kidney-sharing programme, identification of the specificity of anti-HLA antibodies in highly sensitised patients and cross-matching allows the detection of acceptable and unacceptable antigens present in the donor (10). This information can be highlighted with the patient's details on the transplant registry database, so preventing the unnecessary transport of kidneys to recipients with high antibody sensitivity (10) (LE: 3).

Recommendations	GR
All recipients and donors must be tested for blood group antigens and blood group incompatibility must be avoided, except intentional living-donor ABO-incompatible transplantation.	B
All centres practising renal transplantation should have access to elective serological profiling of all potential, and actual, waiting-list recipients to define the percentage and specificity of PRA and their isotypes, IgG or IgM.	B
The laboratory service should provide a 24-h donor-recipient cross-matching service to be able to quickly inform a surgeon of the CDC cross-match result before a deceased donor renal transplant (within 5 h).	B

PRA = panel-reactive antibody; CDC = complement-dependent cytotoxicity (testing).

7.3 Acute allograft rejection

Acute allograft rejection can be classified into either T-cell mediated (acute cellular rejection, ACR) or antibody-mediated (acute humoral rejection, AHR) according to the most recent Banff criteria (1-7). Tubulo-interstitial infiltrate of T-cells, macrophages, and to a lesser extent, neutrophils invading the tubular epithelium is a hallmark of T-cell mediated ACR.

Humoral rejection commonly accompanies ACR and causes the same clinical signs. As in ACR, the diagnosis of AHR becomes apparent on renal allograft biopsy. It can be categorised into capillary or arterial antibody-mediated rejection. During post-operative humoral rejection, antibodies are formed against donor antigen on the endothelium. In 20-25% of cases, these antibodies may be detected in the serum during rejection (4, 5). Acute humoral rejection is under-diagnosed (11,12). On biopsy, the appearance may be of oedema and haemorrhage with focal necrosis. The C4d fraction of complement in renal biopsy is required for diagnosis according to the current Banff criteria (6,7,11,12). Not surprisingly, the prognosis is poorer than when ACR occurs alone (4,5,11,12) (LE: 3).

Because it is impossible to differentiate acute rejection solely on clinical indicators from other causes of renal dysfunction (e.g. acute tubular necrosis or CNI nephrotoxicity), a biopsy is necessary to correctly diagnose and treat the patient (1-6) (LE: 3). If possible, all rejections must be verified by renal biopsy and graded according to the most recent Banff criteria, except when contraindications for a renal biopsy are present (6-8) (LE: 3). Renal transplant biopsy should be conducted preferably under ultrasound control, using an automated needle biopsy system (e.g. tru-cut, biopsy gun) (13) (LE: 3).

Recommendations	GR
Renal transplant practitioners must be continuously aware of the possibility of acute rejection, particularly during the first 6 months after renal transplant.	B
During hospitalisation, regular blood and urine samples should be taken for renal and haematological studies in addition to regular ultrasound examinations.	B
Rejection should be strongly suspected in any patient who suffers fever, graft tenderness, or reduced urine output. In case of suspected acute rejection, other potential causes of graft dysfunction need to be ruled out immediately.	B
All patients with suspected acute rejection episodes should undergo renal biopsy, which should be graded according to the most recent Banff criteria. Only if contraindications to renal biopsy are present, can 'blind' steroid bolus therapy be initiated. Steroid treatment for rejection may start before biopsy is performed.	B

There should be routine access to ultrasound-guided biopsy of the transplant and sufficient expertise in the hospital pathology department to allow a clear-cut diagnosis of rejection or other type of allograft dysfunction.	B
Staff and facilities on renal transplant units should be sufficiently equipped to admit a patient with acute rejection immediately to allow rapid diagnosis and treatment.	B
Patients who suffer acute cellular rejection should be tested as soon as possible for anti-HLA IgG antibodies reactive with the graft.	B

7.3.1 ***Treatment of T-cell mediated acute rejection***

As only a few randomised trials have investigated different treatment options for this clinical problem, therapy is mainly based on empirical experience than on clinical evidence (1-4,14). Parenteral methylprednisolone (500 mg to 1 g) should be given intravenously as one pulse per day for 3 days (1-4) (LE: 3). Anuria or a steep rise in the serum creatinine may indicate steroid-refractory rejection and the need for another 3-day course of pulsed methylprednisolone therapy (1-4) (LE: 3). In addition, baseline immunosuppression should be re-evaluated to ensure adequate drug exposure (1-4) (LE: 3).

In severe rejection, a conversion from cyclosporine to tacrolimus should be considered (1-4) (LE: 3). T-cell depleting biological agents, such as anti lymphocyte globulin (ALG) or anti-CD3 monoclonal antibody (OKT3), may be considered in severe steroid-refractory cases (1-4,14) (LE: 1a). If biological agents are used, other immunological suppression should be reduced or stopped and daily T-cell monitoring should be done to minimise the dose of the biological agent (15,16) (LE: 4). Before immunosuppression is intensified, especially before the use of T-cell depleting agents, the prognosis of the graft should be critically assessed against the risks of the aggravated immunosuppression. The patient should be counselled adequately (LE: 4).

Recommendations	**GR**
Treatment with steroid bolus therapy is recommended.	B
In severe or steroid-resistant rejection, consider intensified immunosuppression, including high-dose steroid treatment, conversion to tacrolimus, and T-cell depleting agents.	B

7.3.2 ***Treatment of acute humoral rejection (AHR)***

Acute humoral rejection is treated in a similar way as T-cell mediated rejection (4,17) (LE: 3). Treatment relies on retrospective studies and empirical treatment guidelines. Treatment with a steroid bolus (at least 3 days of 500 mg/day) and conversion to tacrolimus therapy with trough levels > 10 ng/mL are common (4,17) (LE: 3). Although T-cell depleting agents appear to have limited value, there are several retrospective case series and a small prospective trial in children and adolescents describing the successful use of the anti-CD20 antibody, rituximab (4,17,18) (LE: 1b). However, no further prospective trials have been published and neither the dose, side-effects nor efficacy parameters have been evaluated in a larger cohort with adequate follow-up. Most centres also try to remove antibodies using plasmapheresis or immunoadsorption columns. Retrospective and prospective case series clearly suggest efficacy (4,17,19) (LE: 1b), although details of the procedures vary widely.

Some centres advocate intravenous immunoglobulin (IVIG)(20), which may modulate and/or suppress antibody production (4,17,20) (LE: 3). Dosages vary widely from 0.2-2.0 g/kg bodyweight. No comparative studies have been published. Several regimens have proven efficacious in AHR. However, the lack of firm evidence does not permit evidence-based recommendations for treatment, except for a beneficial effect of early antibody removal.

Recommendations	**GR**
Treatment of acute hormonal injection should include early antibody elimination.	B
In addition, steroid bolus therapy, conversion to tacrolimus, T-cell depleting agents and intravenous immunoglobulin treatment are used frequently.	B
Anti-CD20 (rituximab) may be efficacious. However, firm evidence on efficacy and side-effects are lacking.	B

7.4 Chronic allograft dysfunction/interstitial fibrosis and tubular atrophy (IF/TA)

Many patients lose their grafts due to chronic allograft dysfunction (9). Histology will usually reveal a chronic process of IF/TA. An unknown, but rather small number of these patients will have ‘true’ immunological CAR (1,2). IF/TA takes months or years to develop and is heralded by proteinuria and hypertension, with a simultaneous or delayed rise in serum creatinine level over months (9). It is likely that IF/TA is more common

in patients who have had early attacks of ACR, which is a good reason for preventing acute cellular rejection. The main differential diagnoses are chronic nephrotoxicity, which is common in patients receiving CNIs, and pre-existing and/or aggravated chronic kidney damage from a marginal donor kidney (9). Histological features on biopsy are fibrosis, cortical atrophy, concentric intimal fibroplasia of larger arteries with capillary dilatation, arteriolar hyalinosis, and thickened split basement membranes. (LE: 3).

7.4.1 ***Diagnosis and treatment***

Diagnosis is by renal biopsy (5,6). In patients diagnosed early, particularly if there is evidence for CNI toxicity, disease progression may be slowed by conversion to a CNI-free regimen (22-24) (LE: 1a). Conversion to m-TOR inhibitors is safe. Favourable outcomes have been observed without significant proteinuria (< 800 mg/day) (24,25) (LE: 1a). Alternatively, successful conversion to a MPA-based regimen has been described, especially in patients beyond the first 3 years' post transplant (22,23) LE: 1b). If there is intolerance to m-TOR inhibitors or MPA, conversion to an azathioprine-based regimen may be successful, though the higher risk of rejection warrants close surveillance (26) (LE: 1a). If the risk of rejection seems too high, another option is substantial reduction of CNI under the protection of MPA (21,27) (LE: 1b). In patients with proteinuria, intervention with an ACE inhibitor, or angiotensin II receptor blocker (28) may slow down renal decompensation (LE: 3). Other supportive measures include the treatment of hypertension, hyperlipidaemia, diabetes, anaemia, acidosis, and bone disease (29-34) (LE: 3). However, ultimately, the patient will require another transplant (if fit enough to go on the transplant waiting list) or dialysis therapy.

Recommendations	**GR**
During the years of follow-up after renal transplantation, regularly monitor serum creatinine, creatinine clearance, blood pressure, and urinary protein excretion.	A
Changes in these parameters over time should trigger hospital admission for renal biopsy and further diagnostic work-up including a search for infectious causes and anti-HLA antibodies. An ultrasound of the graft should rule out obstruction and renal artery stenosis.	
If a specific cause for deteriorating renal function can be identified, appropriate treatment should be instituted.	A
If unspecific IF/TA is confirmed, begin appropriate medical treatment (e.g. control of hypertension, proteinuria).	A
Supportive measures should aim to adequately treat the consequences of chronic kidney disease (e.g. anaemia, acidosis, bone disease) and cardiovascular risk factors (e.g. hyperlipidaemia, diabetes).	
In patients with IF/TA under current CNI therapy and/or with histological signs suggestive for CNI toxicity (e.g. arteriolar hyalinosis, striped fibrosis) without significant proteinuria (< 800 mg/day), conversion to an m-TOR inhibitor or substantial CNI reduction under MPA protection may be indicated. In chronic maintenance patients beyond 5 years, post-transplant CNI withdrawal under MPA and steroids is another safe option.	A

8. MALIGNANCY

There are three situations in which malignancy occurs in kidney transplant recipients:
- transmitted malignancy by the donor;
- known or latent prior malignancy in the recipients;
- 'de-novo' malignancies developed in the recipient after transplantation.

8.1 Transmission of a donor neoplasia to the recipient

The risk of a donor disease transmission is estimated at 0.2% (1) with increased use of older donors and marginal kidneys. Donors can be divided into three groups according to the risk of transmission of cancer:
- donors without cancer;
- donors with a per-operative diagnosis of cancer;
- donors with a history of cancer.

However, even in the first situation, there remains a very small risk that donors may carry an infraclinical tumour, particularly of the prostate (2).

Pre-operative suspicion of cancer was reported in 337 (4.4%) out of 7608 donors (3). Among them, there were 131 donors suitable for donation, who donated a total of 241 organs without any donor-related tumour transmission to the recipients. In 1069 donors with a history of cancer and no tumour transmission, the most common cancers were non-melanoma skin cancer (31%), central nervous system (CNS) tumours (25%), and uterine and cervical cancers (13%) (4). Melanoma and choriocarcinoma are the most aggressive donor-transmitted malignancies (5).

Individuals with active cancer or a history of metastatic cancer or who have had cancers with a high

risk of recurrence (e.g. medulloblastoma and glioblastoma multiform) should not be donors (6). Occasionally, brain metastasis may masquerade as a primary brain tumour or cerebral haemorrhage and must be excluded as it is a contraindication for donation.

However, a prior history of neoplasia is no longer an absolute contraindication for organ donation. Non-melanoma low-grade skin cancer and selected CNS tumours that have not undergone surgical manipulation may also be acceptable. The following tumours are not contraindications to donation:

- basal cell carcinoma;
- non-metastatic spinocellular carcinoma of the skin;
- cervical carcinoma *in situ;*
- carcinoma in situ of the vocal cords.

There is no consensus on donors with transitional cell carcinoma of the bladder at the TaG1 Tumour Node Metastasis (TNM) stage. Screening for prostate cancer is different from country to country and is suggested only when there are reasons for such a test.

Donors affected by certain low-grade (grades 1 and 2) brain tumours (Table 21) are suitable for kidney donation. Individuals affected by brain tumours of any grade who have undergone ventriculo-peritoneal shunting must be excluded because of the high risk of systemic dissemination of tumour cells through the shunt (LE: 3).

Table 21: Low-grade brain tumours that do not exclude organ donation

Low-grade astrocytoma
Pituitary adenomas
Epidermoid cysts
Colloid cysts of the third ventricle
Pilocytic astrocytoma, ependymoma
Low-grade oligodendroglioma (Schmidt A and B)
Choroid plexus papilloma
Ganglionic cell tumour (ganglioma, gangliocytoma)
Benign meningioma
Craniopharyngioma
Haemangioblastoma (not associated with Von Hippel Lindau syndrome)
Acoustic Schwannoma
Pineocytoma
Well-differentiated teratoma

When a kidney has been transplanted from a donor with a post-transplant diagnosis of cancer, graft nephrectomy and suspension of immunosuppression are not always necessary. The risks and benefits should be discussed with the recipient.

Due to a low risk of recurrence, kidneys with small renal cell carcinoma (RCC) can be considered for local excision and transplant after the recipient has given informed consent. The risk of RCC transmission to the contralateral kidney and/or to other organs is even lower; again, the patient's informed consent is necessary (LE: 4).

Recommendations	**GR**
Donors with active cancer or history of metastatic cancer and cancers with a high risk of recurrence should not be considered as possible donors.	C
A prior history of neoplasia is no longer an absolute contraindication for organ donation.	C

8.2 Prior malignancy in the recipient

Any active tumour in the recipient is an absolute contraindication for kidney transplantation because of the risk of dissemination and fatal outcome. However, a previous history of cancer does not automatically exclude transplantation. It can be difficult to decide who should be considered as suitable for transplantation and particularly 'when'. So far, clinical decision has been mainly based on the Cincinnati Registry, which essentially

considers the type of tumour and the delay between its treatment and kidney transplantation. However, a better approach would be based on type of tumour, TNM stages, and the risk of recurrence after treatment.

For most tumours, the waiting time for transplantation is 2 years on the Registry. However, a 2-year waiting period would eliminate only 13% of colorectal recurrences, 19% of breast cancer recurrences, and 40% of prostatic cancer recurrences (7,8). In contrast, a 5-year waiting period would eliminate most recurrences, but this is not practical in the elderly (9) and unnecessary for most tumours. There is therefore not enough evidence to support a fixed waiting period before transplantation.

Recipients who have tumours with a low recurrence rate can be considered for immediate transplantation after successful treatment of the tumour (e.g. incidental RCC, non-melanoma skin cancer, and *in-situ* uterine/cervical cancer). In the remaining cases, because of the risk of dormant metastases, the waiting period should be individualised according to the type and TNM stage and grade of the tumour, age and recipient's general condition. Patients on the waiting list and after transplantation must be evaluated regularly to detect recurrence (LE: 4).

Modification of immunosuppression may be considered in these patients following a recent report that the use of m-TOR inhibitors is associated with a reduced incidence of malignancy (10), as is similarly a reduction in immunosuppressive therapy.

Recommendations	GR
Any active tumour in the recipient is an absolute contraindication for kidney transplantation because of the risk of dissemination and fatal outcome.	C
The waiting period before transplant in recipients with a history of malignancy depends on the type, TNM stage and grade of the tumour, and recipient's age and general health.	C
Recipients with tumours that have a low recurrence rate can be considered for immediate transplantation after successful treatment.	C
Close follow-up is mandatory particularly after transplantation.	C

TNM = Tumour Node Metastasis

Patients with ESRD on the waiting list for kidney transplantation will be ageing, and thus carry a higher, potential risk of latent neoplasia being activated following kidney transplantation. Candidates for kidney transplantation, particularly > 50 years old, should be screened for the presence of a pre-existing cancer (Table 22).

Table 22: Screening of potential recipients for malignancy

Exhaustive history and physical examination, including a dermatological examination
Gynaecological examination: vaginal cytology and colposcopy, regardless of age
Mammography in women over 40 years old or with a family history of breast cancer
Prostate examination: prostate-specific antigen (PSA) levels and digital rectal examination (DRE) in men aged over 50 years
Faecal occult blood testing or colonoscopy according to current guidelines
Chest x-ray
Abdominal ultrasound to exclude renal cell carcinoma or other abdominal tumour

8.3 'De-novo' tumours in the recipient

The risk of cancer after kidney transplantation is several times higher than in the general population (11,12). Post-transplantation cancer is one of the most common long-term causes of death; with up to 35% of heart transplant recipients dying of cancer (13). Most malignancy affects the skin (40%) or the lymphatic system (11%). Several factors contribute to the high prevalence of cancers in transplant recipients (Table 23). Annual screening is mandatory to detect a new cancer or co-morbidity.

Table 23: Factors increasing risk of de-novo tumour in recipient

Sun exposure: skin cancer
Analgesic abuse: urothelial cancer
Acquired multicystic renal disease: renal cancer
Immunosuppressants, e.g. CNIs and lymphocyte-depleting antibodies
Viral infections, e.g. EBV, herpes 8 virus, human papillomavirus, HBV, HCV, HEV

8.3.1 *Skin cancer and Kaposi's sarcoma*

The risk of skin cancer increases with age (> 50 years) (14), cyclosporine (10), and duration of immunosuppression. Its incidence rises with time to 5% at 5 years, 16% at 10 years, and 52% at 20 years' post transplant (15). Skin cancer represents 40-60% of post-transplantation tumours, with up to 50% of all skin cancers being squamous cell. The male-to-female ratio is 4.8 to 1.3 (16). It is closely linked to sun and ultraviolet exposure, the presence of HLA-B27 antigen and the degree of immunosuppression. Skin cancer often recurs, particularly in heart and kidney recipients (17). An annual dermatological examination and use of total sun block are recommended (18,19) (LE: 2a).

The prevalence of Kaposi's sarcoma ranges from 0.5% to 4%, depending on the country (20). It is associated with HHV8 positive serology. Screening for HHV8 in high-risk patients (Mediterranean countries) and prophylactic measures may be considered (21) (LE: 3). The use of m-TOR inhibitors may be preferrable over CNIs, which seem to promote the appearance of Kaposi´s sarcoma (19) (LE: 3).

Recommendations	GR
Oral and written information on the risk of skin cancer and protective measures should be given.	C
Dermatological examination before, and at least annually after, transplantation is mandatory.	C
The use of m-TOR inhibitors instead of Calcineurin-inhibitors is advised in patients with Kaposi's sarcoma or a history of Kaposi's sarcoma.	C

8.3.2 *Lymphatic disease*

Post-transplantation lymphoproliferative disease (PTLD) is a life-threatening complication because of extra-nodal dissemination and a poor outcome (12,22). The incidence (1-5%) has increased since the introduction of cyclosporine (23) and the induction regimen by ALG and OKT3 with a SIR (standardized incidence ratio) between 9 and 29 (24). The disease usually occurs within the first year after transplantation and is characterised by non-Hodgkin's lymphomas and EBV-infected B-lymphocytes. Treatment involves reduction or even suspension of immunosuppressive therapy, with a remission rate of 50-68%. Anti-CD20 antibody therapy, with or without chemotherapy, and antiviral drugs (acyclovir, ganciclovir) may be helpful (25,26) (LE: 3).

Recommendations	GR
Use of induction therapy with T-cell depleting agents should be restricted whenever possible.	C
Clinical examination every 3 months during the first post-transplant year is advised for young recipients and for patients who have received T-cell depleting agents.	C

8.3.3 *Gynaecological cancers*

Cervical cancer is 3 to 16 times more common in transplanted females compared to the general population. In 70% of cases, it will be *in-situ* carcinoma or cervical intraepithelial neoplasia (CIN).

Cervical cancer appears to be arising from infection of the cervix with sexually transmitted oncogenic strains of human papillomavirus (HPV). Increased risk of cervical cancer in transplant recipients is due to re-activation of latent HPV in the immunosuppressed recipient. The prevalence of HPV in the cervix of transplanted females is almost 45%, though this figure is currently decreasing, as is also CIN prevalence (27). Data on successful HPV immunization are not available, but young female transplant recipients may benefit from HPV immunisation.

Annual colposcopy and cytology are required. Mammography and gynaecological ultrasound should be periodically performed, although formal evidence for this preventive strategy is lacking (28) (LE: 4).

8.3.4 *Prostate cancer*

The prevalence of clinical prostatic adenocarcinoma in the male transplanted population is 0.3% to 1.8%. Prevalence increases with the age of the recipient and can reach 5.8% if PSA screening is performed in all males. All recipients over 50 years old should have an annual PSA test and DRE. Prostate serum antigen levels are not modified by kidney transplantation and most prostate cancers detected in transplanted patients are clinically localised (84%) at diagnosis (29) (LE: 4).

8.3.5 *Bowel cancer*

The association of colon cancer with kidney transplantation is much more controversial than for other cancers, even though an increased risk factor of 2.6 has been reported at 10 years' post transplant. However, it is difficult to advise on the most appropriate method of follow-up and its frequency. An annual faecal blood test is acceptable and cost-effective, but not performed routinely worldwide. Colonoscopy every 5 years is also acceptable in the absence of other factors implying a high risk of colon cancer, despite the absence of data on

screening in this population. A risk factor is the re-activation of CMV and EBV infections (28) (LE: 4).

8.3.6 ***Urothelial tumours***

The incidence of urothelial tumours is three times higher than in the general population (29). Tumours are usually transitional cell neoplasia, though the incidences of bladder adenocarcinoma and nephrogenic adenoma have both increased. Urinary cytology is routinely performed in patients with microhaematuria, analgesic nephropathy, or a prior history of urothelial cancer, despite its poor sensitivity of 30%. Recipients with gross haematuria should undergo a detailed study of the whole urinary system, bladder, ureters, and kidneys.

8.3.7 ***Renal tumours***

Renal cell carcinoma usually occurs in the patient's own kidneys, but can also present in the graft. The prevalence ranges between 0.5% and 3.9%, which is 10 to 100 times greter than in the general population (29). The main risk factor is the presence of acquired chronic kidney disease (ACKD). Other risk factors include previous history of RCC, Von Hippel Landau disease, and (perhaps) polycystic kidneys. The main histological patterns are RCC and tubulopapillary carcinoma (30).

Annual ultrasound of the patient's native kidneys and the graft is recommended (28,29) (LE: 4). Any renal solid tumour should be treated with retroperitoneoscopic or laparoscopic nephrectomy (LE: 4).

8.3.8 ***Chest x-ray***

An annual chest x-ray is recommended in order to detect lung cancer and cardiothorarcic abnormalities (28) (LE: 4).

Recommendations	**GR**
The risk of cancer is several times greater in transplanted patients than in the general population and is the main concern of the medical team in the long-term follow-up of all organ recipients.	B/C
Screening should be carried out annually for cancers of the skin, lymphatic system and native kidneys. For all other organs, screening should be the same as in the general population.	B/C

9. ANNUAL SCREENING

The risk of cancer and cardiac disease is several-fold higher in transplanted patients than in the general population (1,2). Cancer is a cause of significant morbidity and mortality in the transplanted population (1). Cardiovascular disease is the most frequent cause of death in renal allograft recipients (2,3) (LE: 3).

9.1 Recommendations for annual screening

The following recommendations can be made for annual screening of a transplant recipient. They include:

- Lifelong regular post-transplant follow-up by an experienced and trained transplant specialist is strongly recommended at least every 6-12 months;
- More frequent follow-up visits (e.g. every 4-8 weeks) for renal function and immunosuppression and side-effects by a physician;
- Annual screening should include a dermatological examination, tumour screening (including a nodal examination, faecal occult screening, chest x-ray, gynaecological and urological examination), and an abdominal ultrasound, including ultrasound of the native and transplanted kidney);
- Special attention during post-transplant care should also focus on proteinuria, recurrence of original disease;
- posttransplant care should aim to detect cardiac disease and cardiovascular risk factors. Cardiac exam and cardiac history should be taken, and if appropriate further diagnostic tests should be prompted to exclude the progression of cardiac disease;
- Blood pressure, blood glucose and blood lipids should be determined at appropriate intervals, and adequate measures to control this risk factors should be instituted;
- The physician should also focus on the adequate prophylaxis, detetction and treatment of concomitant diseases (e.g. bone disease, anemia) and infections.

