TABLE OF CONTENTS PAGE

1. BACKGROUND

1.1 Publication history

The first European Association of Urology (EAU) Guidelines on Bladder Cancer were published in 2002 (1). It was later decided to develop separate guidelines for different categories of urothelial tumours:

- TaT1 papillary tumours (non-muscle-invasive bladder cancer);
- Carcinoma *in situ* (CIS);
- Muscle-invasive bladder tumours;
- Upper urinary tract tumours.

Separate guidelines have been published in European Urology for TaT1, CIS, and upper urinary tract tumours (2-4). For logistical reasons, the guidelines group on non-muscle-invasive bladder cancer decided to integrate the guidelines of TaT1 tumours and CIS in one issue. This overview represents the updated EAU guidelines for non-muscle-invasive bladder cancer (CIS, Ta, T1).

1.2 Methodology

The systematic literature search for each section of the non-muscle-invasive bladder cancer guidelines was performed by the panel members. For identification of original and review articles, the Medline, Web of Science, and Embase databases were used. For the current upgrade, all articles published between 2008 and 2010 on TaT1 tumours and between 2004 and 2010 on CIS were considered. Focus of the searches was identification of all level 1 scientific papers (systematic reviews and meta-analyses of randomised controlled trials [RCTs]) in accordance with EAU methodology. Panel members rated papers following a classification system modified from the Oxford Centre for Evidence-based Medicine Levels of Evidence (LE) (5). Additionally, recommendations have been graded to provide transparency between the underlying evidence and a recommendation given.

Table 1: Level of evidence*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

**Modified from Sackett et al. (5).*

It should be noted that when recommendations are graded, the link between the level of evidence and grade of recommendation (GR) is not directly linear. Availability of RCTs may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Alternatively, absence of high level of evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful for the reader. The quality of the underlying scientific evidence - although a very important factor - has to be balanced against benefits and burdens, values and preferences, and costs when a grade is assigned (6-8).

The EAU Guidelines Office do not perform cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever this data is available, the expert panel will include the information.

Table 2: Grade of recommendation*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency that addressed the specific recommendations, including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett et al. (5).*

2. EPIDEMIOLOGY

Bladder carcinoma is the most common malignancy of the urinary tract. The worldwide age standardised incidence rate (ASR) is 10.1 per 100,000 for males and 2.5 per 100,000 for females (9). In Europe, the highest incidence has been reported in the Western (23.6 in males and 5.4 in females) and Southern (27.1 in males and 4.1 in females) regions, followed by Northern Europe (16.9 in males and 4.9 in females). The lowest incidence is observed in Eastern European countries (14.7 in males and 2.2 in females) (10).

The global world mortality rate among males is 4 per 100,000 versus 1.1 per 100,000 among females. The ASR (per 100,000) only varies between 5.6 in developed countries and 3.1 in developing countries for males. For females the ASR varies between 1.4 in developed countries and 0.9 in less developed areas (9). In Europe, mortality rates show a substantial decline over the last decade of about 16% in men and about 12% in women (11).

Approximately 75-85% of patients with bladder cancer present with a disease that is confined to the mucosa (stage Ta, CIS) or submucosa (stage T1). These categories are grouped as non-muscle-invasive bladder tumours.

3. RISK FACTORS

Many of the aetiological factors for the development of bladder tumours are known and urologists should be aware of the types of occupational exposure that might be related to urothelial carcinogens (12-14). Aromatic amines were the first to be recognised. At-risk groups include workers in the following industries: printing, iron and aluminium processing, industrial painting, gas and tar manufacturing (LE: 3).

Another prominent risk factor is cigarette smoking, which triples the risk of developing bladder cancer (15-17) (LE: 2a). Smoking leads to a higher mortality rate from bladder cancer during long-term follow-up, even though, in a multivariate analysis, the prognostic effect of smoking was weaker than that of other factors, such as stage, grade, size, and multifocality of the tumour (18).

4. CLASSIFICATION

4.1 Tumour, Node, Metastasis Classification (TNM)

The 2002 TNM classification approved by the Union International Contre le Cancer (UICC) has been widely accepted. This version was updated in 2009, but it has no changes for bladder tumours (Table 3) (19).

Table 3: 2009 TNM