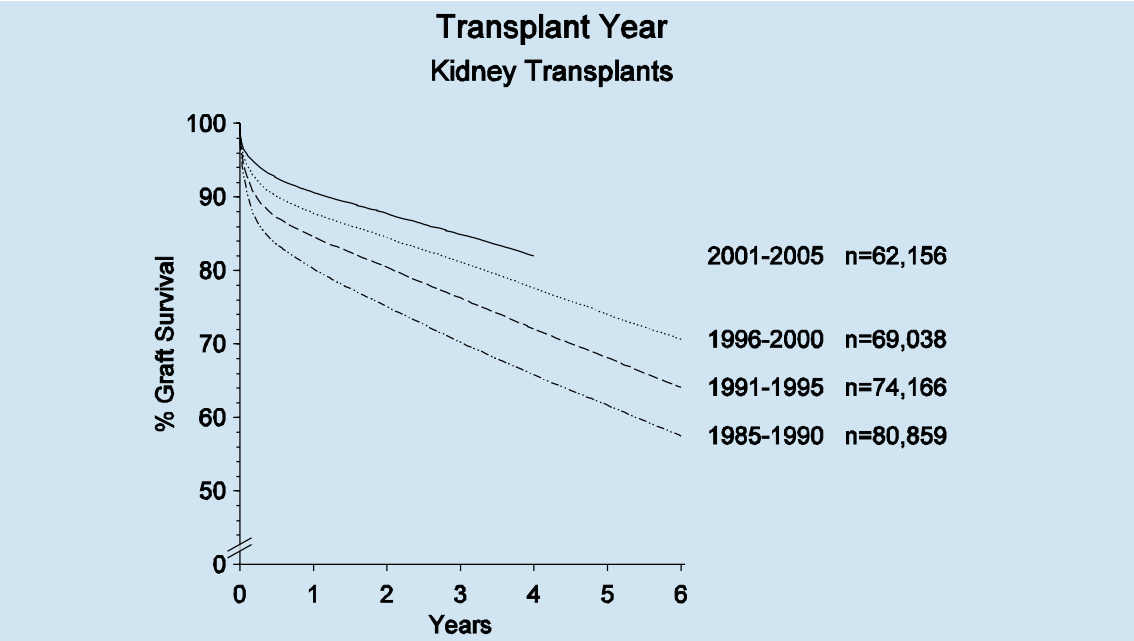
10. GRAFT AND PATIENT SURVIVAL

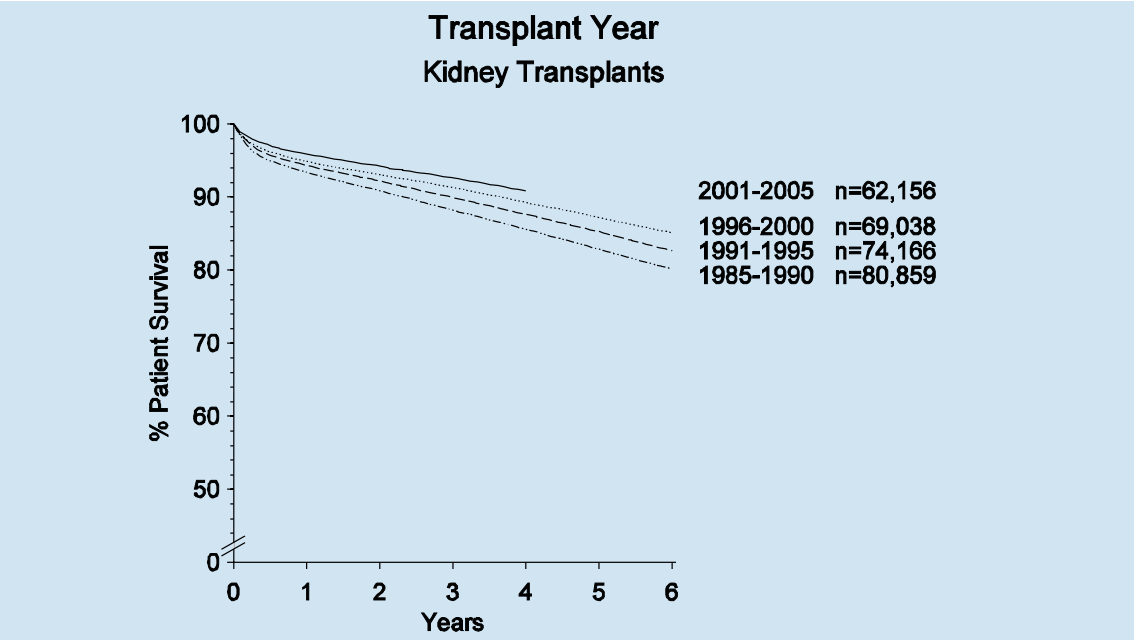
Recommendations	LE	GR
Graft survival following unselected kidney transplantation should be at least 85% after 1 year and 70% after 5 years (1,2) (Figure 1).	3	B
Patient survival following unselected kidney transplantation should be at least 90% after 1 year and 85% after 5 years (1,2) (Figure 2).	3	B

Figure 1: Improvement of graft survival following kidney transplantation during the last two decades



Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.

Figure 2: Improvement of patient survival following kidney transplantation during the last two decades



Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.

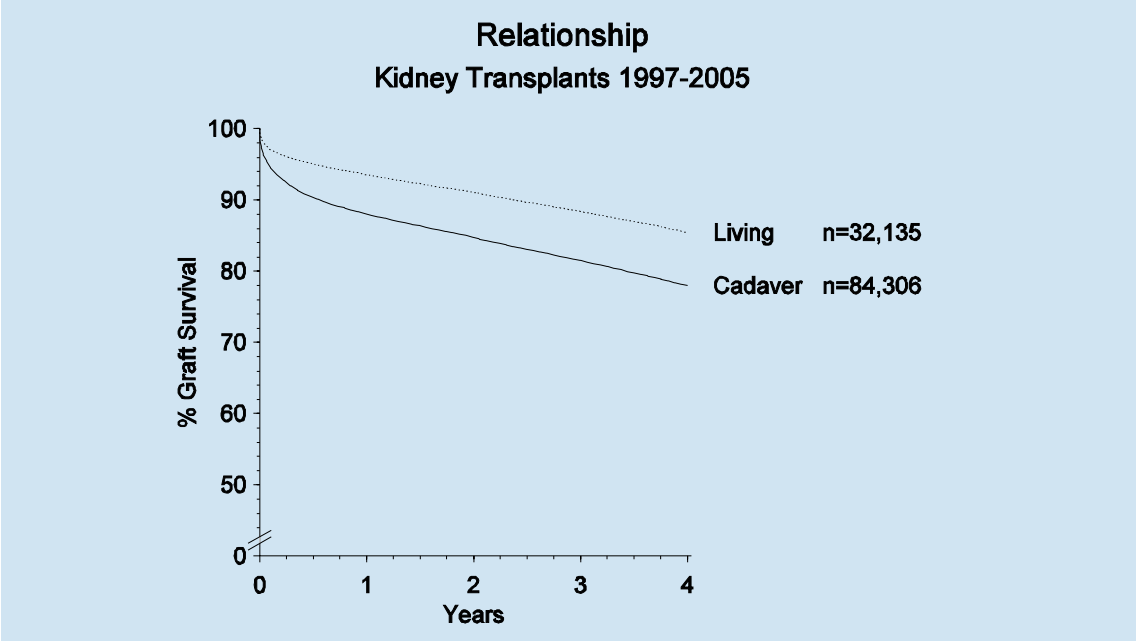
This general outcome following kidney transplantation depends on several criteria that are discussed below:

10.1 Deceased and living donors

10.1.1 Graft survival

Graft survival after living-donor kidney transplantation is generally better than after deceased-donor kidney transplantation (Figure 3). A better selection of donors, absence of brain death and a shorter cold ischaemia time are the most likely explanations.

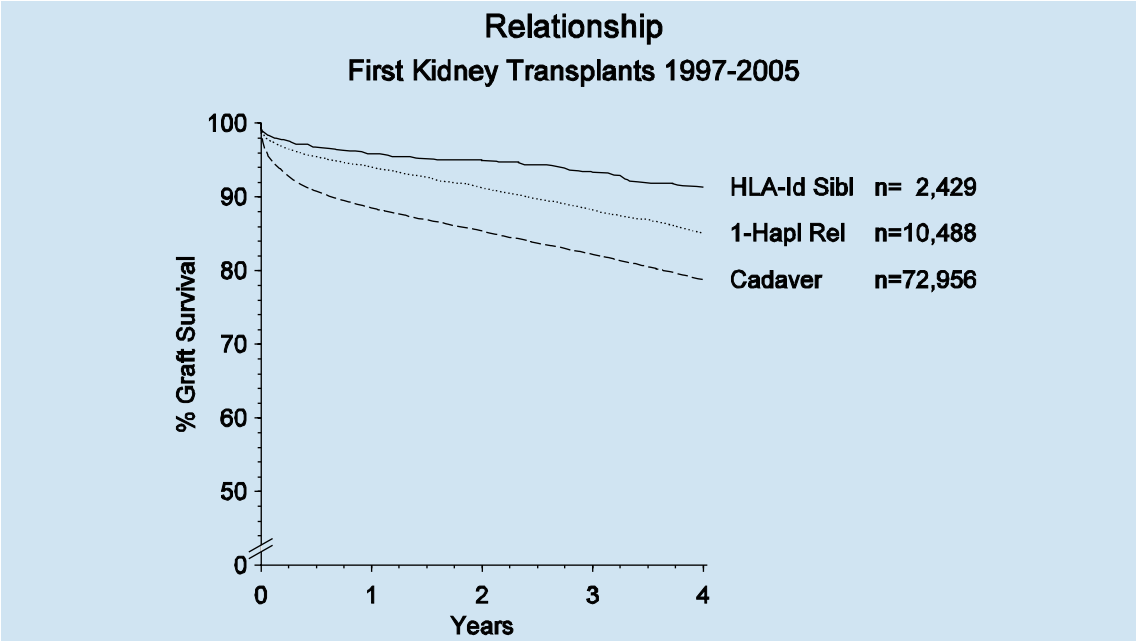
Figure 3: Graft survival following deceased- and living-donor kidney transplantation



Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.

The 1-year graft survival of living-donor kidney is in mean 97% for HLA-identical siblings and 95% for 1-haplotype-identical related donors compared to 88% for deceased-donor kidneys (Figure 4). The 3-year graft survival of living-donor kidney is in mean 95% for HLA-identical siblings and 90% for 1-haplotype-identical related donors compared to 83% for deceased- donor kidneys (Figure 4).

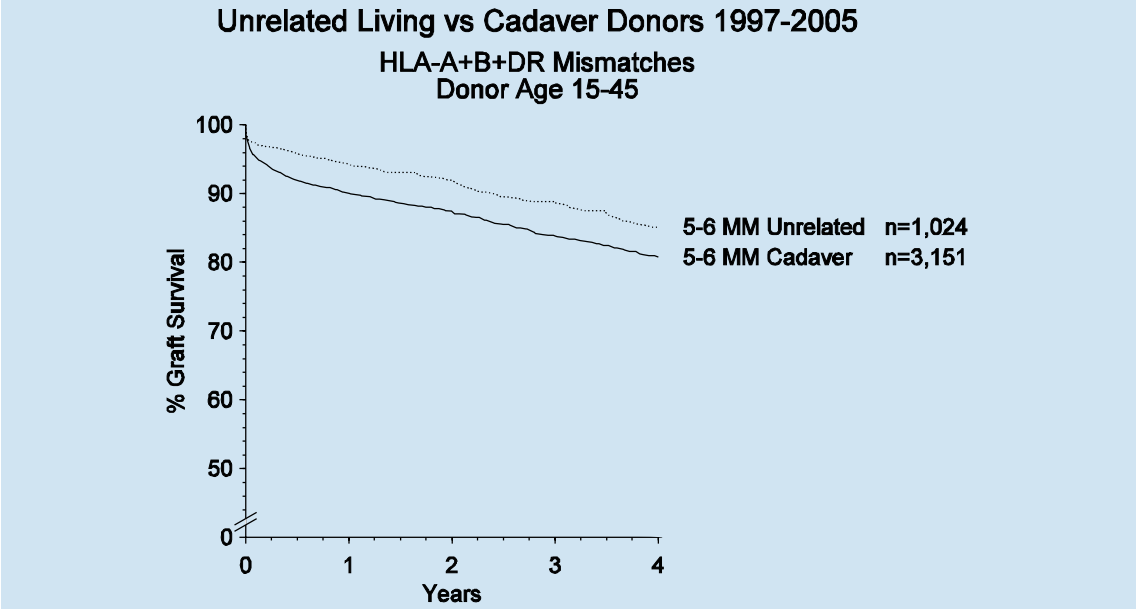
Figure 4: Graft survival following deceased- and living-donor kidney transplantation.



Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.

Excellent graft outcomes have been reported in unrelated living-donor transplantation, even if the donor-recipient pairs were poorly HLA-matched (3). CTS data show that poorly matched kidneys from unrelated living donors demonstrate a much better outcome than poorly matched kidneys from deceased donors. However, this difference almost disappears in donors aged between 15 and 45 years old (Figure 5). This suggests that a good outcome in unrelated living-donor transplantation may mainly be due to optimal selection of donors and absence of brain death.

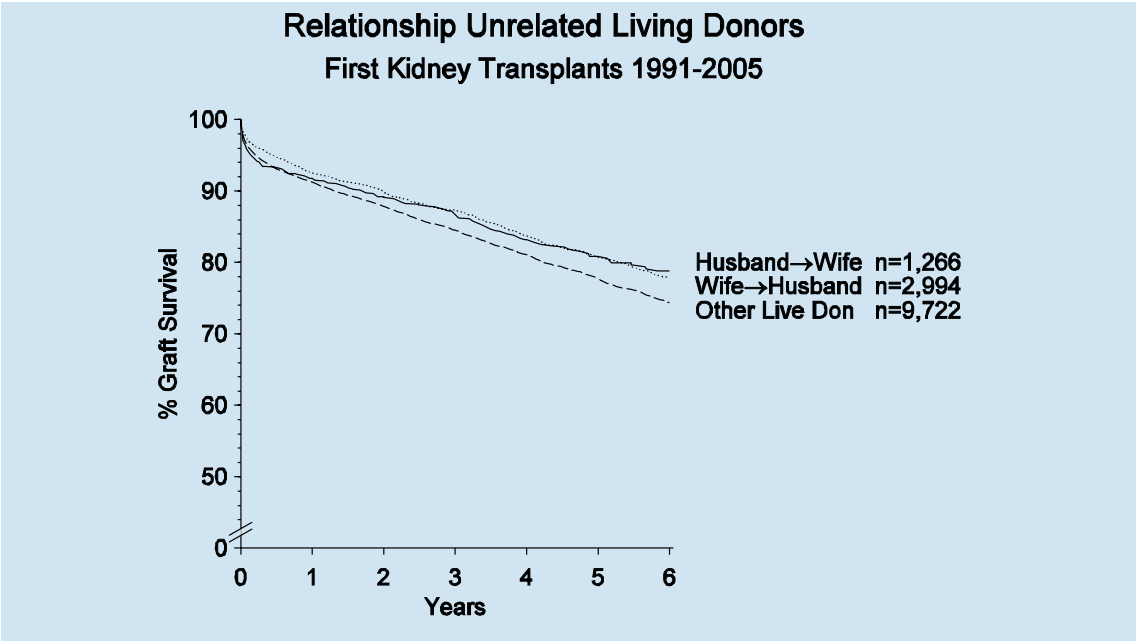
Figure 5: Graft survival in poorly HLA-matched deceased-donor and unrelated living-donor kidney transplantation



Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.

Husband-to-wife and wife-to-husband transplantations performed between 1991 and 2005 show virtually identical results with a 3-year graft survival of 87% (Figure 6). If a wife recipient has been pregnant, the outcome may be worse (3).

Figure 6: Graft survival in living unrelated kidney transplantation



Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.

10.1.2 ***Patient survival***

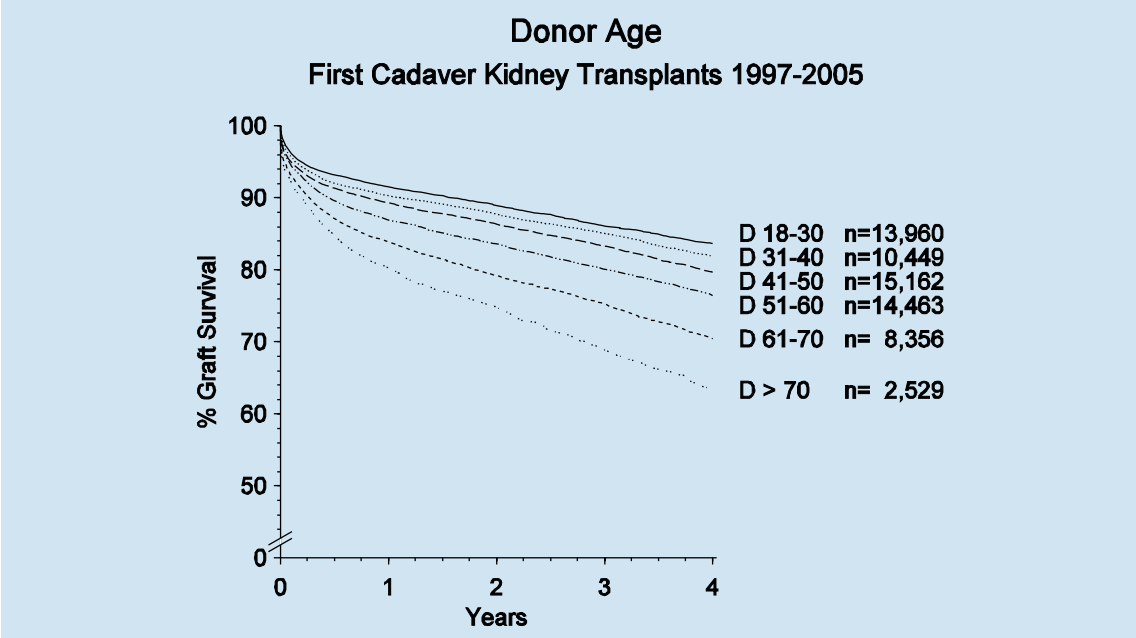
Nowadays, patient survival following living-donor kidney transplantation is about 98% after 1 year and 90% after 5 years. This is better than patient survival following deceased donor kidney transplantation with a 1-year survival rate of 95% and a 5-year survival rate of about 80% (1,2).

10.2 Age of donor and recipient

10.2.1 ***Donor's age***

The donor's age has a highly significant influence on the outcome of kidney transplantation in deceased-donor transplantation. With increasing age of donor (except in paediatric transplantation), there is a worsening of initial function, long-term function and survival rate. The 3-year graft-survival rate of a deceased-donor transplant is up to 20% higher for donors aged 18-30 years than for donors older than 70 years (Figure 7) (1,2,4).

Figure 7: Impact of donor's age on graft survival in deceased-donor kidney transplantation



Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.

Other than in deceased-donor transplantation, donor's age appears to influence graft outcome only marginally in living-donor transplantation (4). The most likely interpretation of this difference is that living donors are selected for organ donation based on their general status of health whereas such selection is not made in the case of deceased donor transplantation. Furthermore, it is likely that the process of brain death, which is associated with the release of cytokines, chemokines, etc., further contributes to the lower success of grafts from elderly deceased donors.

10.2.2 ***Recipient's age***

The recipient's age has an important impact on transplant outcome (5). Five-year graft survival in recipients aged 18-34 years is 72% versus 59% in recipients more than 65 years old (2). Nevertheless, the transplantation of kidneys from old donors to old recipients is feasible with acceptable success rates (6). The importance of HLA-matching is not clear in this 'old for old' group.

10.3 HLA-matching

Despite impressive improvements in graft success rates in recent years (Figure 1), the 'relative' impact of HLA compatibility on graft outcome has not changed. Between 1995 and 2004, the relative risk for graft loss was 0.77 for 0-1 HLA-A+B+DR mismatches and 1.17 for 5-6 HLA-A+B+DR mismatches. These relative risk values were almost identical with the 0.76 and 1.16 values calculated for 0-1 and 5-6 mismatches, respectively, for transplantations between 1985 and 1994 (7,8).

According to UNOS, in patients transplanted between 1997 and 2005, recipients of 0 HLA-A+B+DR mismatched deceased-donor kidneys showed an 11% lower 5-year graft survival than recipients of 6 mismatched kidney transplants which is similar to the CTS data (Figure 8). Also similar to the findings in the

CTS database, UNOS data confirm that graft outcome gradually worsens with every additional mismatch (2). HLA matching is still important even with 'modern' immunosuppressive agents such as tacrolimus, MMF, rapamycin, or IL-2 receptor antibodies (Figure 9). It is still debatable whether HLA-DR compatibility influences graft outcome more than compatibility for HLA-A+B.

Figure 8: Impact of HLA compatibility on deceased-donor kidney graft survival

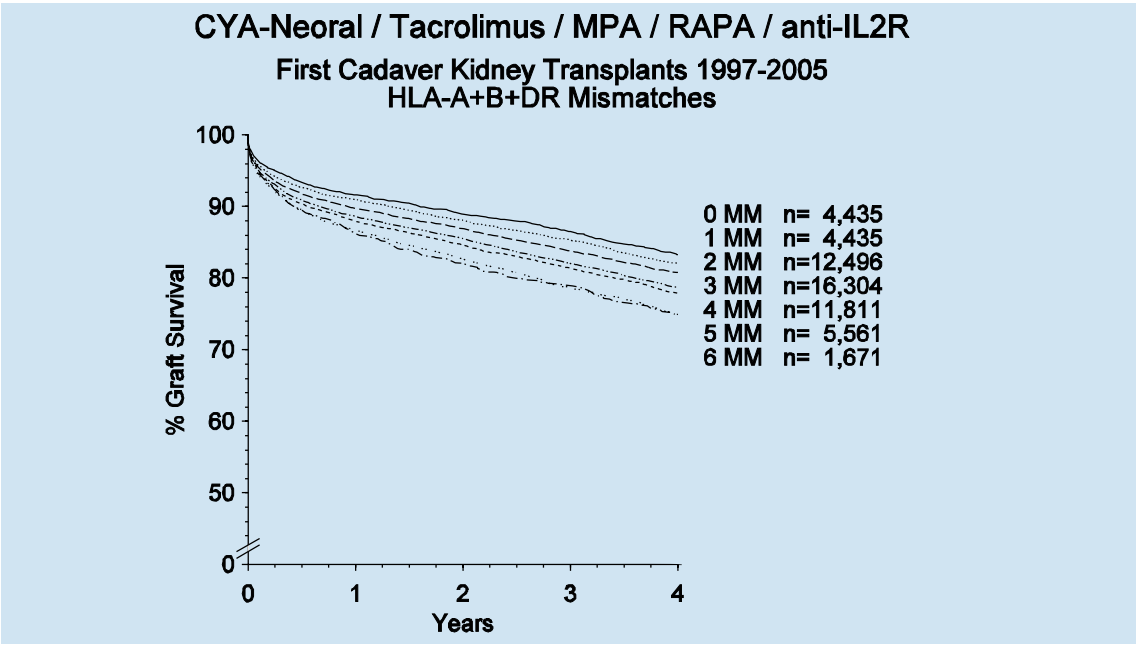
Figure 9: Impact of HLA compatibility on kidney graft survival under 'modern-day' immunosuppression

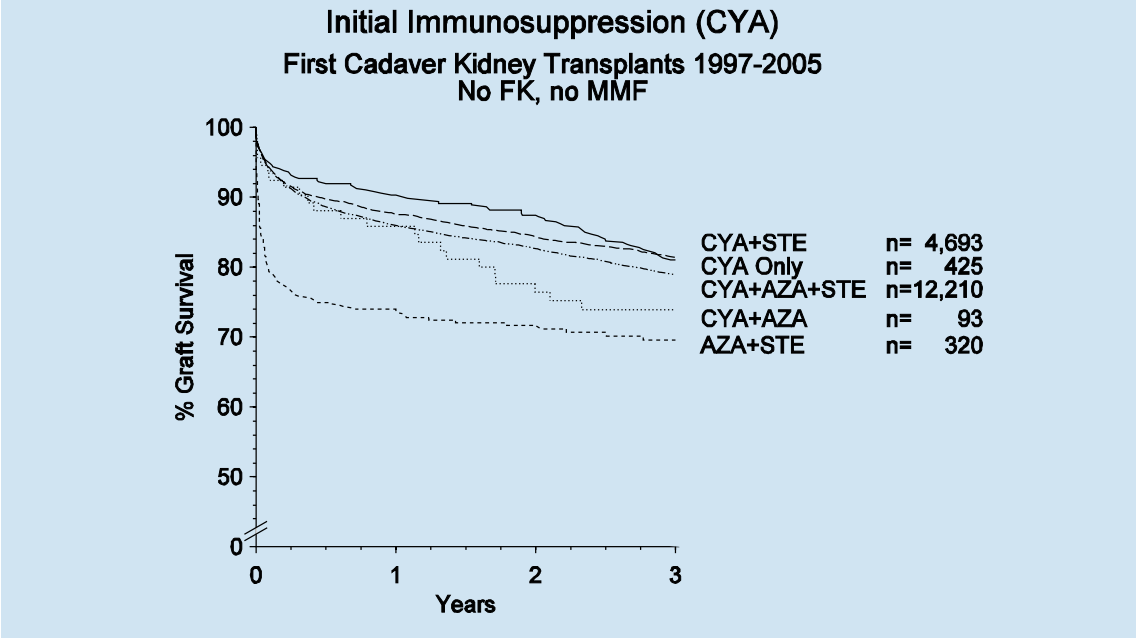


Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.
CYA = cyclosporine A; MPA = mycophenolate mofetil; RAPA = rapamycin.

10.4 Immunosuppression

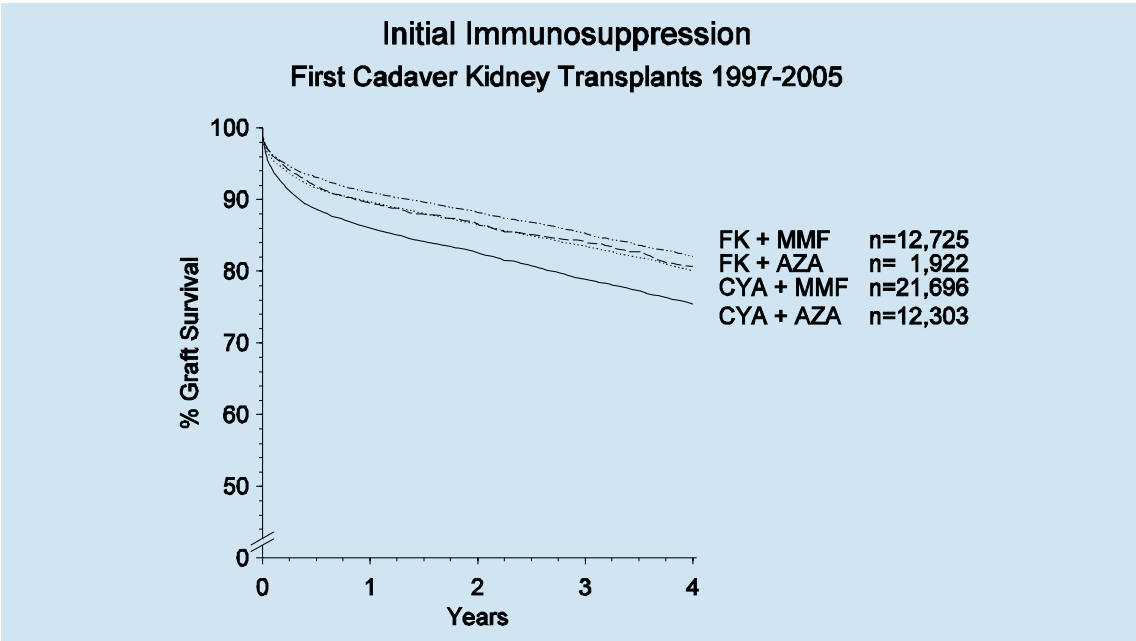
Data from the CTS study clearly demonstrates the advantage of cyclosporine A-based immunosuppression. Graft-survival rates are about 15% superior to survival rates following immunosuppression without cyclosporine A (Figure 10). However, different combinations of 'modern' immunosuppressive drugs do not appear to result in major differences in graft outcome (Figure 11).

Figure 10: Influence of cyclosporine A-based immunosuppression on kidney graft survival in first transplant recipients



Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.
FK: FK506; MMF: mycophenolate mofetil; CYA = cyclosporine A; AZA = azathioprine; STE = steroids.

Figure 11: Influence of different immunosuppressive agent combinations on graft survival following kidney transplantation

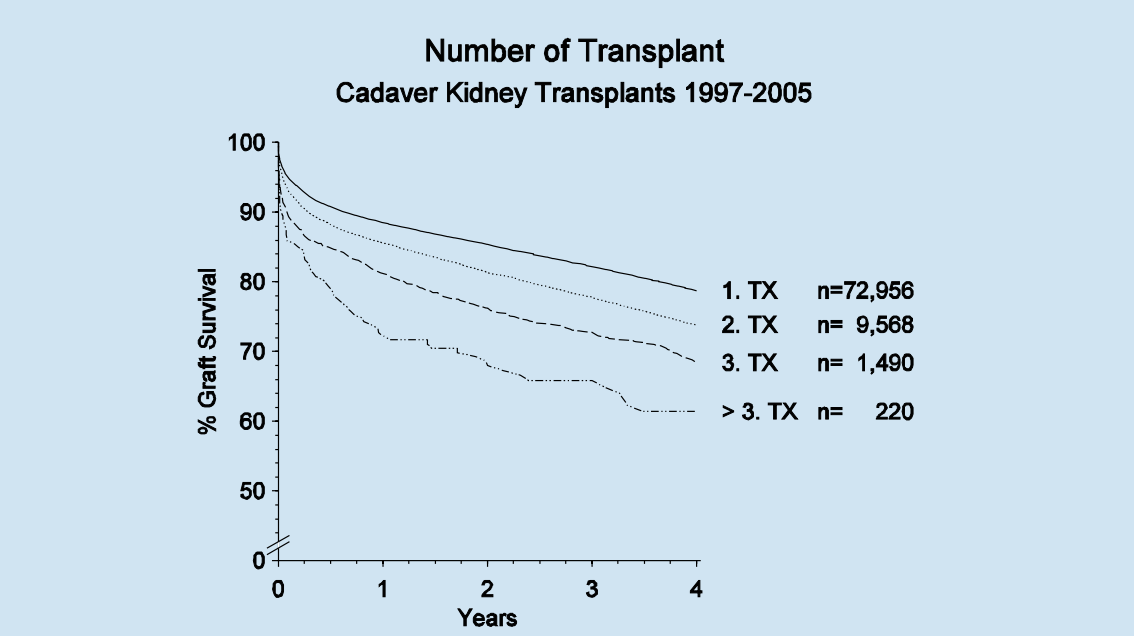


Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.
CYA = cyclosporine A; FK: FK506; AZA = azathioprine; MMF: mycophenolate mofetil.

10.5 Number of transplantations

The 4-year graft survival rate decreases by about 5% from the first to second and second to third transplantation. The 4-year graft survival rate for the first deceased-donor transplantation is 80% versus 75% for the second, 70% for the third, and 63% for the fourth or more transplants (Figure 12). For living donors, the worsening of graft function between first and second transplantation is less marked (about 2%) (1).

Figure 12: Number of transplantations and kidney graft survival



Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.

10.6 Cold ischaemia time

The success of unrelated living-donor kidney transplantation suggests that short cold ischaemia time plays an important role in kidney transplantation. However, according to CTS data, graft survival is influenced only marginally by ischaemia times up to 24 h (Figure 13) and that HLA matching has a significant effect on outcome, even with a short ischaemic preservation time (Figure 14). Compared to other preservation solutions, UW-solution was associated with significantly better outcome in the CTS study with ischaemia > 24 h (7).

Figure 13: Impact of cold ischaemia time on graft survival in deceased-donor kidney transplantation

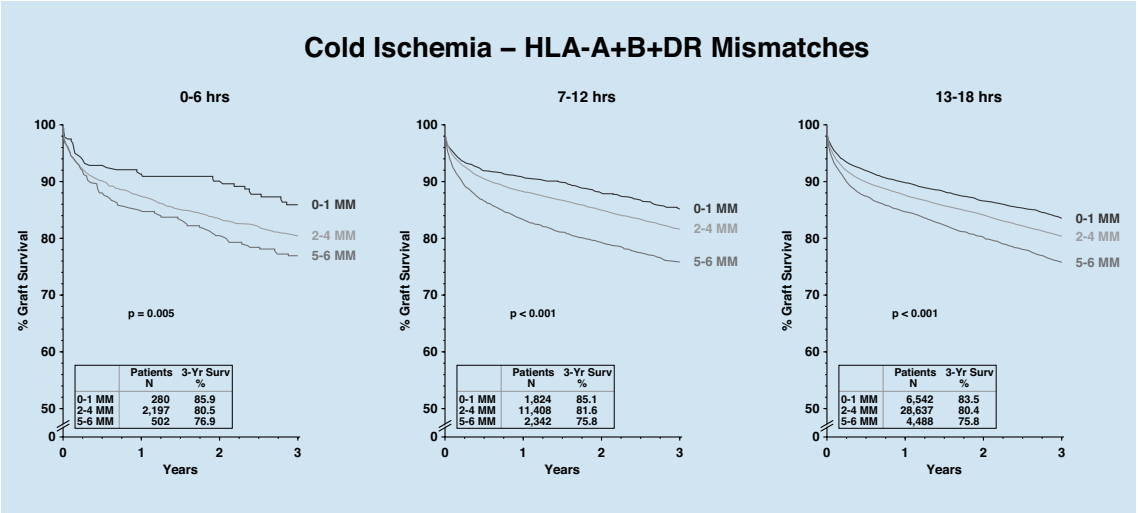
Figure 14: HLA-match dependent impact of cold ischaemia time on graft survival in deceased-donor kidney transplantations performed between 1990 and 2005



Reproduced from CTS Collaborative Transplant Study by kind permission of Prof. Dr. G. Opelz, Heidelberg, Germany.

10.7 Time on dialysis

According to CTS data, graft outcome is best if the patient never received dialysis and diminishes with every additional year of dialysis treatment (Figure 15). These findings are in agreement with data from reports that underline the importance of pre-emptive transplantation (9).

Figure 15: Impact of time on dialysis on graft survival in deceased-donor kidney transplantation

11. ABBREVIATIONS USED IN THE TEXT

This list may not include the most commonly known abbreviations

ABO	blood group system consisting of groups A, AB, B and O
ACD	acid-citrate-dextrose
ACKD	acquired cystic kidney disease
ACR	acute cellular rejection
ADPKD	autosomal dominant polycystic kidney disease
AHR	acute humoral rejection
ALG	anti-lymphocyte globulin
AM	acceptable mismatch
Anti-GBM	anti-glomerular basement
ATG	anti-thymocyte globulin
AVF	arterio-venous fistula
AZA	azathioprine
BMI	body mass index
CAR	chronic allograft rejection
CDC	complement-dependent cytotoxicity test
CMV	cytomegalovirus
CNIs	Calcineurin-inhibitors
CsA-ME	cyclosporine A micro-emulsion
CT	computed tomography
CTS	Collaborative Transplant Study
CYA	cyclosporine A
DTT	dithiothreitol (test)
DRE	digital rectal examination
EAU	European Association of Urology
EBV	Epstein-Barr virus
EC	EuroCollins (solution)
EC-MPS	enteric-coated mycophenolate sodium
EDTA	ethylenediaminetetra-acetic acid
EDHEP	European Donor Hospital Education Program
ELISA	enzyme-linked immunosorbent assay
ESRD	end stage renal disease
ESWL	extracorporeal shockwave lithotripsy
ET	Eurotransplant
FSGS	focal and segmental glomerulosclerosis
GFR	glomerular filtration rate
GR	grade of recommendation
HAR	hyper-acute rejection
HbA1C	glycosylated haemoglobin
HBcAb	hepatitis B core antibody
HBsAg	hepatitis B surface antigen
HBV	hepatitis B virus
hCG	human chorionic gonadotrophin
HCV	hepatitis C virus
HIV	human immunodeficiency virus
HLA	human leukocyte antigen, histocompatibility antigen
HTK	histidine-tryptophan-ketoglutarates
IF	interstitial fibrosis
IL-2	interleukin-2
IMPDH	inosine monophosphate dehydrogenase (inhibitors)
IVIG	intravenous immunoglobulin
LCDD	light-chain deposit disease
LE	level of evidence
LLDN	laparoscopic live donor nephrectomy
MMF	mycophenolate mofetil
MPA	mycophenalic acid
MRI	magnetic resonance imaging
NHBD	non-heartbeating donor

OKT3	anti-CD3 monoclonal antibody
OLDN	open live donor nephrectomy
PRA	panel-reactive antibody
PSA	prostate-specific antigen
PTLD	post-transplantation lymphoproliferative disease
RAPA	rapamycin
RCC	renal cell carcinoma
ST	Scandia Transplant
STE	steroids
TA	tubular atrophy
TB	Tuberculosis
TNM	Tumour Node Metastasis
TRAS	Transparant Renal Artery Stenosis
UNOS/OPT	United Network for Organ Sharing/The Organ Procurement and Transplantation Network
UW	University of Wisconsin (solution)
VATER	Vertebrae, Anus, Trachea, Esophagus, and Renal
WHO	World Health Organization

Conflict of interest
All members of the Renal Transplantation Guidelines working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on

Lasers and Technologies

1. INTRODUCTION

The European Association of Urology (EAU) Guidelines Office have set up a Guidelines Working Panel to analyse the scientific evidence published in the world literature on lasers in urological practice. The working panel consists of experts who, through these guidelines, present the findings of their analysis, together with recommendations for the application of laser techniques in urology. The guidelines also include information on the characteristics of lasers, which the panel believes will be very helpful to clinicians.

The aim of this document is to provide information on technical considerations and supplement the information in other EAU organ-specific guidelines documents, rather than be in competition.

These guidelines on the use of lasers and novel technologies in urology provide information to clinical practitioners on physical background, physiological and technical aspects, as well as present the first clinical results from these new and evolving technologies. Emphasis is given on interaction between technical tools and human tissue, surgical aspects and abilities, advantages and disadvantages of new tools, including operator convenience. In this document the panel focused on lasers, with the intention to expand further in the years to come.

The application of lasers in treating urological disorders is a swiftly developing area, with laser technology currently used for a variety of urological procedures. In some therapeutic areas, lasers have become the primary method of treatment and standard of care.

As with many other surgical or interventional procedures, there is a lack of high-quality publications. But particularly in the field of lasers, where technological advances are occurring so rapidly, many technologies will never be in use long enough for long-term study. This is obviously a challenge for anyone attempting to establish an evidence-based discussion of this topic, and the panel are very aware that these guidelines will require re-evaluating and updating within a short time frame. It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences and individual circumstances of patients into account.

1.1 Safety

Safety is very important when using lasers. All intra-operative personnel should wear proper eye protection to avoid corneal or retinal damage. This is particularly important with neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers, which penetrate deeply and can burn the retina faster than the blink reflex can protect it. Although holmium:YAG (Ho:YAG) lasers do not penetrate as deeply, they can cause corneal defects if aimed at the unprotected eye. For all lasers, adequate draping should be used to cover external areas, with wet towels draped over cutaneous lesions. Ideally, reflective surfaces (e.g. metal instruments) should be kept away from the field of treatment; however, if this is not possible, the field of treatment should be draped with wet drapes. Furthermore, it is very dangerous to use a laser if oxygen is in use anywhere near the operative field, as this may result in a laser fire and significant burns (1).

1.2 Methodology

The primary objective of this structured presentation of the current evidence base in this area is to assist clinicians in making informed choices regarding the use of lasers in their practice.

A secondary objective was to apply EAU guidelines methodology to this area where there is limited evidence available.

1.2.1 Data identification

Structured literature searches using an expert consultant were designed for each section of this document. Searches were carried out in the Cochrane Library database of Systematic Reviews, the Cochrane Library of Controlled Clinical Trials, and Medline and Embase on the Dialog-Datastar platform. The controlled terminology of the respective databases was used and both MesH and EMTREE were analysed for relevant entry terms.

The search strategies covered the last 25 years for Medline and for Embase (1974). A total number of 436 papers were identified, of which one was a Cochrane review (laser prostatectomy for benign prostatic obstruction (BPO) (2). A separate literature search for cost-effectiveness was carried out and yielded seven unique publications.

*1.2.2 **Publication history***

A scientific paper is now available based on this document (4). This resulted in minor changes to this published version of the Guidelines on Laser Technologies.

*1.2.3 **Quality assessment of the evidence***

The expert panel extracted relevant data from individual publications, the key findings of which are presented in tables throughout the document. Papers were assigned a level of evidence and recommendations have been graded following the listings in Tables 1 and 2.

Table 1: Level of evidence (LE)

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials.
1b	Evidence obtained from at least one randomised trial.
2a	Evidence obtained from one well-designed controlled study without randomisation.
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study.
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports.
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected Authorities.

Modified from Sackett et al. (3)

Table 2: Grade of recommendation (GR)

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial.
B	Based on well-conducted clinical studies, but without randomised clinical trials.
C	Made despite the absence of directly applicable clinical studies of good quality.

Modified from Sackett et al. (3)

2. LASER-BASED TREATMENTS FOR BLADDER OUTLET OBSTRUCTION (BOO) AND BENIGN PROSTATIC ENLARGEMENT (BPE)

2.1 Introduction

Benign prostate obstruction (BPO) and enlargement (BPE) can be treated with a range of laser treatments using different laser systems and applications. The different systems produce different qualitative and quantitative

effects in tissue, such as coagulation, vaporisation or resection and enucleation via incision (Table 3). Laser treatment is considered to be an alternative treatment to transurethral resection of the prostate (TURP). It must therefore achieve the same improvement in symptoms and quality of life (QoL) as TURP. It must also improve all urodynamic parameters, such as maximal urinary flow rate (Q_{max}), post-void residual urine volume (PVR) and maximal detrusor pressure (Pdetmax) with less morbidity and shorter hospitalisation than with TURP.

This section focuses on contemporary laser treatments for the management of BPE or BPO.

2.2 Physical principles of laser action

LASER is an acronym that stands for Light Amplification by Stimulated Emission of Radiation. Laser radiation is simply the directed light of a narrow bandwidth. This is synonymous to a single colour and applies to all regions of the invisible and visible electromagnetic spectrum (1).

2.2.1 ***Reflection***

When the laser beam encounters tissue, a percentage of the beam is reflected by the boundary layer and may therefore heat and damage surrounding tissue. Reflection mainly depends on the optical properties of the tissue and the irrigant surrounding it. Because reflection is not very much affected by wavelength, it can be ignored when evaluating a laser wavelength for surgical purposes.

2.2.2 ***Scattering***

The heterogeneous composition of tissue causes an intruding laser beam to scatter. Scattering diverts part of the laser beam away from its intended direction and therefore its intended purpose. The amount of scattering depends on the size of the particles and the wavelength of the laser. Shorter wavelengths are scattered to a much higher degree than longer wavelengths, i.e. blue laser radiation is scattered more than green, green more than red, and red more than infrared.

2.2.3 ***Absorption***

Absorption is the most important process of light interaction, though it is not the only process. Intensity of the laser beam decreases exponentially as the absorbing medium increases in density. Absorbed laser radiation is converted into heat, causing a local rise in temperature. Depending on the amount of heat produced, tissue will coagulate or even vaporise. Heat is more likely to be generated next to the tissue surface than further below because of the exponential decrease in beam intensity as it passes into the tissue and the immediate action of the absorption process.

However, absorption can only occur in the presence of a chromophore. Chromophores are chemical groups capable of absorbing light at a particular frequency and thereby imparting colour to a molecule. Examples of body chromophores are melanin, blood and water. Figure 1 shows the wavelength dependence and absorption length of a laser beam. The absorption length defines the optical pathway, along which 63% of incident laser energy is absorbed.

2.2.4 ***Extinction length***

The *extinction length* defines the depth of tissue up to which 90% of the incident laser beam is absorbed and converted into heat. An extinction length is equal to 2.3 absorption lengths. Haemoglobin and water are widely used as chromophores for surgical lasers (Figure 1).

For a short time after absorption of a circular laser beam, the generated heat is confined in a cylindrical-shaped volume, which has the height of the laser beam's extinction length and the approximate diameter of the laser fibre. The density of the absorbed energy determines the effect of the laser on tissue.

It is important to match the achieved effect along the extinction length with the intended surgical effect. At the same power wattage, a laser wavelength with a long extinction length may create a deep necrosis, whereas a laser wavelength with a much shorter extinction length will produce an increase in temperature above boiling point and immediate vaporisation of tissue.

Table 3: Lasers: crystals, abbreviations, wavelength, techniques and acronyms

Active crystal	Abbreviation	Wavelength (nm)	Technique	Acronym
Holmium	Ho:YAG	2140	Holmium laser ablation	HoLAP
			Holmium laser resection of prostate	HoLRP
			Holmium laser enucleation of prostate	HoLEP
Neodym	Nd:YAG	1064	Visual laser ablation of prostate	VLAP
			Contact laser ablation of prostate	CLAP
			Interstitial laser coagulation (of prostate)	ILC
Kalium titanyl phosphate	KTP:Nd:YAG (SHG)	532	Photoselective vaporisation of prostate	PVP
Lithium borat	LBO:Nd:YAG (SHG)	532	Photoselective vaporisation	PVP
Thulium	Tm:YAG	2013	Thullium laser vaporisation of prostate	ThuVAP

		980	Vaporisation	-
		1318	Vaporisation	-
		1470	Vaporisation	-

2.3 Historical use of lasers

*2.3.1 **Nd:YAG laser***

The Nd:YAG laser has a wavelength of 1.064 nm. It has a long extinction length and penetrates tissue by approximately 4-18 mm, making it suitable for haemostasis and tissue coagulation. At that time it appeared to be ideal for the treatment of benign prostatic hypertrophy (BPH) (2). Since 1985, many Nd:YAG laser-driven transurethral treatments have been described for both BPE and BPO (3).

*2.3.2 **Nd:YAG laser-based techniques***

Several Nd:YAG approaches have been extensively studied, including: visual laser ablation of the prostate (VLAP) (4); contact laser ablation of the prostate (CLAP) (5); interstitial laser coagulation (ILC) (6), and Nd:YAG laser hybrid techniques (7).

However, all these techniques have been superseded by the advent of newer laser-based techniques (8). As these techniques are no longer contemporary, they will not be discussed further in these guidelines. However, they are discussed in the EAU guidelines on the conservative treatment of non-neurogenic male lower urinary tract symptoms (LUTS) (9).

3. CONTEMPORARY LASER SYSTEMS

3.1 Introduction

Following the first generation of laser-based treatments for BOO and BPE, four (groups of) laser systems are currently used:

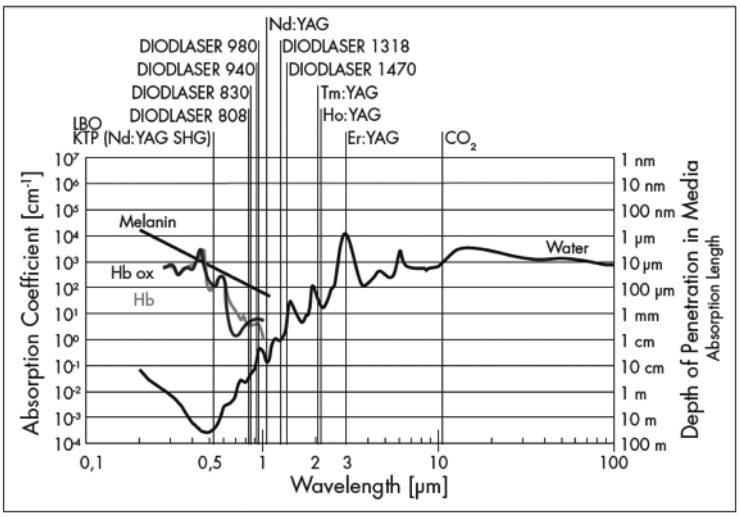
- KTP (kalium titanyl phosphate, KTP:Nd:YAG [SHG]) and LBO (lithium borat, LBO:Nd:YAG [SHG]) lasers;
- Diode lasers (various);
- Holmium (Ho):YAG (yttrium-aluminum-garnet) lasers;
- Thulium (Tm):YAG (yttrium-aluminum-garnet) lasers.

All the above-mentioned contemporary (and historical) laser therapies for the treatment of BOO and BPE use physiological sodium 0.9% solution for irrigation. This eliminates the risk of hypotonic hypervolaemic transurethral resection of the prostate (TURP) syndrome, which occured in 1.4% of patients in large TURP reported series (1). A second advantage (that applies to all endoscopic minimal invasive therapies for the prostate) is the avoidance of secondary wound healing skin disorders, which occured in 5.5% of the patients in a major series of open prostatectomy (OP) (2).

3.2 KTP (kalium titanyl phosphate, KTP:Nd:YAG [SHG] and LBO (lithium borat, LBO:Nd:YAG [SHG]) lasers

The KTP and LBO lasers are both derived from the Nd:YAG laser. The addition of a KTP or LBO crystal to the laser resonator converts the Nd:YAG wavelength from 1064 nm to 532 nm. This is a green wavelength, which is strongly absorbed by oxyhaemoglobin. The resultant laser has a short extinction length and penetrates vascular tissue by only a few micrometres. In red, well-circulated tissue, the density of absorbed power is high and immediately raises the tissue temperature above the boiling point (Figure 1). This causes tissue to vaporise, leaving behind a coagulated seam where the increased tissue temperature has resulted in haemostasis (3). In this seam, haemoglobin is bleached but not vaporised. The applied laser energy must travel through the coagulated seam, where the laser beam experiences mainly scattering. The lack of absorption in coagulated tissue impairs its removal, while the scattering of the green wavelength reduces the laser beam's intensity, impairing its vaporising effect on the next tissue layer (4).

Figure 1: Wavelength of different laser types, depth of penetration in media and absorption coefficient



Er:YAG = Erbium: yttrium-aluminum-garnet laser; Ho:YAG = Holmium: yttrium aluminium garnet; KTP = potassium titanyl-phosphate; LBO = lithium triborate; Nd:YAG = Neodymium-doped: yttrium aluminium garnet; Tm:YAG = Thulium: yttrium aluminium garnet.

3.2.1 ***Physical properties***

All new lasers are extensively studied in preclinical trials in comparison with the most common vaporising laser, i.e. an 80 W KTP or 120 W LBO laser. The specific heat capacities of renal (3.89 kJ/kg/°K) and prostatic tissues (3.80 kJ/kg/°K) are almost equivalent, so making the isolated, blood-perfused, porcine kidney a very useful model for the study of laser procedures (5).

Animal models have been very useful in evaluating laser characteristics, including tissue ablation rate, efficacy of ablation in correlation to the power setting (output power efficiency), haemostatic properties, and the extent of morphological tissue necrosis. Table 4 provides a comparison of different lasers and their individual characteristics derived from a series of ex-vivo comparison studies in a porcine, perfused kidney model. The data has been given as a statistical mean or interval, according to the original publication.

3.2.1.1 Ablation capacity

The tissue ablation rate achieved with KTP and LBO lasers increases with increasing output power. In comparison to the Tm:YAG laser (70 W) KTP laser, the tissue ablation rate reached 3.99 g/10 min (80 W KTP) and 6.56 g/10 min (70 W Tm:YG) ($p < 0.05$). When compared to TURP, both laser devices produced significantly lower rates of tissue removal (8.28 g/10 min) (6). However, the LBO laser, with its tissue ablation rate of 7.01 g/10 min laser ablation at 120 W offered a significantly higher ablation capacity compared with KTP laser at 80 W ($p < 0.005$) (7).

3.2.1.2 Bleeding rate

The KTP laser shows excellent haemostatic potential, with a bleeding rate for the 80 W KTP laser of 0.21 g/min compared with 0.16 g/min for the continuous wave (cw) 70 W Tm:YAG laser. In contrast, TURP is associated with a much higher bleeding rate of 20.14 g/min ($p < 0.05$) (6). The bleeding rate for the 120 W LBO laser was also higher at 0.65 g/min when compared to 80 W KTP with 0.21g/min, respectively ($p < 0.05$) (7).

3.2.1.3 Coagulation zone

In the porcine perfused kidney tissue ablation model, the KTP laser ($p = 0.05$) showed a 2.5-fold deeper coagulation zone (666.9 µm) than the cw Tm:YAG (264.7 µm) laser and TURP (287.1 µm). Tissue ablation resulted in a dense coagulation zone at the tissue surface (6). The corresponding depths of the coagulation zones at 120 W LBO laser and 80 W KTP laser were 835 µm and 667 µm ($p < 0.05$), respectively (7).

Table 4: Ex-vivo study on ablative capacity, haemostatic properties and coagulation zone due to tissue penetration in porcine perfused kidney model

*3.2.2 **Surgical technique of KTP/LBO lasers***

Both KTP and LBO lasers operate at a wavelength at which absorption in water is minimal. In the absence of an haemoglobin molecule, the extinction length increases dramatically and the beam penetrates deeply into irrigant and/or tissue. This technique is described as the photoselective vaporisation of prostate (PVP) (9). In addition, side-firing fibres are used in PVP to ensure that the surgeon has better, direct, visual control of the point at which the laser beam strikes the tissue.

Laser energy is directed towards prostatic tissue using a 70° 600 µm side-firing probe. Under direct vision, vaporisation is performed with a fibre-sweeping technique, starting at the bladder neck and continuing with the lateral lobes and the apex. The prostate gland is vaporised from inside the gland to its outer layers. This also occurs with TURP, but in contrast to TURP, no tissue remains for histopathological evaluation (10).

Since 2006, a LBO laser with a power of 120 W and collimated beam has been available (7,11).

As with all lasers, surgeon must wear safety goggles. These goggles must include a coloured filter in the KTP/ LBO laser setting.

*3.2.3 **Urodynamic results and symptom reduction***

In 1998, Malek et al. (12) showed that the 60 W KTP laser was both feasible and safe. Since then, most laser therapy trials prior to 2010 have used the 80 W KTP laser. There has been only limited data on the higher-powered 120-W LBO laser. Almost 10 years after the clinical introduction of 532-nm lasers, two randomised controlled trials (RCT) were published comparing 80 W KTP with TURP with follow-up periods up to 12 months (13,14). One of the trials compared 80 W KTP with OP (15), while the other trial compared 120 W LBO laser with TURP (16) (Table 5).

One RCT showed equivalent results to TURP (12) at 1-year follow-up, while another, non-randomised, two-centre study reported equivocal results (17). In contrast, a second RCT clearly showed that TURP resulted in greater urodynamic improvement (Q_{max}) than the KTP PVP laser (14). Another study comparing KTP PVP with OP showed equivalence in Q_{max} improvement, PVR and symptom score reduction at 18-month follow-up (15). Prostate-specific antigen (PSA), as a surrogate marker of tissue removal, decreased by 68.2% with OP and 61.2% with KTP PVP (15). However, other studies have reported much lower rates for PSA reduction using KTP PVP, including 45% reduction (18), 41.7% (19) and 37% (20).

Kalium titanyl phosphate PVP showed a higher retreatment rate in larger prostates > 80 ml within a 12 month follow-up (21). The study comparing LBO PVP treatment with TURP showed equivalence in Q_{max} improvement, PVR and symptom score reduction at 36-month follow-up (16). PVP demonstrated reduced detrusor pressure at maximum flow (Pdetqmax) (22) at 1-year follow-up. In addition, prospective, non-randomised trials have demonstrated the safety and efficiency of LBO PVP laser in patients receiving ongoing oral anticoagulation (23), in patients with retention (24), or with prostates > 80 mL (21).

In studies comparing TURP with KTP PVP, OT time was significantly shorter in prostates larger than 80 ml by 30 to 50 min (17). This difference comes down to 9 min with the LBO PVP (120 Watt) (16).

Table 5: KTP and LBO lasers: improvement in urodynamic parameters, symptom score and PSA reduction

Reference	Laser source (power)	Follow-up (mo)	Patients (n)	Mean prostate size (mL)	PSA reduc-tion (%)	Change in symptoms (%)	Change in Q_{max} (mL/s) (%)	PVR change (%)	LE

KTP = potassium titanyl-phosphate laser; LBO = lithium triborate; OP = open prostatectomy; PVP = photoselective vaporisation of the prostate; TURP = transurethral resection of the prostate.

3.2.4 ***Risk and complications, durability of results***

3.2.4.1 Intra-operative complications

Several studies have proven the intra-operative safety of PVP with KTP and LBO lasers, including prospective studies (25-27) and RCTs in comparison to TURP (13,14,28,29) or OP (15). Furthermore, safety was demonstrated in subgroup analyses of patients with large prostates (30,31), receiving anticoagulant therapy (31,24), or in retention (31,24).

An RCT comparing 80 W KTP PVP with TURP demonstrated significantly less blood loss in KTP PVP (0.45 g/dL) versus TURP (1.46 g/dL, $p < 0.005$), resulting in a blood transfusion rate in TURP (13). Another RCT of 80 W KTP PVP compared with TURP supported these findings with a blood transfusion rate of 8.1% for TURP (14). In an RCT comparing LBO PVP to OP, the transfusion rate was 0% following KTP PVP, but 13.3% for OP (15). A total of 7.69% of patients in the KTP PVP group required intra-operative conversion to TURP for the control of bleeding, most probably due to capsule perforation (15). A study comparing LBO PVP laser therapy with TURP reported a blood transfusion rate of 20%, a capsule perforation rate of 16.7%, and a TURP syndrome of 5% for the TURP treatment arm, but none of these complications were reported for LBO PVP (16).

These findings are supported by a number of studies (not including RCTs). A major multicentre study of 500 patients comparing PVP to TURP reported an intra-operative bleeding rate in 3.6%, capsule perforation in 0.2% and conversion to TURP due to bleeding, prostate size or fibre defect in 5.2% of patients. No blood transfusions were necessary. The highest rate of intra-operative bleeding occurred in a subgroup of patients with prostates > 80 mL (5.7% of subgroup) (25). One non-RCT study of LBO PVP reported an intra-operative bleeding rate of 2.6%, capsule perforation of 1% and blood transfusion rate of 0.4% (27). In another non-RCT on LBO PVP, various subgroups of patients were compared, including patients not in retention with patients in retention, patients taking anticoagulant therapy versus patients not taking anticoagulants, and prostate size < 80 mL versus > 80 mL. Intra-operative bleeding which required conversion to TURP occurred in 1.5-3.8% (> 80 mL). Capsule perforation occurred in 0.8-1.5% of patients taking anticoagulants (31). These findings have been supported by studies from other authors in the same patient subgroups (23,24,30,32).

3.2.4.2 Early post-operative complications

An RCT that compared KTP PVP to TURP in patients with prostates > 70 mL found a significantly higher rate of urinary retention after KTP PVP (15.3 vs 2.7%, $p < 0.05$). Reinterventions were necessary in 17.6% of patients following KTP PVP versus 0% for TURP (14). Another RCT reported 0% and 16.7% clot retention in KTP PVP and TURP, respectively, while transient urinary retention with recatheterisation occurred in 5% of both groups.

Urinary tract infection (UTI) occurred in 3.3% and 5% of KTP PVP and TURP, respectively, while re-admissions were necessary in 1.6% and 5%, respectively (13).

An RCT comparing KTP PVP with OP for prostatic adenomas > 80 mL showed no statistical significant difference in the incidence of post-operative complications. Prolonged dysuria was noted in 7.6% of KTP PVP and 11.6% of OP patients, while UTIs were reported in 21.5% of KTP PVP versus 27% of OP patients (15). In an RCT comparing LBO PVP with TURP, clot retention occurred in 10% of TURP-treated patients compared with none in the LBO PVP group. In the same study, dysuria within 30 days following surgery was reported in 31.7% of TURP and 93.3% of LBO PVP. In contrast, a non-RCT study on LBO PVP reported dysuria in 7.5-14.6 % in all patient subgroups (31).

The above findings are supported by the data of a major study of 500 patients (25). Following PVP using the KTP laser, haematuria was reported in 9.8%, blood transfusion in 0.4%, revision in 0.6%, acute renal failure in 0.6%, urosepsis in 0.4%, dysuria in 14.8%, transient urge incontinence in 2.4%, and UTI in 6.8% (25).

Haematuria was significantly more common in patients taking anticoagulation treatment (17.2 vs 5.4%, $p = 0.001$) (23) or with prostates > 80 mL (17.2 vs 9.8%, $p < 0.05$) (25). Patients with prostates < 40 mL had a significantly higher rate of dysuria than the overall study population (24.3 vs 14.8%, $p < 0.01$) (25).

3.2.4.3 Late complications and durability of results

The longest follow-up of an RCT in evaluating the longevity and long-term morbidity of KTP PVP and LBO PVP is the study of Al-Ansari comparing LBO PVP to TURP with a follow-up of 36 months (16). Longer follow-up of 60 months is presented by a non-randomised study of Hai. Retreatment with PVP due to recurrent adenoma occurred in 7.7% of 246 patients, three (1.2%) underwent incision of the bladder neck resulting in an overall retreatment rate of 8.9% (33).

In an RCT with a 6-month follow-up, 8.1% in the TURP group and 5.1% in the KTP PVP group underwent internal urethrotomy in response to a urethral stricture. Reintervention was required in 17.9% of patients treated with KTP PVP because coagulated tissue was significantly obstructing the bladder outlet. Retrograde ejaculation rates were similar in both groups (56.7% TURP and 49.9% KTP PVP) (14). Another RCT with a 12-month follow-up reported submeatal/urethral strictures or bladder-neck stenosis in 13.3% of TURP patients and 8.3% of KTP PVP patients (13). In an RCT of KTP PVP versus OP, and an 18-month follow-up, the reoperation rates due to urethral stricture were 3.1% versus 1.6%, bladder neck contracture (0% vs 3.3%), or need for apical resection (1.5%), with a total of 4.6% of KTP PVP and 5% OP, respectively (15). Comparing LBO PVP with TURP reported a significantly lower retreatment rate of 1.8% for LBO PVP versus 11% for TURP. Bladder neck contractures were incised in 3.6% and 7.4%, respectively.

These findings are supported by a large case series RCT for KTP PVP, with a global retreatment rate of 14.8% due to recurrent or persisting adenoma tissue (6.8%), bladder neck strictures (3.6%), or urethral strictures (4.4%) (32). The limitation of this study lies in the number of patients available at 5-year follow-up (27/500) (25). Anticoagulation and urinary retention at the time of surgery have no significant influence on the rate of long-term complications (23,24).

It is possible that KTP PVP has reduced efficacy in patients with larger prostates. According to a prospective, multicentre study, PVP efficacy was lower in patients with larger prostates and PSA levels > 6.1 ng/mL (34), but this finding has not been supported by other studies (25,30). Bladder neck strictures seem to occur more often in patients with prostate glands < 40 mL (7.8 vs 3.6%, $p < 0.05$) (25).

There is evidence from RCTs that persistent urinary stress incontinence is rare. Incontinence varies from 1.4% for KTP PVP (34) to 0.7% for LBO PVP (27).

There is limited data on sexual function following PVP. After a 24-month follow-up, overall sexual function in men undergoing KTP PVP was found to be maintained. In those IIEF-5 (International Index of Erectile Function-5) > 19, the pre-operative median value was significantly decreased from 22 to 16.7 ($p < 0.05$) (36). In an RCT of LBO PVP compared with TURP, none of the 82 patients in follow-up for 36 months presented with erectile dysfunction, and there was a comparable rate of retrograde ejaculation (PVP 49.9% vs TURP 56.7%, $p = 0.21$) (14). Another study, comparing KTP PVP and OP, reported no change in erectile function post-operatively (15). In a case series of LBO PVP, erectile function remained stable or improved in patients with mild or mild-to-moderate erectile dysfunction (37-39).

3.2.5 *Conclusions and recommendations for the use of KTP and LBO lasers*

Conclusions	LE
In patients with small to moderate-sized prostates, TURP remains the standard of care.	1a
KTP PVP and LBO PVP are safe and effective in the treatment of BOO and BPE in patients with a small or medium prostate gland.	1b
Over a follow-up of 3-5 years, re-treatment rates appear comparable to those with TURP.	1b (at 3 yr) 4 (at 5 yr)
KTP PVP and LBO PVP are safe and effective for patients receiving anticoagulation medication or patients in retention.	4

Recommendations	GR
KTP/LBO PVP is a treatment alternative for patients with BOO and BPE for small and medium glands.	A
KTP/LBO PVP can be offered as an alternative to TURP for patients with refractory urinary retention.	B
KTP/LBO PVP can be offered to patients using anticoagulant medication.	B
KTP/LBO PVP is a safe method for volume reduction in large size prostate glands.	A

BOO = bladder outlet obstruction; BPE = benign prostatic enlargement; KTP = potassium titanyl-phosphate laser; LBO = lithium triborate; PVP = photoselective vaporisation of the prostate; TURP = transurethral resection of the prostate.

3.3 Diode lasers

*3.3.1 **General aspects***

The term diode laser refers to the method of laser beam generation.

Laser light can be generated by a resonator or a diode. The main advantages of diode lasers compared with Nd:YAG lasers are a smaller box size and a much higher wall-plug efficiency (i.e. how much of the mains supply is converted into laser power). These differences arise out of the technical principles behind the generation of laser radiation and energy. Depending on the type of laser generator, the efficiency of diode lasers is more than one order of magnitude better. Furthermore, the thermal power loss of diode lasers is much less and therefore they can be operated from a standard wall mounted power outlet.

Diode lasers in the wavelength range of 808-980 nm experience a similar absorption in water and generate a similar tissue effect to the Nd:YAG laser (1,2). Other diode lasers have wavelengths of 1318 and 1470 nm (3). The 830 nm (Indigo) diode laser has been extensively used in interstitial laser coagulation (ILC) (4).

Various types of diode lasers operating at wavelengths of 940, 980 or 1470 nm are available for the application in diode-laser prostatectomy. Currently, there are only a few studies investigating the clinical applications of diode lasers and the maximum follow-up is 1 year.

3.3.2 ***Physical properties***

3.3.2.1 *Ablation capacity*

In the porcine perfused kidney model, the 1318 nm diode laser achieved the highest ablation rate (12.43 g/10 min, 100 W) when compared to the 1470 nm diode laser (5.27 g/10 min, 80 W), the 980 nm diode laser (8.99g/10 min, 200 W), or the 120 W LBO laser (7.01 g/10 min, 120 W). The same result was achieved when the output power efficiency (g/W/10 min) was calculated (3). The 980 nm and 1.470 nm diode lasers showed no statistical difference when compared with the LBO laser (3). The 940 nm diode laser also showed a large ablation capacity when tested in canine prostate (15.17 g/10 min) (5). In a further study, the 980 nm diode laser showed increased tissue ablation rates in the continuous-wave (cw) mode, with increasing output power levels reaching 7 g/10 min at 120 W while the KTP laser displayed a significantly lower ablation capacity. Compared with TURP, both laser devices resulted in significantly lower tissue removal (6) (Table 6).

3.3.2.2 *Bleeding rate*

In a perfused ex-vivo porcine kidney, the haemostatic properties, calculated by bleeding rate, of the 980 nm (0.35 g/min), the 1318 nm (0.27 g/min) and the 1470 nm (0.24 g/min) diode lasers were significantly better than for the LBO laser (0.65 g/min) (3). For the 940 nm diode laser, 60 W resulted in a bleeding rate of 0.21 g/min (5).

3.3.2.3 *Coagulation zone*

The 980 nm (4.62 mm), 1318 nm (4.18 mm) and the 1470 nm (1.30 mm) diode laser showed significantly deeper necrotic zones compared to the LBO laser (0.84 mm) (3). The 980 nm diode laser was shown to achieve a mean coagulation zone of 8.43 mm, 9.15 mm and 9.58 mm in a porcine, perfused kidney model at 60, 90, and 120 W output powers, respectively. Compared with 80 W KTP, the coagulation capacity in the porcine kidney model for diode lasers was 7.7 to 8.7 times deeper ($p < 0.0001$). A shift towards the pulsed emitting mode did not change these results ($p < 0.001$) (6). These results are within the range of the Nd:YAG laser (2).

In a further in-vivo study, the 1470 nm diode laser achieved a coagulation zone of 2.30 mm at 100 W (7). The diode laser had an up to 2.7 times deeper coagulation capacity than KTP ($p < 0.005$). The 940 nm diode laser was studied in a porcine perfused kidney model. The coagulation depth measured 0.86 (10 W) up to 9.54 mm (60 W). In the same study, the coagulation depth in a canine prostate model was limited to 4 mm (200 W continuous wave mode) (7).

3.3.3 *Diode laser techniques*

Diode lasers work at a wavelength at which absorption in water is low. As with KTO and LBO lasers, procedures executed with diode lasers use side-firing techniques to ensure better direct visual control of the surgeon on the point of impact of the laser beam on the tissue (1). Reported techniques are vaporizing techniques (8-12). Because laser penetration levels are deeper and the coagulation zone is wider (3,7,13), some authors have suggested power should be reduced when treating the apex with the underlying sphincter region (10,11).

3.3.4 *Clinical results*

3.3.4.1 *Urodynamic parameters, symptom score reduction, PSA reduction*

Clinical data is limited to short-term follow-up (maximum follow-up 1 year) and comprises case-control studies or cohort studies (randomised cohort trials) (9-12,14). Two trials compared diode laser treatment with LBO laser systems as a standard treatment arm (9,14). The most substantial data is for the 980 nm diode laser (9-11,14).

At the end of the follow-up period, there was a significant improvement in urodynamic parameters (peak urinary flow [Q_{max}], PVR) (Table 7). There was a reduction in PSA levels, as a surrogate parameter marker for a reduction in prostatic tissue, in the range of 30% (11) and 58% (10). However, an RCT, as well as a non-RCT, did not show significant differences in improved urodynamic parameters and symptom score reduction (Table 7).

Table 7: Results of diode lasers with regard to improvement of urodynamic parameters, symptom score and PSA reduction

PSA = prostate-specific antigen; Q_{max} = peak (maximal) urinary flow rate; PVR = postvoid residual urine volume; LE = level of evidence; LBO PVP = LBO photoselective vaporisation.

3.3.5 *Risk and complications, durability of results*

3.3.5.1 *Intra-operative complications*

Published available studies of 980 nm (9-11,14-17) and 1470 nm (12) diode lasers are all case series or case control series or comparative studies. The studies have indicated a high level of intra-operative safety. In the RCT, which compares the safety and efficacy of the 980 nm diode laser versus the 120 W LBO laser, the rate of intra-operative bleeding was significantly lower in the diode laser group (0% vs 13%). Anticoagulant medication was being taken by 23.6% of patients receiving diode laser treatment and 25.0% of patients in the LBO PVP group (9).

These findings are supported by a non-RCT, which found almost the same results (0% vs 11.9%). In this study (14) 52% of patients in the laser diode treatment arm and 43% in the LBP PVP treatment arm were on anticoagulant medication (14). This study is supported by preclinical studies on the novel laser energy sources, showing almost equal haemostatic potential and coagulation features to the Nd:YAG laser (6). Furthermore, one comparative non-RCT reported no capsule perforation with the 980 nm diode laser. The necessity for

conversion to TURP was reported in 4% (980 nm diode) and 8% (LBO PVP) of patients (9).

3.3.5.2 Early post-operative complications

Although there is only a limited amount of data, several conclusions can still be made. The incidence of early post-operative complications reported is low. No post-operative blood transfusions occurred.

In a comparison of the 980 nm diode laser to LBO PVP, a non-RCT showed the following complications: post-operative haematuria in 20% versus 19%, transient incontinence in 14.5% versus 2.4% ($p < 0.05$), transient urgency in 34.5% versus 16.7% ($p < 0.05$), scrotal oedema 3.6% versus 0%, anal pain 3.6% versus 0%, and epididymitis 1.2% versus 9.1% (14).

A comparative study reported dysuria in 24% (980 nm diode laser) versus 18% (LBO PVP), urinary incontinence 7% versus 0% and a blood transfusion rate of 0% versus 2% (14). The recatheterisation rate was between 4.3% (11) and 20% (9).

3.3.5.3 ***Late complications***

Diode laser vaporisation of the prostate seems to carry a high rate of late complications. In a case series, 32.1% of patients needed reoperation within a follow-up of 12 months after 980 nm diode treatment due to obstructive necrotic tissue or bladder neck stricture (15).

This finding is supported by an RCT comparing the 980 nm diode laser with LBO: 9.1% versus 3.6%, respectively, of patients required reoperation with TURP due to bladder neck obstruction; 5.5% versus 2,4% developed urethral strictures; and 1.8% versus 0% developed urethral stone formation (14).

Another study, which compared diode laser to LBO PVP found higher rates of bladder neck stricture (14.5% vs 1.6%, $p < 0.01$), higher retreatment rates (18.2% vs 1.6%, $p < 0.01$) and persistence of stress urinary incontinence (9.1% vs 0%; $p < 0.05$) (9).

However, other reports have shown only transient combined urge and stress incontinence in 4.3% of patients for 2 weeks (11). This discrepancy has been a controversial issue conducted via scientific communication within the urological community (16). A further case series has reported sloughed-off tissue in 14.5% in cystoscopic intervention and a reoperation rate with TURP in 7.3% of patients. Urinary stress incontinence remained in 1.8% of patients during a 6-month follow-up period (10). Furthermore, in 20% of patients, a repeat of TURP was necessary within a 1-year follow-up after treatment with a 1.470 nm diode laser (12).

3.3.5.4 Practical considerations

In view of the available data on the use of the diode laser, it should not be a standard treatment option for BPE. The literature show a retreatment rate of up to 35%. Transitory and permanent incontinence seem to be higher than for alternative treatments. This treatment may offer a high inter-operative control of bleeding for patients on anticoagulative drugs.

3.3.5.5 Recommendation for prostate treatment with diode lasers

Recommendation	LE	GR
In patients presenting with BOO and BPE and who have bleeding disorders or are receiving anticoagulants, diode laser treatment is an alternative.	1b	C

BOO = bladder outlet obstruction; BPE = benign prostatic enlargement

3.4 Holmium (Ho:YAG) laser

3.4.1 ***General aspects***

The crystalline matrix for the holmium laser is yttrium-aluminium-garnet (YAG). In order to prevent excessive heating inside the crystal, chromium, thulium and holmium are mixed with the YAG melt from the crystal. Excitation energy is virtually handed to the holmium via a cascade from chromium over thulium. However, heat accumulation within the laser crystals restricts the holmium laser under flash lamp excitation at room temperature to pulsed operation at moderate repetition rates. Holmium laser radiation has a short extinction length in tissue due to strong absorption of the water molecule around 2140 nm (Figure 1). At this wavelength, the depth of penetration is approximately 400 µm. The density of absorbed power in irrigant and/or in tissue is high and results in an immediate increase of temperature above the boiling point.

In a typical endourological setting, the onset of vaporisation is in the irrigant next to the fibre tip, where a steam bubble is generated with each laser pulse. The diameter of the bubble depends on the energy of the laser pulse

and is a few millimetres wide. The duration of this steam bubble is similar to duration of the laser pulse, which is about 500 µs (18). This duration is too short for human perception and therefore invisible.

In holmium laser enucleation of the prostate (HoLEP), the steam bubbles separate tissue layers by tearing the tissue apart (19). In soft tissue surgery, tissue vaporisation is dominated by the way in which the steam bubble tears tissue and laser radiation is absorbed in tissue. This explains the white fibrous appearance of the surgical sites during holmium laser surgery on soft tissue under irrigation. The tissue effect is rapid and haemostasis of the holmium laser is excellent.

Common pulse energy settings for holmium lasers are in the range of 2 J. Depending on the flash lamp driver technology installed, the laser pulse duration may be between 150 µs and 1 ms. About 100 µs is required for heat to diffuse out of a short cylinder established by the fibre diameter and the extinction length (thermal relaxation time). The heat generated during the absorption process accumulates during the duration of the laser pulse at the point of impact, until heat conduction levels out the temperature profile.

In laser lithotripsy, some laser radiation is absorbed inside the stone generating an immediate build-up of steam pressure, which causes fragmentation. A laser pulse duration that is shorter or of the order of the thermal relaxation time confines the absorbed energy within the above-mentioned cylinder. The shorter the laser pulse duration at a given pulse energy, the higher the pulse peak power will be and the more effective is stone fragmentation (20).

3.4.2 ***Physical properties***

General physical properties have been covered in section 3.4.1. Ho:YAG lasers have not been investigated to that extend like KTP, LBO, Tm:YAG and various diode lasers. Therefore, very limited data on these aspects is available so far.

3.4.3 ***Holmium laser techniques***

All holmium laser techniques are based on vaporisation. The energy is delivered to the prostate through an end-firing laser fibre with a diameter of about 500-600 µm. Holmium laser techniques evolved from holmium laser ablation of the prostate (HoLAP) (21) to holmium laser resecting techniques (HoLRP) (22) and, finally with the introduction of the tissue morcelator, to the holmium laser enuclation technique (HoLEP) (23). A later modification combined HoLEP with electrocautery resection of the enucleated lobe, while still attached at the bladder neck (24). As for physical characteristics, the vaporising effect of holmium laser-emitted energy is limited (15%) compared to other lasers.

3.4.4 ***Holmium laser vaporisation (ablation) of the prostate (HoLAP)***

Today, HoLAP procedure is carried out using a side-firing fibre in close contact with the surface in a sweeping fashion like PVP. The energy absorbed by the water molecule means that this technique would be safe, even if performed with bare fibre. In this manner, prostatic tissue is ablated and a cavity created similar to TURP. The strong absorption of holmium laser energy by water (Figure 1) results in a sufficiently high energy density to vaporise prostatic tissue, so creating tissue ablation without deep coagulation.

There are little data on HoLAP treatment of the prostate. A single RCT has compared 60 W and 80 W HoLAP versus TURP in 36 patients (25). Q_{max} improvement was equivocal at 3, 6, and 12 months after the operation, while prostate volume was reduced by 39% (HoLAP) and 47% (TURP), respectively. However, no RCT exists for the new high-power, 100 W HoLAP versus TURP or OP. One RCT comparing 100 W HoLAP with KTP reported results from a short- and intermediate-term follow-up (Table 8). Anticoagulant medication was being taken by 12.2% of patients treated with HoLAP and 15.3% treated with TURP. No difference was found except for operation time, which was 1.5-fold greater than that for TURP (26,27).

3.4.5 ***Holmium laser resection of the prostate***

In contrast to HoLAP vaporisation, the HoLRP procedure uses vaporisation only to cut small pieces out of the prostate. This results in multiple small prostate chips falling into the bladder before being removed with a syringe at the end of the operation, similar to TURP.

Because the technological emphasis has been on HoLEP, the clinical application of HoLRP and HoLAP declined. Thus, most of the clinical data available in holmium-based literature discusses HoLEP.

The HoLRP technique is limited to small prostates. Resection time of larger prostates would take almost double the time of HoLEP, making HoLRP less suitable for treatment of BPE/BOO. One RCT compared TURP

with HoLRP in 120 patients with BOO. The patients had prostates < 100 mL in volume. The study published results at three time-points in the follow-up period (28-30). Resection time was almost doubled for HoLRP when compared to TURP (42.1 versus 25.8 minutes, p < 0.005). The mean catheter time was significantly shorter (20.0 versus 37.2 hours, p < 0.005). Symptomatic and urodynamic improvement were equivalent in the two groups. However, at 12 and 18 months after the operation, HoLRP showed superior results to TURP (25.2 versus 20.4 mL/s, respectively, at 12 months, and 25.1 versus 19.2 mL/s at 18 months). The superiority of HoLRP vanished at 24 months, until the end of the study at 48 months after the operation. The Q_{max} of patients treated by HoLRP or TURP was 22.2 versus 18.5 mL/s, respectively. This data is inconclusive because it is not possible to determine whether HoLRP is better or worse than standard treatment. However, the results favoured HoLRP with regard to quality of life, hospitalisation time and catheterisation time. Patients with large median lobes and patients in urinary retention can be safely treated (31,32).

*3.4.6 **Holmium laser enucleation of the prostate***

Holmium laser enucleation of the prostate (HoLEP) is based on the same physical principle as HoLRP. However, during the HoLEP procedure, the surgical capsule of the prostate is exposed by incision and vaporisation of the periurethral prostatic tissue. After identifying the plane at the surgical capsule, the prostatic adenoma is separated from the capsule by disruption of the adenoma from the capsule, similarly to OP. Disruption is achieved by the pulsating steam bubble caused in front of the fibre by the pulsed laser energy emitting mode of Ho:YAG lasers. The introduction of HoLEP resulted in a significant improvement in the technique. The entire lobes are enucleated, moved into the bladder and morcellated (23), or fragmented with the TUR-sling at the bladder neck (mushroom technique) (24).

Several RCTs have compared HoLEP with TURP and OP, with the main findings given in Table 8.

A meta-analysis observed a tendency towards HoLEP for an improved symptom score during the entire follow-up period of up to 30 months, with larger mean changes in post-operative measurements. However, the differences in the individual studies were not statistically significant (weighted mean difference –0.82, 95% CI: –1.76-0.12; p=0.09). In the same meta-analysis, the same result was found for Q_{max} at 12-month follow-up. Compared with TURP, significantly higher Q_{max} rates were reported for HoLEP (weighted mean difference 1.48 mL/s, 95% CI: 0.58-2.40; p=0.002) (33).

In another meta-analysis, HoLEP was superior (pooled estimates) to TURP with regard to catheterisation time (17.7-31.0 h vs 43.4-57.8 h, respectively; p< 0·001), hospital stay (27.6-59.0 vs 48.3-85.5 days; p=0.001). In contrast, TURP was superior (pooled estimates of the difference) to HoLEP with regards to the duration of operation (33.1-73.8 vs 62.1-94.6 h respectively; p=0·001) (34).

Beside the evaluated RCTs, other non-RCT studies demonstrated that HoLEP has a low morbidity and is also effective in patients with urinary retention (35,36). One RCT compared changes in the urodynamic parameters of HoLEP versus TURP using computer urodynamic investigation (37). Pressure-flow studies before surgery and 6 months after the operation indicated that Pdetqmax after HoLEP (76.2 vs 20.8 cm H_2O) decreased significantly more compared to TURP (70 vs 40.7 cm H_2O; p < 0.001). Furthermore, the Schaefer BOO grade before and 6 months after the operation decreased significantly more after HoLEP (3.5 vs 0.2) compared to TURP (3.7 to 1.2; p < 0.001).

In recent years, a considerable number of studies regarding intermediate and long-term outcome of HoLEP alone in comparison to TURP or OP have been published. Gilling et al. (38) reported long-term data with a mean follow-up of 6.1 years showing that HoLEP results are durable and most patients remain satisfied. In prostates > 100 mL, HoLEP proved to be as effective as OP, regarding improvement in micturition with equally low re-operation rates at 5-year follow-up (39).

*3.4.7 **Risk and complications, durability of results***

The published literature describing Ho:YAG treatment of the prostate is dominated by discussion of HoLEP with few publications for HoLAP and very few for HoLRP. The introduction of KTP resulted in less interest in Ho:YAg as a solely vaporising laser. However, the recent availability of 100 W Ho:YAG laser devices has led to a renewed interest in HoLAP because of the popularity of vaporising using a side-fire technique (26,27).

*3.4.8 **Intra-operative complications***

3.4.8.1 HoLAP

An RCT comparing HoLAP with KTP PVP reported no intra-operative bleeding in the HoLAP-treated group, while three KTP PVP-patients required intra-operative conversion to TURP electrocauterisation (27). Another RCT comparing HoLAP versus TURP did not report any intra-operative complications (25).

3.4.8.2 HoLRP

The RCTs available for HoLRP (28-30) tend to focus on the outcome for improved symptom score and urodynamic parameters. Intra-operative complications for HoLRP are not specifically displayed. In comparison, the TURP treatment arm in these studies showed a blood transfusion rate of 6.7%. Furthermore, the available case series do not focus on intra-operative complications (31,32,47).

3.4.8.3 HoLEP

The safety and low intra-operative morbidity of HoLEP has been proven in seven RCTs (40-46).

Several reviews (48) and two meta-analyses (33,34) have investigated the safety and peri-operative mobidity of HoLEP. One meta-analysis found a lower rate of blood transfusion after holmium laser enucleation (relative risk 0.27, 95% CI: 0.07-0.95; p=0.04) compared with TURP (33); a finding supported by a second meta-analysis (34). In addition, a second meta-analysis showed that HoLEP reduced catheterisation time and duration of hospital stay, although TURP resulted in a shorter total operation time (34).

In a review of studies published from 2003 until 2006, 1,847 patients were identified who had been treated with HoLEP. The blood transfusion rate was 1% and peri-operative mortality was 0.05%. A further review showed a capsular perforation rate ranging from 0.3% (49) to 10% (50). The perforations were mainly classified as small capsular lacerations and the patients' course was not affected. Superficial mucosal laceration with the morcellation device was reported ranging from 0.5% (50) to 18.2% (46). The rate of superficial ureteric orifice injury that did not require insertion of a ureteral stent or nephrostomy ranged from 1.0% (51) to 2.1% (52). The incidence of incomplete morcellation ranged from 1.9% (52) to 3.7% (54) in all cases. Cardiac adverse events were reported in up to 1.2% of patients (52).

The experience of the surgeon was the most important factor affecting the overall occurrence of complications (55,56) and intra-operative complications. In trained hands, prostate size had no statistically significant influence on complications (57). The likelihood of capsular perforations increased with smaller prostates, while injury of the ureteric orifice occurred more often during resection of large and endovesically growing median lobes (52,55).

Two meta-analyses have demonstrated that in comparison to TURP and OP, patients undergoing HoLEP have a shorter catheterisation time and hospital stay, reduced blood loss and a smaller likelihood of blood transfusions, but comparable functional outcomes (33,34).

*3.4.9 **Early post-operative complications***

3.4.9.1 HoLAP

An RCT comparing HoLAP with TURP reported that 20% of patients had mild urgency or burning after catheter removal. These problems did not resolve until the first month (25). Another study, comparing HoLAP with KTP PVP, did not specifically address peri-operative complications. However, seven patients (12.2%) in the HoLAP group and six (11.5%) in the KTP PVP group required recatheterisation (26,27). Dysuria and irritative symptoms following surgery resolved before the first post-operative visit at 1 month (25).

3.4.9.2 HoLRP

An RCT comparing HoLRP to TURP has reported the rate for UTIs as 4.9% versus 8.4%, respectively. There are no other broad assessments of peri-operative complications (30).

3.4.9.3 HoLEP

Peri-operative complications within the first months after HoLEP have been assessed by several RCTs, case

series, comparative studies and meta-analyses (34,41,48). In an RCT comparing HoLEP and OP for patients with prostates > 70 g, transitory urge incontinence was equally observed in 34.1% (HoLEP) and 38.6% (OP) of patients at 3 months' follow-up, whereas dysuria was significantly more frequent in the HoLEP group (68.2 vs 41.0%, p < 0.001) (44). In contrast, the reported rate of transitory urge incontinence showed no significant difference in a multicentre RCT comparing HoLEP and TURP. Dysuria occurred significantly more often in patients after HoLEP (58.9 vs 29.5%, p = 0.0002) (46). Haemorrhage requiring coagulation is reported in 0-6% (58) and clot retention in 0% (59) to 3.6% (60).

3.4.10 ***Late complications***

3.4.10.1 HoLAP

An RCT comparing HoLAP with TURP found one patient with stress urinary incontince and one patient had opted out of the study at 6 months' follow-up. Two patients in the TURP group were treated for bladder neck contracture at 2 and 6 months by cold-knife incision. No significant difference was found in the potency and antegrade ejaculation rate between the two groups. The potency rate after 1 year was 90% for the laser group and 100% for the TURP group. The antegrade ejaculation rate was 50% in both groups (25). The retreatment rate at 7 years' follow-up was 15% (61).

An RCT comparing HoLAP versus KTP PVP found comparable complication rates at follow-up after 36 months. The overall retreatment rate was 15.8% for HoLAP and 19.3% for PVP. Urethral stricture rate was 3.5% and 5.8%, respectively. Bladder neck contracture occured in 5.3% versus 7.7%, respectively. The re-operation was reported to be 7% for HoLAP-treated patients versus 5.8% for KTP PVP (26,27).

One patient (1.8%) with HoLAP versus two patients (3.8%) with PVP had urgency and urge incontinence that did not resolve with anticholinergic therapy at the last follow-up. There was no significant difference in post-operative complications between the two groups. The overall retreatment rate was 15.8% for HoLAP versus 19.3% for PVP.

Retrograde ejaculation of sexually active patients was reported in 36.3% of the HoLAP group compared with 43.3% of the KTP PVP group. Between the two groups, no significant difference between pre-operative and post-operative sexual function in terms of orgasmic function, sexual desire, or intercourse or overall satisfaction was reported (26).

3.4.10.2 HoLRP

One RCT reported no difference between HoLRP and TURP in terms of urodynamic parameters, potency, continence, symptoms scores and major morbidity at 48 months. Complication rates were comparable. Peristing *de novo* urine leakage was reported to be 3.3% in the HoLRP group versus 1.7% in the TURP group. The overall retreatment rate was 8.2% for HoLRP versus 11.8% for TURP. 1.7% in the TURP arm needed artificial sphicter implantation. Urethral stricture rate was 9.8% versus 10.1%, respectively. Bladder neck incision for bladder neck contracture occurred in 4.9% versus 5.1%, respectively (30). Pre-operatively 50% of HoLRP versus 70% of TURP were potent, at the 4-year follow-up (53% of HoLRP versus of 60% TURP patient had sufficient erection for intercourse. A decrease in erectile quality was reported in 8% of the HoLRP and 17% of the TURP groups. However, 10% of the HoLRP group and 7% of the TURP group reported an improvement of erections (30).

3.4.10.3 HoLEP

In a meta-analysis, no statistically significant differences were noted between HoLEP and TURP for urethral stricture (2.6 versus 4,4%; p = 0.944), stress incontinence (1.5 versus 1.5%; p = 0.980), blood transfusion (0 versus 2.2%; p = 0.14) and reintervention (4.3 versus 8.8%; p = 0.059). No obvious publication bias was noted (p = 0.170, Egger's test) (34).

A further meta-analysis evaluated the risk of erectile dysfunction after HOLEP compared to standard treatment. Erectile dysfunction rates showed were similar to TURP (33). In the same meta-analysis the rate of strictures during follow-up after holmium laser enucleation was similar to those after transurethral resection (33).

Numerous trials involving the long-term outcome of HoLEP have been published and have confirmed the long-term and significant improvement in voiding parameters and the low complication rate. In a 6-year follow-up analysis of 38 patients treated with HoLEP, urge incontinence was reported in three of 38 (7.9%) patients, mixed incontinence in 10.5% and stress incontinence in 2.6%. Re-operation was necessary in 1.4% after 5 years and one patient 1.4% underwent urethrotomy at 6 months (38,61)

Comparable long-term results were reported from other studies with a re-operation rate of 4.2% due to residual adenoma, urethral strictures (1.7%), meatal stenosis (0.8%) and bladder neck contracture (0.8%), resulting in a 5-year surgical retreatment rate of 8%. The earlier group of patients showed a higher retreatment rate (8 vs 1.4%) (62). Another study observed a re-operation rate of 2.7% during a 36-month follow-up. In the group of patients with prostates < 50 mL, the incidences of urethral stenosis and bladder neck contracture were significantly higher (63).

Re-operation rates in a RCT comparing HoLEP with TURP were comparable at 3-year follow-up with a rate of 7.2 and 6.6%, respectively (64). These data are confirmed by other prospective trials comparing HoLEP to TURP (43). In an RCT comparing HoLEP versus OP, the re-operation rate at 5-year follow-up was 5% for HoLEP and 6.7% for OP-treated patients (39).

Studies focussing on sexual function after HoLEP are rare. Due to retrograde ejaculation HoLEP and TURP significantly lowered the IIEF orgasmic function domain in one RCT. Similar results were observed in the comparison of HoLEP and OP, with no significant reduction of erectile function compared with baseline (39). Patients after HoLEP and TURP reported retograde ejaculation in 75% and 62%, respectively (45,61).

3.4.11 ***Practical considerations***

Although the literature has mainly focused on HoLEP, both HoLAP and HoLRP are suitable as alternatives for vaporising (HoLAP) or resecting (HoLRP) approaches in the treatment of BOO and BPE. One issue for both techniques that needs to be considered is the longer ablation or resection time. HoLEP is the most studied novel minimal therapy approach and is a real alternative to TURP for medium- and large-sized prostates for OP. However, the excellent early results obtained with HoLEP, as the prototype for transurethral laser enucleation, have not been matched by the wider use of this technique.

3.4.12 ***Recommendations for holmium (Ho:YAG) laser treatment***

Recommendations	LE	GR
HoLAP can be offered to patients with BOO or BPE with small- to medium-sized prostates.	1b	A
HoLRP can be offered to patients with BOO or BPE with small- to medium-sized glands.	1b	A
HoLEP can be offered to any patient with BOO and BPE.	1a	A
HoLEP can be offered to patients in chronic urinary retention.	2b	B
HoLEP can be offered to patients on anticoagulant or antiplatelet medication.	2b	B

BOO = bladder outlet obstruction; BPE = benign prostatic enlargement

3.5 Thulium:yttrium-aluminium-garnet (Tm:YAG) laser

Laser energy is emitted at a wavelength of about 2000 nm in a continuous-wave fashion (1-4). In contrast to the flash-lamp excitation of the holmium laser, thulium ions are directly excited by high- power laser diodes. Although a thulium laser has the same absorption characteristics as a holmium laser in water and tissue, it has superior properties in soft tissue surgery because of the continuous-wave output. Due to the slightly shorter wavelength, the depth of penetration is decreased to 250 µm. The wavelength is close to the absorption peak of water and, together with the short penetration depth, this results in a high-energy density leading to rapid vaporisation of water and tissue. Instead of the tearing action on tissue caused by the pulsed emission of Ho:YAG, the continuous-wave output of Tm:YAG allows smooth incision and vaporisation of tissue with excellent haemostasis. The ubiquity of the water molecule as the target chromophore provides constant conditions for the laser tissue chromophore and therefore tissue interaction. Water retains its absorption properties when heated by the laser beam up to the boiling point, which marks the onset of tissue vaporisation.

The tissue left behind after each laser pass is covered by a coagulated seam of tissue, which provides haemostasis. It still contains sufficient water for efficient absorption of the following laser pass. Thus the laser tissue effect remains unchanged and effective throughout the entire surgical procedure. In contrast to the pulsed emission mode of Ho:YAG, the continuous emission does not allow lithotripsy.

*3.5.1 **Physical properties***

To date, one clinical paper has reported data on vaporisation efficacy using the Tm:YAG 2013 nm (2 µm) continuous-wave (cw) laser. There is one publication each for the 70 W and 120 W Tm:YAG 2-µm cw laser devices in an identical, experimental, organ perfused, porcine kidney model.

3.5.1.1 Ablation capacity

The tissue ablation rate increases with increasing output power. In comparison to the KTP laser, the tissue ablation rate reached (mean) 6.56 g/10 min (70 W Tm:YAG) and 3.99 g/10 min (80 W KTP) ($p > 0.05$). When compared to TURP, both laser devices produced significantly lower rates of tissue removal (8.28 g/10min) (5).

The ablative potential of Thu:YAG lasers was confirmed in a further study. At 70 W, 3.03 g/10 min were ablated using the 550 µm bare fibre. At 120 W, the amount of ablated tissue increased to 16.41 g/10 min using the 550 µm bare fibre. These rates were reduced when using a larger fibre core diameter (800 µm), as energy density is a function of core diameter (6).

3.5.1.2 Bleeding rate

The thulium laser has good haemostatic potential. In the same model, the bleeding rate for the cw 70 W Thulium laser reached 0.16 ± 0.07 g/min, compared to 0.21 ± 0.07 g/min for the 80 W KTP laser. In contrast, TURP showed a significantly increased bleeding rate of 20.14 g/min ($p < 0.05$) (5). The results were unaffected by increasing the energy output and core diameter (6).

3.5.1.3 Coagulation zone

In the kidney perfused tissue ablation model, continuous-wave thulium showed the shallowest coagulation depth. Histological examination revealed that tissue ablation resulted in a dense coagulation zone at the tissue surface. The corresponding depth of the coagulation zone was 264.7 ± 41.3 µm for the continuous-wave thulium laser, which is almost as deep as that achieved with TURP (287.1 ± 27.5 µm), but less than the 2.5-fold deeper coagulation zone (0.6669 mm) of the KTP laser ($p < 0.05$) (Table 4) (5). With increased power output and increased fibre diameter, the extent of coagulation and the necrotic tissue zone remained stable (6).

Tissue ablation increased with increasing power and was superior to that achieved with the 80 W KTP laser. Furthermore, the bleeding rate was for the cw 70 W Thulium laser reached 0.16 ± 0.07 g/min, compared to 0.21 ± 0.07 g/min for the 80 W KTP laser, though considerably lower than with monopolar TURP (5). In contrast to the 120 W LBO laser (7), the bleeding rate remained stable for the 120 W Tm:YAG laser with an increase in ablation rate. In addition, the study demonstrated shallow penetration and an energy-independent zone of tissue necrosis of 0.4 mm (6).

3.5.2 ***Thulium laser techniques***

Four different technical approaches have been described so far:
1) Tm:YAG vaporisation of the prostate (ThuVaR);
2) Tm:YAG vaporesection (ThuVARP);
3) Tm:YAG vapoenucleation (ThuVEP);
4) Tm:YAG laser enucleation of the prostate (ThuLEP) (8).

As the data from prospective RCTs is very sparse, these techniques cannot be assessed to levels of evidence. But, a number of studies, including two RCTs and one non-RCT have been published so far. The evidence of these studies will be discussed below.

3.5.2.1 Thulium laser vaporisation of the prostate

ThuVaR is a solely vaporising technique. Because the beam is fully absorbed in water, there is no necessity for side-fire application, as with KTP or LBO. A multicentre, non-randomised, case series study has reported clinical data of pure vaporisation of the prostate in 99 patients with small prostates (< 35 mL). As the results are presented alongside the results for patients with larger prostates (> 35 mL), the clinical data cannot be separated. The improvement of urodynamic parameters in the whole group of patients (n = 200) shows clinically efficient vaporisation or vaporesection in 12 months of follow-up (Table 9). These findings reflect the results of two preclinical trials in an organ-perfused model investigating the physical properties of Tm:YAG.

In comparison with a KTP laser, the 70 W Tm:YAG laser showed a larger ablation capacity, reduced bleeding rate and shallower coagulation zone (5). The 70 W Tm:YAG and the novel 120 W KTP showed a similar bleeding rate and coagulation properties (6), in contrast to 120 W LBO, which showed a higher bleeding rate and slight increase in coagulation zone (7). Higher energy resulted in a marked increase of ablation capacity in both Tm:YAG and LBO lasers (Table 4).

Twelve patients on anticoagulant drugs have been treated safely with ThUVAP/ThuVARP (9). The operation time was between 25 and 140 minutes, with catheterisation for 16 hours and no transfusion required (10). No urethral stricture or bladder neck sclerosis was reported. However, seven patients received insufficient vaporisation and required retreatment, while four patients had urinary retention after catheter removal. Six per cent of ThuVAP patients demonstrated irritative voiding symptoms post-operatively, which resolved in 1-3 months.

3.5.2.2 Thulium laser resection of the prostate (ThuVARP)

ThuVARP is a technique that resects the prostate in TUR-like tissue chips. Although Thu:YAG is similar to the Ho:YAG with regard to its shallow tissue and water penetration and haemostasis, vaporisation capacity is significantly increased by the continuous-wave emitting mode. Therefore, tissue ablation is not only achieved by resection, but also by simultaneous vaporisation.

The largest number of thulium-associated publications have been published on ThuVARP. One RCT, one non-randomised controlled study and three prospective studies have been published since 2007. In total, 730 patients have been included in these trials, which have all been reported in peer-reviewed journals.

One RCT (11) and one non-RCT (12) compared ThuVARP with monopolar TURP. The two procedures showed similar clinical outcomes and an improvement in urodynamic parameters with reduced morbidity. The Tm:YAG-treated patient group showed reduced bleeding with lower transfusion rates and shorter catheter and hospitalisation times compared to the TURP-treated patient group (11,12). All other studies (13-16) showed clinical and urodynamic results in the range of the above studies with durable improvement in voiding function (Table 9), up to an 18-month follow-up. Post-operative PSA levels as a surrogate parameter for volume reduction declined by 56% (16) and 69.4% (15).

3.5.2.3 Thulium laser vapoenucleation of the prostate (ThuVEP)

The evolution in Tm:YAG prostate surgery has virtually followed the same path as for Ho:YAG surgery. ThuVEP

was introduced in 2008 for patients with larger prostates (10). Published data in peer-reviewed journals is sparse (1-3,17,18).

The clinical efficacy of ThuVEP versus HoLEP was studied in one prospective RCT (17) and ThuVEP alone was studied in three prospective non-RCTs (1,2,18) Efficient tissue reduction and consistent improvement in clinical symptoms was observed within the follow-up period of up to 18 months (1,2,18). Blood loss was reduced in the Tm:YAG group, when compared to HoLEP, with equi-effective de-obstruction within a short follow-up interval of 3 months (17). In patients with refractory urinary retention (RUR), no differences with regards to improvement of urodynamic parameters and peri-operative complications were recorded, except for a higher rate of UTIs (15.5 vs 4.6) in patients with RUR (4). ThuVEP was safely applied to 96 high-risk patients, of whom 16 were on anticoagulant drugs. Within the whole study group, six patients developed UTI, three of whom required either post-operative transfusion or second-look surgery due to clot retention, or had insufficient voiding function (13). Post-operative PSA levels, as a surrogate parameter for volume reduction, declined by 56.1 (11) to 69.4% (10) for ThuVARP and 88% for ThuVEP (18).

3.5.2.4 Thulium laser enucleation of the prostate (ThuLEP)

ThuLEP is a transurethral technique with widely blunt dissection of the adenoma, such as OP. Permanent incisions are made at the apex and the bladder neck, the nutrifying vessels from the peripheral to the transition zone are punctiformly coagulated, leaving the capsule widely untouched. Except for a description of the technique, no clinical data has been reported so far (19).

Table 9: Results of ThuVAP, ThuVARP, ThuVEP for improvement in urodynamic parameters

Trial	Laser source/ Technique	Follow-up	N	Mean prostate size (mL)	PSA reduc-tion (%)	Change in symp-toms (%)	Change in Q_{max} (mL/s) (%)	PVR change (%)	LE

* for both groups.

PSA = prostate specific antigen; PVR = postvoid residual urine volume; LE = level of evidence; ThuVAP = thulium laser vaporisation of the prostate; ThuVARP = Tm:YAG vaporesection; ThuVEP = Tm:YAG vapoenucleation; TURP = transurethral resection of the prostate.

3.5.3 ***Risk and complications, durability of results***

Several case series studies and two RCTs (11,17) have proven the intra-operative safety of Tm:YAG surgery of the prostate, as well as in subgroups of patients with large prostates (1,10), on anticoagulation therapy (3,9), or in retention (2).

3.5.3.1 Intra-operative complications

The rate of intra-operative complications occurring during ThuVARP or ThuVEP is low. There is no report on the occurrence of TURP syndrome. Intra- or early post-operative bleeding was reported in 3.4% of patients undergoing enucleation of the prostate and the rate of blood transfusions varied from 0% (17) to 2.2% (2) for ThuVEP. Transfusions are not reported during or after vaporesection of the prostate, whereas in a level 1b, prospective, randomised trial, blood transfusion was necessary in 4% (11) and 9.5% (12), respectively with TURP, while TURP syndrome occurred in 2.1% of patients (11).

3.5.3.2 Early post-operative complications

In the early post-operative course after THUVEP, symptomatic UTI occurred in 6.8% (10), in 2.2% a secondlook procedure during hospitalisation was necessary. In 1.1% of patients recatheterisation was necessary (10). Comparing the complications of patients with pre-operative urinary retention and indwelling catheter prior to enucleation of the prostate with catheter-naïve patients, a significantly higher rate of post-operative haematuria (3.1% vs 1.4%) and UTI (15.4% vs 4.2%) was observed in patients with pre-operative urinary retention (2).

The 3.9% rate of UTIs after ThuVARP was significantly lower than the 8.3% UTI rate after TURP (11), while similar UTI rates (6.9% vs 7.1%) were reported by another study.

Transitory early urge incontinence occurred less often than after TURP (23.1 vs 31.3%) (11). No difference was seen in the occurrence of mild-to-moderate dysuria for ThuVARP in 8.6% versus 7.1% for TURP, respectively. Irritative symptoms occurred in 26.2% and 29.3%, respectively (12).

3.5.3.3 Late complications and retreatment rate

In the current literature, data with a follow-up of 18 months after ThuVARP and ThuVEP are available. Within the 18 months follow-up after ThuVARP, no re-operation or recatheterisations occurred (14). *De novo* erectile dysfunction was not reported. A total of 55% of patients reported retrograde ejaculation after ThuVARP compared to 65% after TURP (11). Another study did not show a significant difference for retrograde ejacuation (44.2% vs 44.7%) (12). No bladder neck stricture occurred. Occurrence of urethral stricture was significantly lower in TuVARP, when compared to TURP (1.9% vs 6.5%, respectively) (11,12).

Within a follow-up of 18 months after ThuVEP, 2.2% of patients needed retreatment using ThuVARP. One patient (1.1%) required transient recatheterisation, while one patient developed a urethral stricture, requiring urethrotomia interna (1%) (1).

Transient recatheterisation was necessary in 5.6% of patients with an indwelling catheter prior to enucleation. The re-operation rate showed no difference between patients with and without an indwelling catheter prior to enucleation (2.8 vs 3.1%) within a 12-month follow-up period (14).

Despite the encouraging results, a follow-up period of 18 months is a relatively short time upon which to make final conclusions.

3.5.4 ***Conclusions and recommendations for use of Thulium:YAG lasers***

Conclusions	**LE**
ThuVARP showed equivalent effectivity when compared to TURP in one RCT and one non-randomised prospective controlled trial with small and medium volume glands. Tm:YAG treated patient showed shorter catheterisation time and shorter hospitalisation time. Adverse events were significantly lower than in TURP (intra-operative and post-operative bleeding).	1b
Currently, only one RCT with a short follow-up has compared ThuVEP to HoLEP. Nevertheless, three prospective cohort studies with a follow-up of 18 months demonstrated efficacy for ThUVEP, as well as low perioperative complications and retreatment rates.	1b
Study data are awaited comparing ThuVEP and ThuLEP to HoLEP. HoLEP is the most extensively studied transurethral enucleation technique to date and long-term anatomical data are of particular interest.	4

Recommendations	LE	GR
ThuVARP is an alternative to TURP for small- and medium-sized prostates.	1b	A
ThuVARP and ThuVEP are suitable for patients at risk of bleeding or taking anticoagulant medication.	3b	C
ThuVEP can be offered as an alternative to TURP, to HoLEP and OP for large size prostates.	1b, 2b	B

4. APPLICATION OF LASER DEVICES FOR THE TREATMENT OF BLADDER CANCER PATHOLOGIES

4.1 Introduction

The use of laser devices in urology was first reported by Staehler et al. in 1978 (1) who described the successful destruction of urinary bladder tumours with a Nd:YAG-laser.

There are only retrospective analyses concerning laser ablation of bladder cancer, mostly single-institution studies with small patient numbers (LE: 3/4). In 2001, there were the first reports of bladder tumours being resected en bloc using the holmium laser (2), while in 2008, there was the first report of a bladder malignancy being resected by thulium laser (3).

4.2 Clinical application and results

Although various lasers have been used to treat bladder tumours, there has been no prospective comparison of the different devices (4). Some studies have compared TUR of the bladder (TURB) with laser treatment in non-controlled, retrospective analyses (5-7). Most studies compared laser therapy to standard TURB procedures. No indwelling catheter was used. Some studies reported carrying out the procedure under local anaesthesia in an ambulant setting (8-11). Although there have been some reports of adjacent bowel injury when using lasers with a deep penetration, the bladder wall remained intact (12,13). Major studies are represented in Table 10. The use of lasers to treat bladder tumours in non-muscle invasive disease has the major drawback of a lack of tissue for histopathological evaluation if only laser vaporisation is used.

Total complication rates were reported ranging from as low as 5.1% up to 43%. Data regarding the morbidity and complications of TURB describe the rate of UTIs as up to 24%, bleeding (2.8-8%), haemorrhage requiring transfusion (0.9-13%) and bladder perforation (1.3-5%) (14-18). The use of holmium laser for en bloc resections may help to evaluate pathological stage and grades in primary bladder tumours for evaluating the pathological stage and grade (8,10,19). At this time, there is not enough data to predict progression rates, but based on currently available data, recurrence rates after holmium laser application in bladder cancer appear similar, or lower, compared with TURB (11). The effect of lower scattering leading to a decrease in local and out-of-field recurrence rates is under debate (20). Overall recurrence rates, however, seem to be comparable to TURB.

According to current data, the optimal indication for laser excision of a bladder tumour is a relatively small tumour located at the trigonum, lateral bladder wall, or bladder neck. It has been suggested that the oncological outcome following laser treatment is comparable to TUR. However, at present, there are no larger studies able to provide reliable long-term equivalence.

In experienced hands, laser treatment of bladder pathologies, e.g. tumours, diverticles, and ureteroceles, provides an alternative to conventional TUR surgery in well-selected patients.

Table 10: Applications of laser devices for the treatment of bladder cancer pathologies

4.3 Conclusions and recommendation for laser treatment of bladder cancer

Conclusions	LE
The use of lasers is feasible for resection, coagulation and enucleation of non-muscle invasive bladder tumours.	3
Transurethral resection of the bladder remains the gold standard.	1a
In laser coagulation of tumours, no tissue for pathological staging is obtained.	
Long-term recurrence and progression rates are unknown for this novel technique.	
Currently, no data are available to indicate superiority of one device over another in bladder pathology.	
Complications are generally directly related to the laser's wavelength (penetration depth) and surgical technique.	

Recommendation	GR
Laser treatment for bladder cancer should only be used in a clinical trial setting or for patients who, due to co-morbidities or other complications, are not fit for conventional treatment.	C

5. APPLICATIONS OF LASERS IN LAPAROSCOPY/ ENDOSCOPY

5.1 Laser-assisted partial nephrectomy

*5.1.1 **Introduction***

The need for hilar clamping in case of laparoscopic partial nephrectomy (PN) is currently necessary to create a bloodless field for renal excision. However, hilar clamping increases the complexity of the operation because of the time constraint and the significant risk for increased times of warm renal ischaemia and subsequent post-operative compromise of renal function. Laser technology presents a promising alternative to achieve tumour excision, pelvicaliceal water tightness and renal haemostasis in a time-sensitive manner, with or without hilar occlusion.

*5.1.2 **Clinical application and results***

Several experimental studies have demonstrated the efficiency of laser-assisted partial nephrectomy in various experimental set-ups. However, up to date only eight small series concerning clinically tested laser-assisted PN have been published, of which only two series were performed laparoscopically (one conventional and one robotic) (Table 11) (1-8) (LE: 3). Consequently, the evidence is considered poor and further investigation is necessary in order to establish the method as a routine alternative for nephron-sparing surgery.

Early experience with laser technology in renal surgery can be traced back in 1982. Preliminary results with the use of carbon dioxide laser for renal ablation were promising, demonstrating a reduction in blood loss, shortening of operative time and preserving of functional integrity in remaining renal tissue (1,2). In 1986, the first series of PN without the need for hilar clamping was reported. Malloy et al. employed the Nd:YAG laser in the treatment of three elderly patients with renal cell carcinoma in a solitary kidney. The Nd:YAG laser was used together with standard open surgical techniques for tumour extraction. No occlusion of the renal artery was needed and the oncological outcome was considered perfect in all three cases (3) (LE: 3).

Initial experience with the use of contact Nd:YAG laser resection in PN was first described in 1993. In a series of six resections, surgeons occluded the renal artery to ensure good intra-operative haemostasis. Cutting properties of the laser were considered more accurate, while energy levels could be reduced causing less damage to the remaining parenchyma. Oncological outcome was considered perfect (4) (LE: 3). Additionally, the combination of both the KTP laser (for cutting) and the YAG laser (for coagulation of large vessels) allowed fast removal of kidney tissue, with minimal blood loss and minimal loss of renal parenchyma in as small a series of three paediatric cases of bilateral Wilms' tumours (5).

The safety and feasibility of laser PN without the need for hilar occlusion was further supported in another small series of patients treated in an open fashion. A total of five patients with renal tumours up to 3.8 cm in size were subjected to open PN. A 2.0-μm continuous wave laser (RevoLix) by LISA laser, which is a diode-pumped solid-state laser emitting a wavelength of 2013 nm and penetrating tissue to a depth of about 0.5 mm was used. In all cases, no peri-operative haemorrhage was noted and no sutures or other means of haemostasis were needed. No post-operative massive bleeding or significant creatinine level alteration were noted. In accordance with the authors, efficient and safe vascular coagulation was possible up to a vessel diameter of 1.5 mm. The laser technique should only be used in peripheral renal tumours (6) (LE: 3).

Successful accomplishment of laparoscopic PN (LPN) without the need for hilar occlusion in three human cases using the Ho:YAG laser was first reported in 2002. The indications for LPN were a complicated renal cyst and a 2.5-cm renal-cell carcinoma in two adult patients and a non-functioning lower pole in a duplicated collecting system in an 8-year-old child. Energy settings used were 2 J/pulse at 60 pulses/sec and 0.8 J/pulse at 40 pulses/sec. Despite the fact that haemostasis was considered adequate, fibrin glue was applied in two

cases and oxidised cellulose in one case to reinforce the tissue against delayed bleeding. No complications were encountered and all patients left the hospital within 3 days.

The two major disadvantages of the technique were increased smoke accumulation during laser activation and significant splashing of blood onto the camera lens during resection, which occasionally impaired visibility (7) (LE: 3).

More recently, preliminary experience with laser robotic partial nephrectomy without hilar clamping was reported in two patients. KTP laser robotic partial nephrectomy was performed with a purpose-built, prototype, robotic, laser delivery instrument. A Greenlight HPS® laser unit was used at settings up to 50 W. In one patient, hilar clamping was necessitated during the procedure because of bleeding from a large central segmental vessel. The depth of thermal injury was estimated to be approximately 1 mm. No major complications were reported (8) (LE: 3).

*5.1.3 **Conclusions about laser-assisted partial nephrectomy***

Conclusions	LE
Current data on nephron-sparing surgery using laser energy as an ablative method remain inconclusive.	
Preliminary results indicate that laser-assisted laparoscopic PN without the need for hilar clamping is feasible.	3
No major complication has been reported in humans.	3
Laser-assisted PN is a promising alternative in renal surgery, which is worth further evaluation in clinical trials.	

5.2 Laser-assisted laparoscopic nerve-sparing radical prostatectomy (LNSRP)

Experimental and preliminary clinical data have highlighted promising future applications of laser technology in laparoscopic nerve-sparing radical prostatectomy (LNSRP) (Table 12). After examining the suitability of the technique in an experimental set-up of radical prostatectomy in dogs, Gianduzzo et al. performed a 532 nm KTP laser robotic nerve-sparing radical prostatectomy in 10 patients using the AuraXP laser unit, delivering 12W through a 300-µm Endostat® fibre. The ability of KTP laser to be selectively absorbed by haemoglobin allows fine dissection, haemostasis and minimal tissue injury at the same time. However, in the current series, additional haemostasis using diathermy, suture or clips was required on several occasions for each case. Complications were one urine leak and one drain-site infection. Long-term potency outcomes were not demonstrated.

This is the first clinical evaluation of KTP laser as an ablative method in nerve-sparing radical prostatectomy (9) (LE: 3). In accordance with the author, the main disadvantage of the technique is the requirement for a filter for the KTP green light emission to prevent interference with the camera system, and the wearing of tinted safety glasses, both of which significantly detract from the laparoscopic view. Experimental data on dogs verify that the ability of KTP laser to preserve cavernous nerve function is comparable to the athermal techniques (sharp dissection and clip placement) (10). However, further clinical assessment is needed to determine the value of this technique.

Promising results in matters of LNSRP using Nd:YAG laser dissection have been reported as well. In a preliminary feasibility study enrolling five patients with clinically localised adenocarcinoma of the prostate neurovascular bundle (NVB) preservation was evaluated. The 1064 nm Nd:YAG laser was used and a continuous-wave mode applied in direct tissue contact at a 8-W power setting was suggested as the appropriate setup for most of the cases. Minimal blood loss, rapid dissection and minimal adjacent tissue injury estimated to be at 687µm (mean) were noted. As the NVBs were excised at the end of the operation for histological analysis erectile functional data could not be assessed, which is a limitation of the current study (9) (LE 3).

Table 12: Clinical experience with laser-assisted laparoscopic nerve-sparing radical prostatectomy

References	Patients (n)	Treatment	Laser beam	Comments or adverse effects	LE
Gianduzzo et al. 2007 (9)	5	LNSRP	1064 nm Nd:YAG laser	Laparoscopic	3

LNSRP = Laser-assisted laparoscopic nerve-sparing radical prostatectomy; Nd:YAG = neodymium-doped yttrium aluminium garnet.

*5.2.1 **Conclusions about laser-assisted laparoscopic nerve-sparing radical prostatectomy***

Conclusions	LE
Data are sparse and safe conclusions cannot be drawn yet.	
Preliminary results indicate that laser-assisted LNSRP is feasible and could possibly enhance neuro-vascular bundle preservation.	3
Laser-assisted LNSRP remains experimental.	

6. RENAL TUMOUR LASER INTERSTITIAL ABLATION

The current consensus for small renal tumours supports thermal coagulation as an alternative treatment option, but only in selected cases of patients with co-morbidities that make them unsuitable candidates for partial nephrectomy (11).

Clinical experience with renal tumour laser interstitial ablation is still limited (Table 13). Renal magnetic resonance imaging (MRI)-guided percutaneous laser thermal ablation (LTA) was first introduced by de Jode and used in a preliminary feasibility study, treating three patients with inoperable renal tumours using a Nd:YAG

laser delivered percutaneously to the renal tumour through a water-cooled interstitial fibre. MRI was used to both guide laser placement and monitor treatment in real time. Tissue necrosis within the targeted tissue was confirmed (12) (LE: 3).

Dick et al. evaluated the safety and feasibility of the technique in a series of nine patients with inoperable renal tumours. The operation took place under local sedation and opiate analgesia alone in 6 out of 9 patients, with the rest under general anaesthesia. A water-cooled 600 µm interstitial fibre was used to deliver 1064 µm Nd:YAG laser energy to the tumour. Laser energy was applied at 25 W for 10-30 minutes per treatment session. In all patients, the percentage enhancement of the tumour significantly decreased after LTA at the mean follow-up period of 16.9 months after the procedure. No subsequent infiltration of tumour into surrounding structures, e.g. peripheral fat and the renal vein, was noted. Reported complications were two cases of peripheral haematoma (resolving with conservative management) and one case of bradycardia (responded rapidly to atropine) (13) (LE: 3).

Table 13: Clinical experience with renal tumour laser interstitial ablation is still limited

Reference	Patients (n)	Disease	Laser beam	Comments	LE
de Jode et al. 1999 (12)	3	Inoperable renal tumours	Nd:YAG laser	Percutaneously or MRI-guided	3
Dick et al. 2002 (13)	9	Inoperable renal tumours	Nd:YAG laser	Percutaneously or MRI-guided	3

6.1 Conclusions and recommendation for laser treatment of small renal masses

Conclusions	LE
Data are poor and safe conclusions cannot be drawn yet regarding oncological outcome and safety.	**4**
Renal tumour interstitial laser ablation remains experimental.	**4**

Recommendation	GR
Laser-assisted laparoscopic PN, laser-assisted LNSRP and renal tumour laser interstitial coagulation are still experimental and should only be used in a clinical trial setting.	C

7. RETROGRADE LASER ENDOURETEROTOMY

7.1 Introduction

Endoureterotomy is often first-line treatment for benign ureteral strictures. Since its introduction in 1997, retrograde laser endoureterotomy has become a popular tool for this procedure (1). Publications concerning the approach are based on retrospective analysis, i.e. single-institution studies resulting in levels 3 and 4 evidence (1-12) (Table 14).

7.2 Clinical application and results

Success rates of laser endoureterotomy are not uniformly evident. Large variations in success rates variations between published literature most probably arise because benign ureteral strictures are comprised of several different entities, each possibly responding differently to laser endoureterotomy [Gdor 2008]. Nevertheless, large retrospective studies are lacking to elucidate which strictures respond well and which do not (LE: 4). Non-ischaemic (e.g. iatrogenic) benign ureteral strictures after calculi management or abdominal surgery are reported to respond well to laser endoureterotomy, with a reported success rate between 68.4% and 91% (LE: 3). Stricture length is probably the most important predictor of outcome. Long ureteric strictures (> 2 cm) tend to be associated with poorer success rates (LE: 3). Stricture duration, ipsilateral renal function, stone impaction and stricture localisation (upper, middle or lower) have been also suggested to affect the outcome, though published results are controversial (LE: 3). Patients with ureteroenteric and malignant strictures do not respond well to laser endoureterotomy. Success rates in these cases are reported to be less than 60% (LE: 3).

The outcome of retrograde laser endoureterotomy compared to open surgical revision is slightly inferior (LE: 2b). However, due to the minimally invasive nature of the technique, laser endoureterotomy is associated with less morbidity and should be considered a first-line treatment option (LE: 3). When compared with other well-substantiated, endourological methods (e.g. hot-wire balloon catheter, endoincision with electrocautery or cold knife), laser endoureterotomy has been reported to have the same or superior long-term results (9). However, currently, there are no larger studies available presenting reliable long-term equivalence.

Holmium:YAG laser appears the only well tested-treatment modality (LE: 4). Currently, other laser energy sources are under evaluation which should still be considered experimental.

Since large studies are lacking and long-term studies are rare, the median time to failure has not yet been elucidated. Stricture recurrence as long as 18 months post-operatively has been reported. Yet, recurrence is most likely to be evident within the first 3 months (LE: 3). Balloon dilation after laser incision and post-operative placement of a ureteral stent for the duration of between 4 weeks to 6 months are common practices that

appear to aid long-term effectiveness (LE: 4). However, there remains a lack of studies comparing treatment failure with or without balloon dilation and post-operative ureteral stenting.

Table 14: Clinical experience with retrograde laser endoureterotomy

Reference	Patients (n)	Disease	Success rate	Mean follow-up (mo)	Comments
Lin et al. 2009 (2)	19	Benign ureteral strictures	52.6%	40.2	Stricture length and severity of hydronephrosis correlated with successful outcome
Gnessin et al. 2009 (3)	35	Benign ureteral strictures	82% symptomatic, 78.7% radiographic	27	Success rate was higher for nonischemic strictures (100% vs 64.7%, p = 0.027). Most failures occur within less than 9 months after surgery
Fu et al. 2009 (4)	18	Benign ureteral strictures, 6 cases complicated with ureteral calculus	88.8%	10.7	Post-operatively, an orthopaedic ureteral stent was left in place for 3-6 months
Corcoran et al. 2009 (5)	9	Benign ureteral strictures (20% idiopathic, 80% after calculi management or abdominal surgery)	85%	25.2	Laser urethrotomy was followed by balloon dilation in most cases
Gdor et al. 2008 (6)	13	Ureteral strictures associated with ureteral calculi (impacted ureteral calculi in 4)	62%	21	In case of impacted ureteral calculi, success rate was 56%. Without a history of impacted calculi, success rate was 75%
Hibi et al. 2007 (7)	20		80%	60.5	All failures occurred within 18 months
Lane et al. 2006 (8)	19	Non-obliterative iatrogenic ureteral strictures	68.4%	36	Failure was uniformly evident within the first 3 months
Razdan et al. 2005 (9)	17	Ureteral strictures of varying causes		40,8	
Kourambas 2001 (10)	7	Ureteral strictures	91%	3	
Singal et al. 1997 (1)	22	Ureteral strictures from a variety of causes and including ureteroenteric anastomoses	76%	9	Failure was uniformly evident within the first 3 months
Watterson et al. 2002 (11)	23	Ureterointestinal strictures	56%	36	Some recurrences occurred 16 months or longer postoperatively
Laven et al. 2001 (12)	19	Ureterointestinal strictures	57%	20.5	

7.3 Conclusions and recommendations for retrograde laser endoureterotomy

Conclusions	LE
Retrograde laser endoureterotomy is a feasible and safe treatment option for ureteral strictures.	3
Open surgical revision remains the gold standard.	1a
Ureteral strictures of different aetiologies appear to respond differently to treatment.	2b
In selected cases, success rate can reach 90%.	
Ureteroenteric anastomosis strictures respond poorly to laser endoureterotomy.	3
Late stricture recurrence should be expected until as long as 18 months post-operatively.	3

Recommendations	GR
Retrograde endoureterotomy should be considered a first-line treatment option for ureteral strictures.	C
Longer follow-up is needed.	C

8. RETROGRADE LASER ENDOPYELOTOMY FOR URETEROPELVIC JUNCTION OBSTRUCTION (UPJO)

8.1 Introduction

Initial experience with laser endopyelotomy for the treatment of ureteropelvic junction obstruction (UPJO) can be traced back to the early 1990s (1). Since then, laser retrograde endopyelotomy has been a well-established method for the treatment of primary or secondary ureteropelvic junction (UPJ) strictures. Publications concerning retrograde laser endopyelotomy are mostly based on retrospective analysis, i.e. single-institution studies resulting in level 3 and 4 evidence data (Table 15) (2-19).

8.2 Clinical application and results

The optimal indication for laser endopyelotomy is a short (< 2 cm) UPJO of intrinsic aetiology in the absence of a very large pelvis, high insertion of the ureter, renal split function below 20%, and ipsilateral renal calculi (LE: 4). When particular inclusion criteria are selected, success rates are reported to be around 80% or even higher in more selected cases in the hands of an experienced urologist (LE: 4). Inferior success rates have been reported in cases of extrinsic cause of UPJO and severe hydronephrosis and in poor renal function (16,17).

The outcome of retrograde laser endopyelotomy compared to open pyeloplasty is slightly inferior (LE: 2b). However, due to the minimally invasive nature of the technique, laser endopyelotomy is associated with minimum blood loss, reduced hospital stay and less post-operative pain and should be one of the first-line treatment options (7) (LE: 2b). In addition, a failed endopyelotomy is not a contraindication for secondary open or laparoscopic pyeloplasty. When compared with other well-substantiated, endourological methods (e.g. hotwire balloon catheter, endoincision with electrocautery or cold knife), laser endopyelotomy is reported to have a similar or higher success rate and a lower rate of complications (8) (LE: 3). However, there are as yet no larger studies to provide reliable long-term equivalence.

The Ho:YAG laser appears to be the only well-tested treatment modality (LE: 4), with other laser energy sources under evaluation and still experimental. Complication rates associated with retrograde laser endopyelotomy have been reported as 12.5%, although the complications referred to are usually minor. Rarely do more serious measures, such as conversion to open surgery, need to be taken (LE: 3).

Despite the fact that long-term studies are rare, the median time to failure is reported to be as high as 7.7 months post-operatively (6). Post-operative placement of ureteral catheters, such as JJ stents for several weeks, is a common practice, despite the lack of studies comparing treatment failure with or without post-operative ureteral stenting.

Table 15: Clinical experience with retrograde laser endopyelotomy for ureteropelvic junction obstruction

Reference	Patients (n)	Disease	Success rate	Mean follow- up (mo)	Comments
Acher et al. 2009 (2)	15	Failed pyeloplasty	100%	6	No complications reported
Stilling et al. 2009 (3)	44	Primary (n=37) and secondary (n=7) UPJO	Symptom relief complete 66%; improved 23%	27.5	Strict inclusion criteria
Savoie et al. 2009 (4)	27	Primary (n=16) and secondary (n=11) UPJO	70%	35	Median time to failure: 2.7 months
Braga et al. 2007 (5)	10	Failed pyeloplasty in children	60% radiographic relief	47	Age < 4 years and narrowed ureteral segment greater than 10 mm were associated with a poor outcome

Doo et al. 2007 (6)	47	UPJO	67.5%	37.3	Median time to failure: 7.7 months
Rassweiler et al. 2007 (7)	113	Extrinsic as well as intrinsic UPJO	72.6% (85.7% intrinsic vs 51.4% extrinsic)	63 months	Complication rate of 5.3%
Ponsky et al. 2006 (8)	37	Primary and secondary UPJO	74.2%	75.6	No major complications reported
Geavlete et al. 2007 (9)	30	Failed pyeloplasty (n=17); failed endopyelotomy (n=13)	83.3% (at 18 months)	31	
el-Nahas et al. 2006 (10)	20	Primary and secondary UPJO	85%	29.9	10% complication rate
Minervini at al. 2005 (11)	30	UPJO	80% (at 10 months)	24	12.5% complication rate
Seveso et al. 2005 (12)	16	Primary (n=10) and secondary (n=6) UPJO	81%	18	One case of intra-operative haemorrhage
Matin et al. 2003 (13)	46	Primary (n=40) and secondary (n=6) UPJO	65.4% symptomatic and 73.1% radiographic	23.2	No intra-operative complications; 11.1% post-operative complications
Hibi et al. 2002 (14)	5	UPJO	80%	12.8	
Giddens et al. 2000 (15)	23	Primary and secondary UPJO	83%	10	Repeat laser incision successful in 50% of primary failures
Biyani et al. 2000 (16)	22	Primary (n=16) and secondary (n=4) UPJO	75%	34	Success rate tends to be poor in patients with poor renal function
Renner et al. 1998 (17)	34	Primary (n=27) and secondary (n=7) UPJO	85%	18	Minor complications in 15%
Conlin et al. 1998 (18)	21	UPJO	81%	12	
Biyani et al. 1997 (19)	8	Primary (n=5) and secondary (n=3) UPJO	87.5%	12.4	

UPJO = ureteropelvic junction obstruction.

8.3 Conclusions and recommendations for laser treatment for UPJO

Conclusions	**LE**
Retrograde laser endopyelotomy is a feasible and safe treatment option for the treatment of uteropelvic junction obstruction.	3
Open or laparoscopic pyeloplasty remains the gold standard.	1a
In selected cases, success rate can reach 90%.	
Treatment morbidity is minimal and major complications are rare.	3
Treatment failure may occur up to 1 year post-operatively.	3

Recommendations	GR
Retrograde laser endopyelotomy could be one of the first-line treatment options.	C
Follow-up should be prolonged for at least 1 year post-operatively.	C
Open or laparoscopic pyeloplasty remain options in cases in which minimally invasive measures fail.	C
Ensure identification of crossing vessels which is of particular relevance in reducing bleeding complications.	B
Ureteric stent placement before the procedure is an option that may affect the post-operative success rate.	C

9. TRANSURETHRAL LASER URETHROTOMY

9.1 Introduction

The introduction of transurethral laser urethrotomy using the Nd:YAG laser can be traced back to 1979 (1). Since then, laser urethrotomy has become a common urological practice worldwide in the management of urethral strictures. Publications concerning this approach are based on retrospective analysis, i.e. single-institution studies leading to level 3 or 4 evidence data (2-19) (Table 16).

9.2 Clinical application and results

Success rates of laser urethrotomy for urethral strictures are reported to be as high as 100% in selected cases (LE: 3). Short segment urethral strictures tend to respond excellently to this treatment modality (LE: 3). However, long (> 1.5 cm) or recurrent urethral strictures are reported to demonstrate inferior results (LE: 3). Periodic urethral dilatation is usually enough for the management of treatment failure (LE: 3).

The types of lasers tested on laser urethrotomy are the Nd:YAG, the KTP, the argon, the Ho:YAG and the diode laser. No superiority of one type of lasers has been demonstrated (LE: 3). There is a lack of large multicentre studies comparing the success rate of laser endourethrotomy with conventional optical urethrotomy. Currently, the midterm effectiveness of both treatment options is considered equal (LE: 3). However, in a randomised control study comparing the effectiveness of Nd:YAG laser with conventional cold-knife optical urethrotomy in the treatment of varying length urethral strictures (0.3-2.4 cm), laser treatment significantly decreased the probability of therapeutic failure and recurrence of strictures (20) (LE: 3).

Table 16: Clinical experience with transurethral laser urethrotomy

Reference	Patients (n)	Disease	Success rate %	Mean follow-up (mo)	Comments
Guo et al. 2010 (2)	238	Urethral strictures	81.9%	6	2-micron thulium laser
Guo et al. 2008 (3)	198	Urethral strictures (n = 179) or atresia (n = 13)	81.7%	6	2 micron thulium laser
Xiao et al. 2008 (4)	34	Urethral strictures	94.7%	3-18	Holmium laser: 4 received urethral dilation and 2 underwent a second holmium laser urethrotomy

Eltahawy et al. 2008 (5)	24	Anastomotic stenosis following radical prostatectomy, 79% recurrent-resistant to other treatment modalities	83%	24	Holmium laser + steroid injection
Futao et al. 2006 (6)	28	Paediatric patients with urethral strictures (n=25) and urethral atresias (n=3)	89.3%	(2-48)	Ho:YAG
Hossain et al. 2004 (7)	30	Short segment anterior urethral stricture	90%	6	Ho:YAG
Dogra et al. 2004 (8)	29	Urethral stricture (< 2.5 cm)	65.51% excellent, 31.03% acceptable	15	Ho:YAG
Gürdal et al. 2003 (9)	21	Recurrent benign urethral strictures 5-20 mm in length	52%	24	Nd:YAG
Dogra et al. 2003 (10)	61	Obliterative post-traumatic urethral strictures in children	100%	24	Nd-YAG
Matsuoka et al. 2002 (11)	31	Ureteral stricture of varying lengths	74%		Ho:YAG
Dogra et al. 2002 (12)	65	Post-traumatic urethral strictures	95.3%	9-44	Nd- YAG
Kamal 2001 (13)	22	Urethral strictures (8 recurrent)	54% (78.5% in non recurrent strictures)	26.7	Diode laser
Schmidlin et al. 1997 (14)	20	Anterior urethral strictures	81%	6	KTP
Becker et al. 1995 (15)	900	Urethral strictures (most iatrogenic)	30%	15.2	Argon
Faerber et al. 1994 (16)	12	Paediatric urethral strictures	83%	12	Nd-YAG
Turek et al. 1992 (17)	37	Benign urethral strictures	59% complete, 20.5% partial success	9.7	KTP
Vicente et al. 1990 (18)	15	Benign urethral strictures	73.3%	12	Cold knife + Nd:YAG laser
Bloiso et al. 1988 (19)	115	31 short strictures 36 bladder neck 48 complicated	96.7% (short strictures); 100% (bladder neck); 22.91% (complicated)	10 (short strictures); 7 (bladder neck); 14 (complicated)	Nd:YAG

Ho:YAG = Holmium: yttrium aluminium garnet; KTP = potassium titanyl-phosphate laser; Nd:YAG = neodymium-doped yttrium aluminium garnet

9.3 Conclusions and recommendations for transurethral laser urethrotomy

Conclusions	**LE**
Transurethral laser urethrotomy is a feasible and safe treatment option for the treatment of urethral strictures.	3
Cold-knife optical urethrotomy remains the gold standard.	1a
Success rates as high as 100% are reported in selected cases	3
Treatment morbidity is minimal and major complications are rare.	3

Recommendations	GR
Transurethral laser urethrotomy could be one of the first-line treatment options for benign urethral strictures.	C

10. LASER CLINICAL APLICATIONS IN UPPER URINARY TRACT STONES AND TUMOURS

10.1 Introduction

The entire upper urinary tract can be accessed and explored with flexible endoscopes. (1-3) Miniaturisation especially with laser fibres became an armamentarium in the endourological field. In Ho:YAG lasers, energy is delivered most commonly in a pulsatile manner, using a thermomechanical action. Absorption depth in tissue is about 1-2 mm, as long as it is used in a water-based medium. This specific light energy provides good homeostasis when used in a pulsed mode of 250-millisecond duration and at low pulse rate. At higher pulse rates, it may also be used for incisions. The frequency-doubled, double-pulse Nd:YAG (FREDDY) laser is a short-pulsed, double-frequency solid-state laser with wavelengths of 532 and 1064 nm. Although FREDDY laser is effective for lithotripsy, it is does not have a soft-tissue application (e.g. tumours). The erbium laser (Er:YAG) laser may be superior to the Ho:YAG laser for precise ablation of strictures with minimal peripheral thermal damage and for more efficient laser lithotripsy (4). Er:YAG laser cuts urethral and ureteral tissues more precisely than Ho:YAG laser and produces less peripheral thermal damage. With any laser, all intra-operative personnel should wear proper eye protection to avoid corneal or retinal damage. This especially is true with Nd:YAG (FREDDY), which penetrates deeply and can burn the retina faster than the blink reflex can protect it. Ho:YAG, which does not penetrate as deeply, but it may cause corneal defects if aimed at the unprotected eye. An adequate draping should be used around external areas. Wet towels should be draped around cutaneous lesions. Reflective surfaces (e.g., metal instruments) should be kept away from the field if possible and, if not possible, should be draped with wet drapes. Furthermore, using laser where oxygen is in use anywhere near the operative field is dangerous. This can result in a laser fire and cause significant burns.

10.2 Upper urinary tract stones

Endoscopic intracorporeal laser lithotripsy is widely used as a treatment for upper urinary tract stone (5-7). Lasers are ideally suited for retrograde intra-renal surgery or percutaneous approach (8).

Flexible quartz fibres deliver laser energy to fragment all types of stones. That energy is delivered in a pulsatile fashion through low-water density quartz fibres. In water, a vaporisation bubble surrounds the fibre tip. This bubble actually destabilises stones, creating fine dust and small fragments. Accurate fibre contact against a calculus is the primary safety factor. Successful stone fragmentation is achieved in on average > 90% of cases (6). Stone fragmentation with Ho: YAG laser further minimises ureteral wall trauma; provided that, the distance between the tip of the fibre and ureter is greater than one mm. the risk of ureteral perforation during laser lithotripsy is negligible since the depth of thermal injury is 0.5 to 1 mm. Ho:YAG laser is fully absorbed within the first few millimetres of tissue; therefore, when applied in water or saline irrigant, minimal risk of surrounding thermal injury exists as compared to Nd:YAG (9,10). Ho:YAG has a minimal fragment migration and retrograde propulsion when low settings compared to Nd:YAG (9).

Hard stones in difficult locations (e.g., lower pole caliceal calculi, stone bearing caliceal stone) can be treated using a thin, 150 to 200-µm, that is easily deflected.

Moreover, the type of eye protection used for Ho:YAG does not affect colour perception. Nd:YAG laser combines of solid and dye lasers. In vitro studies (11), It has been compared with Ho:YAG lasers across several parameters relating to stone treatment; fragmentation was significantly better with Nd:YAG laser than with Ho:YAG laser. Nevertheless, in 2006, a study reported Nd:YAG laser provided suspect fragmentation of calcium oxalate monohydrate stones and ineffective fragmentation of cystine stones (12). In addition to that, stone retropulsion was significantly greater (9,11,13). Alexandrite laser has been used, it is safe and effective, although it is rarely use in recent clinical practice. (14).

All of the initial laser lithotrities (pulsed dye, Q-switched YAG and alexandrite) fragmented stones through the generation of a shock wave. Those waves disrupt the stone along fracture lines.

The Holmium laser works through a photo-thermal mechanism, which involves the direct absorption of the laser energy by the stone. The absence of strong wave in Holmium laser avoids the retropulsion phenomenon (15). Nevertheless, it is still strong enough to create stone dust and thereby facilitate stone fragmentation with smaller fragments than those produced by pulsed lasers or other devices. Residual fragments place patients at higher risk for recurrent stone formation or growth (16). Holmium laser energy is absorbed by all stone compositions; this laser can be used to fragment all stone types (17). Cyanide production was reported as a side effect of uric acid stones fragmentation (18).

10.2.1 ***Conclusions***

	LE
Pulsed lasers are an effective and safe treatment for UUT stones, using endoscopes.	
Lasers present a safe option for defragmenting stones in the upper urinary tract.	1

10.3 Upper urinary tract urothelial tumours

The aim of the conservative management of upper tract urothelial tumours (UUT-UT) is to preserve renal function (19-21). This may be considered imperative or absolutely indicated in patients with a solitary anatomic kidney, solitary functioning kidney or limited renal function.

The development of sophisticated endourologic techniques for the treatment of benign urologic disease has translated to the treatment of malignant neoplasms, with the use of flexible ureteroscope and laser ablation becoming common place in urologic practice (19-23). Further, the cancer-control efficacy of this management approach has been established (20,21).

Even though nephro-ureterectomy is the gold standard; the current literature supports the use of lasers in patients with UUT-UT; however, meticulous and long-term follow up is needed (23,25). Ho:YAG and Nd:YAG lasers are presently the most commonly used lasers. The laser combining of both is convenient and effective but Ho:YAG can be used alone, preferentially with the variable pulse duration. Nd:YAG laser energy is used to coagulate with a thermal effect that extends deeper than other lasers. Holmium is more precise, with less of a coagulative effect. Laser therapy for tumour ablation is safe in patients with bleeding diathesis (25). In contrast to tumour ablation (Holmium/Thulium), in case of tumour vaporisation no pathology specimen will be available (Nd:YAG/ Holmium/Thulium). Therefore multiple prior biopsy samples to determine depth of invasion should be obtained. Appropriate staging of the tumour (CT/biopsy) is important to allow selection of patients for nephron-sparing surgery. There are reports on percutaneous laser treatment of TCC of the kidney and this technique has been recognised in urological practice (26-28).

A true drawback with the Nd:YAG laser is that the area of destruction is deep and not fully visualised. Within the renal pelvis, the energy choice depends mainly upon the size of the lesion. Larger vascular tumours (> 1 cm) can be coagulated initially with the Nd:YAG and then ablated and cleared with the Holmium when a combination laser is available. Lower Holmium energy tends to maximise the coagulative effect and minimise the risk of bleeding (e.g. 0.5 to 0.6 joules and 5 hertz). The stricture rate in larger series has ranged from 5% to 13.7% (29). Because of the miniaturisation of instruments and development of laser fibres, the incidence of stricture rate is considered lower. Moreover, the stricture rate is considered lower due to minimal fibrotic reaction after laser use in comparison with electrocautery devices. To avoid urothelial damage and possible stricture, all endoscopic laser modalities should be used under direct vision, through the working channel of an endoscope.

10.4 Conclusion and recommendations for laser treatment of UUT urothelial tumours

Conclusion	**LE**
Nephro-ureterectomy is still the gold standard for UUT urothelial tumours	1a

Recommendations	**GR**
Laser ablation of small low-grade upper tract transitional cell carcinoma with close follow-up can be a safe alternative treatment to nephroureterectomy in patients with normal contralateral kidneys	B
Endoscopic conservative treatment can be the preferred treatment in high-risk patients, as well as those with bilateral disease, solitary kidney or reduced renal function	C

11. ABBREVIATIONS USED IN THE TEXT

(This list is not comprehensive for the most common abbreviations)

BPE	benign prostatic enlargement
BOO	bladder outlet obstruction
BPO	benign prostatic obstruction
CW	continuous wave
EAU	European Association of Urology
Er:YAG	erbium: yttrium-aluminum-garnet laser
GR	grade of recommendation
HoLAP	Holmium laser ablation of the prostate
HoLEP	Holmium laser enucleation of the prostate
HoLRP	Holmium laser resection of the prostate
Ho:YAG	Holmium: yttrium aluminium garnet
IIEF-5	international index of erectile function (abbreviated version)
KTP	laser potassium titanyl-phosphate laser
LBO	lithium triborate
LE	level of evidence
LNSRP	Laser-assisted laparoscopic nerve-sparing radical prostatectomy
LPN	laparoscopic partial nephrectomy
LTA	laser thermal ablation
MRI	magnetic resonance imaging
Nd:YAG	neodymium-doped yttrium aluminium garnet
Nd:YAG (FREDDY)	frequency-doubled, double-pulse laser
Nd:YAG laser (LBO)	Lithium borat modulated Nd:YAG laser
NVB	prostate nevrovascular bundle
OP	open prostatectomy
PN	partial nephrectomy
PSA	prostate specific antigen
PVP	photoselective vaporisation of the prostate
PVR	postvoid residual urine
Q_{max}	urinary peak flow
QoL	Quality of Life
Tm:YAG laser	Thulium:Yttrium-Aluminium-Garnet laser
ThuVAP	Thulium laser vaporisation of the prostate
ThuVaR	Tm:YAG Vaporisation of the prostate
ThuVARP	Tm:YAG Vaporesection
ThuVEP	Tm:YAG Vapoenucleation
ThuLEP	Tm:YAG laser enucleation of the prostate
TUR	transurethral resection
TURP	transurethral resection of the prostate
TURB	TUR of the bladder
UPJO	ureteropelvic junction obstruction
UTI	urinary tract infection

Conflict of interest

All members of the New Technologies Guidelines working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on

Reporting and Grading of Complications after Urologic Surgical Procedures

1. INTRODUCTION

Evidence of variations in clinical practice, together with rising costs associated with constrained resources in most health care systems over the past decade, has triggered growing interest in evaluating the quality of our surgical work (1-3). At present, the main methods of assessing surgical results for audit and quality assurance remain mortality and morbidity (4-6). Thus measurement of morbidity requires an accurate definition of a surgical complication. Although the incidence of postoperative complications is still the most frequently used surrogate marker of quality in surgery (1,3,7), the direct cause-and-effect relationship between surgery and complications is often difficult to assess. This uncertainty carries a risk of underreporting surgical complications, with substantial consequences.

Most published articles focus only on positive outcomes (e.g. trifecta in prostate cancer after radical prostatectomy) (8). There is a need to compare complications for each specific approach in a systematic, objective, and reproducible way. As yet, no definitions for complications or guidelines for reporting surgical outcomes have been universally accepted. Reporting and grading of complications in a structured fashion is only one aspect of the quality of outcome reporting. In 2002, Martin et al. proposed 10 criteria that should be met when reporting complications following surgery (9) (Table 1). Clavien and Dindo proposed a system for grading the severity of postoperative complications (10) that was subsequently revised and validated (11) (Table 2).

Table 1: Martin et al. criteria of accurate and comprehensive reporting of surgical complications (9)

Criteria	Requirement
Method of accruing data defined	Prospective or retrospective accrual of data are indicated
Duration of follow-up indicated	Report clarifies the time period of postoperative accrual of complications such as 30 days or same hospitalisation
Outpatient information included	Study indicates that complications first identified following discharge are included in the analysis
Definition of complications provided	Article defines at least one complication with specific inclusion criteria
Mortality rate and causes of death listed	The number of patients who died in the postoperative period of study are recorded together with cause of death
Morbidity rate and total complications indicated	The number of patients with any complication and the total number of complications are recorded
Procedure-specific complications included	
Severity grade utilised	Any grading system designed to clarify severity of complications including major and minor is reported
Length-of-stay data	Median or mean length of stay indicated in the study
Risk factors included in the analysis	Evidence of risk stratification and method used indicated by study

Table 2: Clavien-Dindo grading system for the classification of surgical complications (11)

Grades	Definitions
Grade I	Any deviation from the normal postoperative course without the need for pharmacological treatment or surgical, endoscopic and radiological interventions. Acceptable therapeutic regimens are: drugs such as antiemetics, antipyretics, analgesics, diuretics and electrolytes, and physiotherapy. This grade also includes wound infections opened at the bedside.
Grade II	Requiring pharmacological treatment with drugs other than those allowed for grade I complications. Blood transfusions and total parenteral nutrition are also included.
Grade III	Requiring surgical, endoscopic or radiological intervention
Grade III-a	Intervention not under general anaesthesia
Grade III-b	Intervention under general anaesthesia
Grade IV	Life-threatening complication (including CNS complications: brain haemorrhage, ischaemic stroke, subarachnoid bleeding, but excluding transient ischaemic attacks) requiring IC/ICU management
Grade IV-a	Single organ dysfunction (including dialysis)
Grade IV-b	Multi-organ dysfunction

Grade V	Death of a patient
Suffix “d”	If the patient suffers from a complication at the time of discharge the suffix “d” (for disability) is added to the respective grade of complication. This label indicates the need for a follow-up to evaluate the complication fully.

Despite these proposals, no current standard guidelines or criteria exist for reporting surgical complications in the area of urology. It appears important that the urologic community create universally accepted criteria for reporting surgical morbidity and outcomes to establish the efficacy of surgical techniques and improve the quality of patient care (12). Adopting an integrated method of characterising and reporting surgical morbidity has the potential to improve patient care on many levels:

- It enables better characterisation of surgical morbidity associated with various surgical techniques.
- It allows comparison of different surgical techniques, which is important due to the relative lack (≤ 1%) of randomised trials in the urologic literature.
- It allows the physician to portray more accurately to patients the risks of a procedure versus other surgical or medical options.
- It allows better sequencing of multimodality approaches.
- It allows earlier recognition of the pattern of complications, thereby allowing for pre-emptive changes in care in an effort to decline the incidence.
- It allows better comparisons between individual surgeons or between institutional experiences.
- It allows identification of quality-of-care measures for benchmarking.

The aim of our work was to review the available reporting systems used for urologic surgical complications, to establish a possible change in attitude towards reporting of complications using standardised systems, to assess systematically the Clavien-Dindo system (currently widely used for the reporting of complications related to urologic surgical interventions), to identify shortcomings in reporting complications, and to present recommendations for the development and implementation of future reporting systems that focus on patient-centred outcomes. The panel did not take intraoperative complications into consideration, which may be addressed in a follow-up project.

1.1 Publication history

This article presents a republication of a scientific paper published in European Urology, the EAU scientific journal (13). Prior to publication, the paper has been subjected to double blind peer review.

In the course of 2012 the authors aim to assess the usage and reproducibility of the proposed model for reporting of complications. These findings will be published upon completion of the assessment.

2. EVIDENCE ACQUISITION

Standardised systems for reporting and classification of surgical complications were identified through a systematic review of the literature. To establish a possible change in attitude towards reporting of complications related to urologic procedures and assessment of the Clavien-Dindo system in urology, two different strategies were used. For the first objective (reporting trends), papers reporting complications after urologic surgery published in European Urology, Journal of Urology, Urology, BJU International, and World Journal of Urology in 1999-2000 and 2009-2010 were reviewed. Selection criteria were the top five general urology journals (from major urologic societies) based on impact factor (IF) and English-language publications. The panel recognised that IF as a quality indicator was debatable but considered that it would have had no impact on the validity of the outcome of this review. Promising articles were identified initially through the tables of contents of the respective journals. All selected papers were full-text retrieved and assessed; papers not reporting complications and reviews were excluded from the analysis. Analysis was done based on a structured form, which was similar for each article and for each journal (Form 1).

Data identification for the second objective (systematic assessment of the Clavien-Dindo system currently used for reporting of complications related to urologic surgical interventions) involved a Medline/Embase search using *Clavien, urology*, and *complications* as keywords. This search produced 63 eligible papers reporting complications using the Clavien-Dindo system. A second search using the search engines of individual urologic journals and publishers that may identify Clavien or Dindo and urology within the full text of a paper produced

141 more papers. Thus the total number of eligible papers was 204. All selected papers were full-text retrieved for analysis, which was done based on a structured form (Form 2). All papers were evaluated by two authors independently, and in case of disagreement, the paper was presented to all members to reach consensus.

Form 1: Data extraction form to assess reporting of complications after urological procedures using the Clavien-Dindo system

Study title: .....

3. EVIDENCE SYNTHESIS

3.1 Systems used to report surgical complications

The systematic review of the literature for standardised systems used for reporting and classification of surgical complications revealed five standardised systems (Table 3).

Table 3: Available classification systems for reporting of complications

Classification	Clinical validation	Simplicity	Severity grading
Clavien-Dindo	Yes	Easy	I-V
MSKCC	Yes	Easy	5
Accordion contracted extended	No	Easy	 4 6
NSQIP	Yes	Complex	Major/minor
NCT-CTC	Yes	Complex	5

MSKCC = Memorial Sloan-Kettering Cancer Centre classification - modification of the original T92 Clavien classification (9,14); NSQIP = National Surgical Quality Improvement Programme (3); NCT-CTC = National Cancer Institute Common Toxicity Criteria (17).

In 1992, Clavien et al. proposed a classification for complications of surgery and introduced a severity grading system called T92 (10), which was based on the main criterion of the intervention needed to resolve the complication. Four grades containing five levels of complications were described. In 2004, Dindo et al. introduced a modification of the T92 classification using five grades containing seven levels (Table 2) (11). This modification was performed to add further precision and to characterise whether an intervention due to the complication led to general anaesthesia, intensive care unit admission, or organ failure, and again, it was based on the type of therapy required to treat the complication. This modified classification, which is known as the Clavien-Dindo system, was validated and tested for interobserver variation in 10 centres around the world (14). The Clavien-Dindo system is widely used, with an exponential increase in recent years, especially in general surgery but also in urology (see Fig. 3 and 4). A few authors have adapted both systems to analyse specific procedures such as living donor liver and kidney transplantation, which has led to confusion (14).

A less extensive modification of the T92 system was made by Martin et al. (9), and (15) and is referred to as the Memorial Sloan-Kettering Cancer Centre (MSKCC) severity grading system; conceptually, it is very similar to T92 but differs in numbering (for details see Table 1 in Strasberg et al. [16]).

The Accordion classification was introduced in 2009 and represents a flexible system that can be used in studies of different size and complexity (17) (Table 4). It is available on an open Web site (http://www.accordionclassification.wustl.edu).

Table 4: Accordion severity classification of postoperative complications: contracted and expanded classification (17)

Contracted classification	Expanded classification
1. Mild complication Requires only minor invasive procedures that can be done at the bedside, such as insertion of intravenous lines, urinary catheters and nasogastric tubes, and drainage of wound infections. Physiotherapy and the following drugs are allowed: antiemetics, antipyretics, analgesics, diuretics and electrolytes.	1. Mild complication Requires only minor invasive procedures that can be done at the bedside, such as insertion of intravenous lines, urinary catheters and nasogastric tubes, and drainage of wound infections. Physiotherapy and the following drugs are allowed: antiemetics, antipyretics, analgesics, diuretics and electrolytes.
2. Moderate complication Requires pharmacological treatment with drugs other than those allowed for minor complications, for example, antibiotics. Blood transfusions and total parenteral nutrition are also included.	2. Moderate complication Requires pharmacological treatment with drugs other than those allowed for minor complications, for example, antibiotics. Blood transfusions and total parenteral nutrition are also included.
3. Severe complication All complications requiring endoscopic or interventional radiology or re-operation, as well as complications resulting in failure of one or more organ systems.	3. Severe: invasive procedure without general anaesthesia Requires management by an endoscopic, interventional procedure or re-operation* without general anaesthesia
4. Death Postoperative death	4. Severe: operation under general anaesthesia Requires management by an operation under general anaesthesia
	5. Severe: organ system failure†
	6. Death Postoperative death

**An example would be wound re-exploration under conscious sedation and/or local anaesthetic.*
†Such complications would normally be managed in an increased acuity setting but in some cases patients with complications of lower severity might also be admitted to an ICU.

The National Surgical Quality Improvement Program was established in 1994 within the US Veterans Administration (VA) health care system, with the aim of identifying and reporting adverse events as one prerequisite for process improvement in health care (3). The system is validated, outcome based, and uses data adjusted for patient preoperative risk. It allows comparison of the performance of different hospitals performing major surgery by the ratio of observed to expected (O/E) adverse events. Statistically low (O/E < 1) or high (O/E > 1) outliers are then identified to support continuous quality improvement activities. The annual use of this system has contributed to the improvement of the standard of surgical care and to lower 30-d mortality and morbidity rates for major noncardiac surgery within the VA.

The National Cancer Institute Common Toxicity Criteria (NCI-CTC) system (17) was first created in 1983, aimed at the recognition and grading of adverse effects of chemotherapy in cancer patients. The system was updated and expanded in 1998 (CTC v2.0), including acute effects of radiotherapy and limited criteria applicable to surgery. In 2003, Common Terminology Criteria for Adverse Events (CTCAE v3.0) was introduced for application to all possible modalities and is organised by organ system categories (all organs are included), with 370 different criteria. An adverse event is defined as any new finding or undesirable event that may not be attributed to treatment. Grading criteria are shown in Table 5. Late and acute effects criteria are merged into a single uniform system and applied without a predetermined time-based designation. The previously used "90-day rule" is not advised currently because each study is unique. The new CTC system was designed to be applied to all possible modalities, and it is organised by organ system categories (all organs are included) with 370 different criteria. The unexpected serious and life-threatening (grades 3 and 4) consequences of surgery are the focus of immediate surgical reporting. CTCAE v3.0 is available on the Cancer Therapy Evaluation Program Web site (www.ctep.info.nih.gov).

Table 5: National Cancer Institute Common Toxicity Criteria grading system for the adverse effects of cancer treatment (17)

Grade	Definition of effects
Grade 1	Minimal and usually asymptomatic that do not interfere with functional endpoints (interventions or medications are generally not indicated for these minor effects).
Grade 2	Moderate, are usually symptomatic. Interventions such as local treatment or medications may be indicated (they may interfere with specific functions but not enough to impair activities of daily living).
Grade 3	Severe and very undesirable. There are usually multiple, disruptive symptoms (more serious interventions, including surgery or hospitalisation, may be indicated).
Grade 4	Potentially life threatening, catastrophic, disabling, or result in loss of organ, organ function, or limb.

Most recently, the International Urogynecological Association (IUGA) and the International Continence Society (ICS) have established a joint working group on terminology for complications related to the insertion of prostheses and grafts in female pelvic floor surgery (18). The document proposes definitions of specific complications, distinguishing local complications, complications to surrounding organs, and systemic complications. New terms have been proposed and defined in detail such as contraction, prominence, separation, exposure, extrusion, perforation, dehiscence, and sinus tract formation. The classification is based on category, time, and site of complications, with the aim of summarising any of a large range of possible clinical scenarios into a code using as few as three numerals and three (or four) letters. Lowercase letters can be added, describing the presence and the type of pain. The ICS-IUGA classification appears at first sight to be complex and not immediately mastered, as outlined by the proponents. The main goal is to establish common language and to promote a homogeneous registry to improve the quality of pelvic floor surgical procedures using prostheses and grafts.

3.2 Attitude of urologists towards reporting complications

A total of 874 eligible papers of 1261 retrieved publications were included in the final analysis. The type of studies reporting complications did not vary between the two time frames selected (1999-2000 vs 2009-2010) ($p > 0.1$). Most of the papers identified were case studies (Fig. 1). However, a shift could be seen in the number of studies using most of the Martin criteria (Fig. 2), as well as in the number of studies using either standardised criteria or the Clavien-Dindo system to report complications (Fig. 3).

Fig. 1: Comparative distribution of papers reporting complications after urologic procedures by study type and time frame

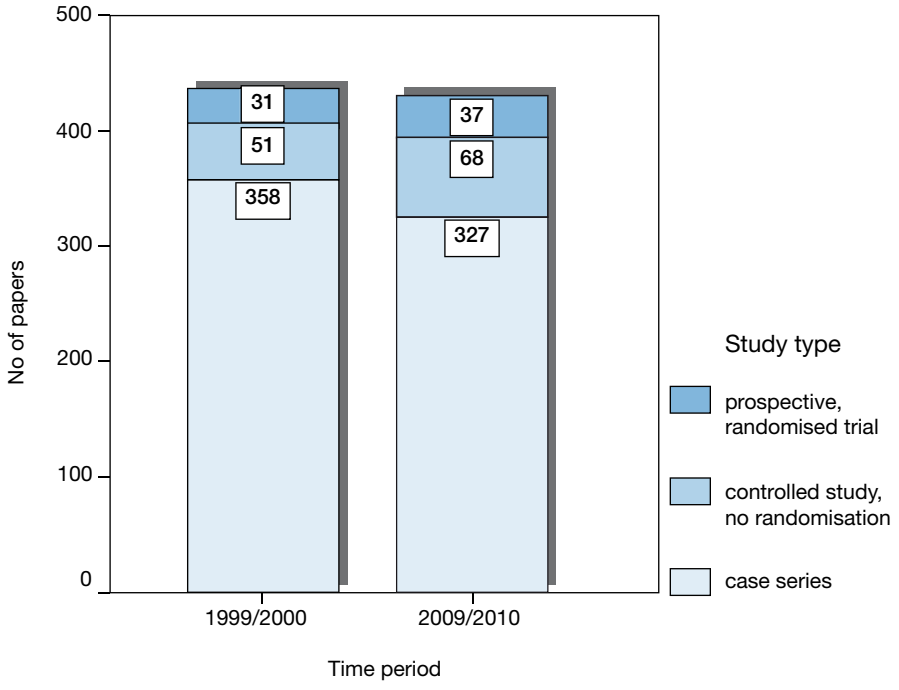

Fig. 2: Comparative distribution of papers reporting complications after urologic procedures by number of Martin criteria met and time frame

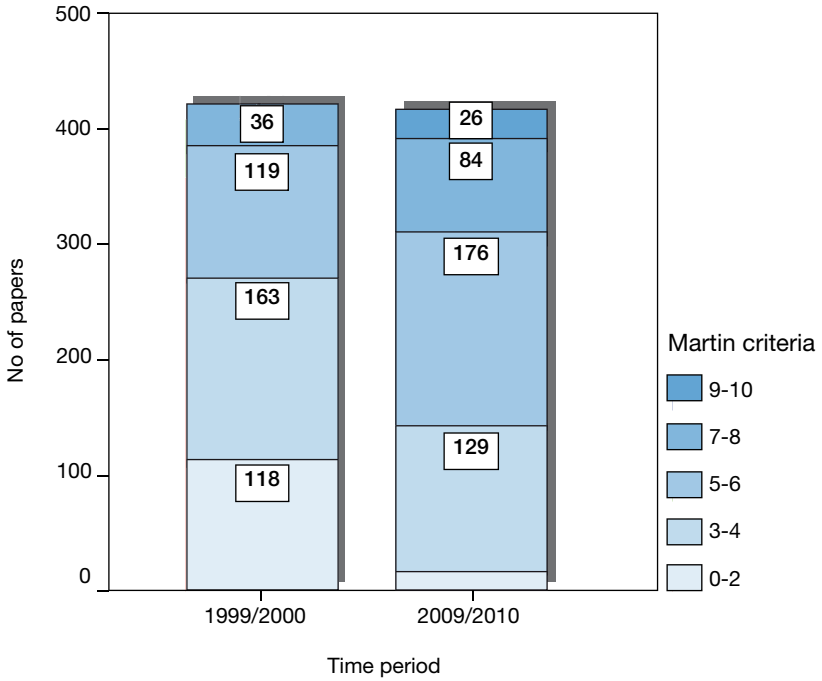

Fig. 3: Comparative distribution of papers reporting complications after urologic procedures by time frame and whether standardised criteria were used (left), and in case they were, whether the Clavien-Dindo system was used (right)

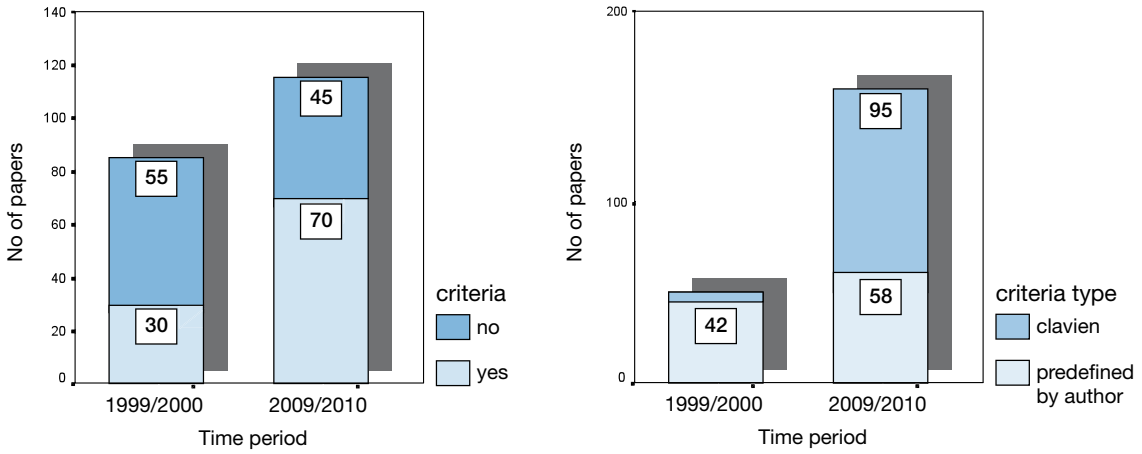


3.3 Assessment of the Clavien-Dindo system for reporting complications after urologic procedures

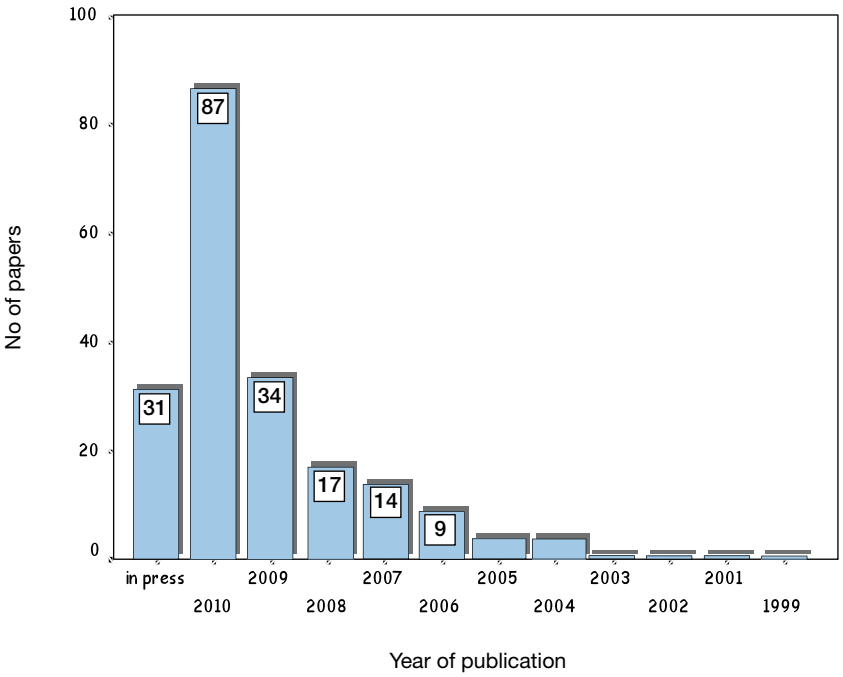
The literature search identified 204 papers published in:

- Urology 38
- Journal of Urology 37
- Journal of Endourology 35
- European Urology 34
- BJU International 19
- World Journal of Urology 15
- and several others 26

The number of papers using the Clavien-Dindo system to report complications after urologic surgical interventions showed an exponential increase (Fig. 4). Most of the studies identified were, again, case series, and 77.9% of the studies fulfilled ≥ 7 of the Martin criteria (range: 3-10; mean: 7.5; standard deviation: 1.5). The

vast majority of papers referred to novel technologies (laparoscopy/robot-assisted procedures), whereas only 13.2% of papers discussed open procedures. The Clavien-Dindo system was not properly used in 72 papers (35.3%): Eight times it was also used to report/grade intraoperative complications; six times the authors used their own modification of the Clavien-Dindo system; in 27 studies, the authors grouped complications into major (Clavien-Dindo ≥ 3) and minor without mentioning specific complications; and in 31 papers, the authors did not assign a grade to the complications reported.

Fig. 4: Distribution of studies using the Clavien-Dindo system to report complications after urologic procedures



3.4 Discussion

The definition of surgical complications still lacks standardisation, which hampers the interpretation of surgical performance and quality assessment (5,7,19). Although many surgeons would argue that their subjective intuition is an appropriate guide to defining what a complication might be, the value of the surgeon's intuition is unreliable in many situations because it lacks objective criteria and depends heavily on the experience of the individual clinician (4,7,20). Second, a surgical complication is not a fixed reality. Instead, it depends on the surgeon's level of skill, the surgeon's learning curve for the procedure, the patient's comorbidity and risk factors, and the facilities available. A surgical complication in a Western country may not be perceived or subjectively weighted as a surgical complication in rural or less developed countries. Similarly, a complication in 2011 may be seen as obsolete within in a few years' time, with a better understanding of the pathophysiology of the underlying malady. As surgical techniques and equipment improve, what were once inevitable negative outcomes may acquire the status of mere surgical complications (2,5,7). Finally, and paradoxically, the higher the expectation of the surgeon and patient, the more potential surgical complications occur (21,22). The clinical relevance of reporting surgical complications is primarily related to the fact that the dissemination of technology is very rapid, with current grades of recommendations based on the level of evidence in their corresponding studies. However, in the surgical field, randomised controlled trials with high levels of evidence are uncommon, and this limitation naturally leads to a low number of recommendations. We have to keep in mind that the guidelines can only rely on the surgical evidence. Thus there is a real discrepancy between the reality of daily surgical practice and the relevance of the low-grade recommendations produced in this area. However, the scientific quality of an article is not only related to its level of evidence. The use of more rigorous methodology and the consensus-related complications of surgical techniques will probably improve the quality of the surgical scientific literature. It is likely that this improvement will renew interest in daily clinical practice in the minds of surgeons. In addition, it will allow recommendations that avoid complications, clearly the most relevant issue in improving patient care.

In defining surgical complications, subjectivity cannot always be avoided, but it should be reduced as much as possible (4). Additionally, different audiences (e.g. patients, nurses, health care providers, and third-party payers) and different surgical communities (e.g. urologists, orthopaedists, and vascular surgeons) view, define,

and perceive complications differently. Currently, no generally accepted standards or definitions exist with regard to the severity of surgical complications. Clavien-Dindo recommended the following definitions of surgical outcomes:

1. Surgical complication: Any deviation from the ideal postoperative course that is not inherent in the procedure and does not comprise a failure to cure;
2. Failure to cure: Diseases or conditions that remained unchanged after surgery;
3. Sequelae: Conditions that are inherent in a procedure and thus would inevitably occur such as scar formation or the inability to walk after an amputation.

Based on the review of the current literature, and with reference to the Accordion Severity Grading System (16), an appropriate definition of a complication is a combination of the following items: an event unrelated to the purposes of the procedure, an unintended result of the procedure, an event occurring in temporal proximity to the procedure, something causing a deviation from the ideal postoperative course, an event that induces a change in management, or something that is morbid (i.e. causes suffering directly by causing pain or indirectly by subjecting the patient to additional interventions).

In contrast to a complication, the sequelae of a procedure should be defined as an after-effect of that procedure. The risk of sequelae is inherent in the procedure (e.g. diabetes after pancreatic resection, rejection after transplantation, limp after amputation, dyspnoea after pneumonectomy, or impairment of renal function after tumour nephrectomy). Failure to cure should be defined as failure to attain or maintain the purpose of the procedure (e.g. failure to remove all stones during ureteroscopy or percutaneous stone surgery, tumour recurrence, stricture recurrence, or recurrence of patency when the purpose of the procedure is to occlude). Sequelae of procedures and failures to cure should be reported but presented separately from complications (14).

However, a complication that results in lasting disability is considered a sequela of a complication. Stroke or acute renal failure (ARF) occurring after a procedure is considered a complication and should be reported as such. However, long-term aphasia resulting from stroke or chronic renal failure after ARF is considered a sequela of that complication. Therefore, it should be reported in a special section devoted specifically to long-term disability.

Patients and their treating physicians do not necessarily mean the same thing when they use the term complication. Several studies have shown substantial discrepancies in the reporting of adverse events and sequelae of a treatment when the estimations of patients and physicians are compared (22). The usual information on potential complications that patients can obtain before a surgical procedure can be taken from the available literature, the specific information given by the treating centre (i.e. home page or patient information brochures), or from direct discussion with the treating surgeon. This information has the potential to be biased from the definition of what is considered a complication, and a standardised system that is not only used for complication reports in the literature but also for patient counselling is important for a realistic estimation of outcomes. In the present literature, patients often report a higher frequency and severity of adverse events compared with that reported by their physicians (23). However, in a recent randomised study, Steinsvik et al. showed that several adverse events, such as bowel problems, were overrated by the physician (24). Overrating and especially underrating of complications by the treating physician leads to confusion and a discrepancy between patient expectation and reality.

Schroeck et al. evaluated variables associated with satisfaction and regret after open and robotic radical prostatectomy (21). Patients who underwent robotic-assisted laparoscopic prostatectomy were more likely to be regretful and dissatisfied, which was not necessarily interpreted as caused by a worse outcome but potentially caused by the higher expectation associated with an innovative procedure. The authors therefore suggested that urologists should carefully portray the risks and benefits of new technologies during preoperative counselling to minimise regret and maximise satisfaction.

Theses examples support the notion that realistic counselling is crucial for the patient's decision-making process and for satisfaction with the achieved result. However, a standardised reporting system for surgical complications can only try to standardise the reporting of the intraoperative and perioperative morbidity of the procedure itself. Short-, mid- or long-term sequelae of a surgical procedure, such as erectile dysfunction or urinary incontinence following radical prostatectomy, are not covered by this classification and need to be reported with other validated tools.

Standardised classification and severity grading of surgical complications is essential for proper interpretation

of surgical outcome data, for comparing the surgical outcomes between institutions or individual surgeons, and for comparing techniques in case randomised trials are either lacking or difficult to perform (i.e. comparison of minimally invasive techniques with open surgery). The urologic community seems to conform to the current demands because recent studies have more often used standardised criteria to report complications (48.3% vs. 35.3%) (Fig. 3). In urologic oncology reports published from January 1995 to December 2005, the corresponding percentage was 33%, with only 19% (6% of the total) using a numerical complication severity grading system (12). The Clavien-Dindo system has gained wide acceptance both in general surgery (14) and the urologic community (Fig. 3, and Fig. 4). Clinical databases designed and controlled by physicians may underreport complications (25). Similarly, a disadvantage of the Clavien-Dindo system is its unreliability when recording is performed by residents, although, when captured, grading of complications was correct in 97% of the cases. Consequently, the authors have proposed that dedicated personnel should evaluate surgical outcomes (2). Special attention should also be paid to proper use of the Clavien-Dindo system because it has not been designed/validated to grade intraoperative complications, and any modifications and revisions can be confusing (14).

Classification and severity grading of surgical complications is an important, albeit not the only criterion of quality when reporting surgical outcome. Approximately 40% of general surgery series and trials and 23% of studies reporting surgical complications in urologic oncology (2) fulfil seven or more Martin criteria. Interestingly, 77.9% of the papers that used the Clavien-Dindo system to report complications after urologic procedures fulfilled seven or more criteria, a fact implying that its use contributes to higher quality reports.

Besides the efficiency of an individual surgeon and the function of an institution, surgical care outcomes also depend on the patient's preoperative risk factors (26). Thus they should always be defined and used in the analysis and report. A substantial proportion of postoperative complications occur after hospital discharge (27); extension of the length of postoperative observation may therefore be necessary. Other quality-of-care indicators are readmissions and reoperations (28) and should be included in both preliminary and final reports.

4. CONCLUSIONS

There is an urgent need for uniform reporting of complications after urologic procedures, which will aid all those involved in patient care and scientific publishing (authors, reviewers, and editors). Urologists have considerably changed their attitude towards using standardised criteria when reporting complications, and there has been an exponential increase of the number of papers using the Clavien-Dindo system. However, a certain number of papers (35.3%) did not use it properly. When reporting the outcomes of urologic procedures, the committee proposes the following:

- Define your complications.
- Preferentially use a standardised system; the Clavien-Dindo grading system is highly recommended.
- When using the Clavien-Dindo system, provide a table of all complications and corresponding grades or list the complications by grade.
- Use the NCI-CTC system in multimodality treatment.
- Improve reporting of complications by following the revised quality criteria (Table 6).
- Define the method of accruing data: retrospective/prospective; through chart review/telephone interview/face-to-face interview/other.
- Define who collected the data: medical doctor/nurse/data manager/other, and whether he or she was involved in the treatment.
- Indicate the duration of follow-up: 30, 60, 90, or >90 d.
- Include outpatient information.
- Include mortality data and causes of death.
- Include definitions of complications.
- Define procedure-specific complications.
- Use a severity grading system (avoiding the distinction minor/major); the Clavien-Dindo system is recommended.
- Include risk factors: American Society of Anaesthesiologists score, Charlson score, Eastern Cooperative Oncology Group, other.
- Include readmissions and causes.
- Include reoperations, types and causes
- Include the percentage of patients lost to follow-up.

- Finally, editors of urologic journals should demand the use of a standardised system to report complications after urologic surgery.

Table 6: Quality criteria for accurate and comprehensive reporting of surgical outcome

1. Define the method of accruing data:
   retrospective _ prospective _ , through:
   chart review _ telephone interview _ face to face interview _ other _
2. Define who collected the data:
   medical doctor _ nurse _ data manager _ other _
   and whether he/she was involved in the treatment: yes _ no _
3. Indicate the duration of follow-up:
   30 days _ 60 days _ 90 days _ > 90 days _
4. Include outpatient information
5. Include mortality data and causes of death
6. Include definitions of complications
7. Define procedure-specific complications
8. Report intraoperative and postoperative complications separately
9. Use a severity grading system for postoperative complications (avoiding the distinction minor/major) - Clavien-Dindo system is recommended
10. Postoperative complications should be presented in a table either by grade or by complication type (specific grades should always be provided; grouping is not accepted)
11. Include risk factors

ASA score _ Charlson score _ ECOG _ other _

12. Include readmissions and causes
13. Include re-operations, types and causes
14. Include the percentage of patients lost to follow-up

6. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

ARF	acute renal failure
ASA	American Society of Anesthesiologists
CNS	central nervous system
CTC AE	Common Terminology criteria for Adverse Events
EAU	European Association of Urology
ECOG	Eastern Cooperative Oncology Group
IC(U)	intensive care (unit)
ICS	International Continence Society
IF	impact factor
IUGA	International Urogynecological Association
MSKCC	Memorial Sloan-Kettering Cancer Centre classification
NSQIP	National Surgical Quality Improvement Programme
NCT-CTC	National Cancer Institute Common Toxicity Criteria
O/E	ratio of observed versus expected
VA	US Veterans Administration

Conflict of interest

All members of the ad hoc EAU Guidelines working group on Reporting and Grading Complications after Urologic Surgical Procedures have provided disclosure statements of all relationships which they have and which may be perceived as a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.
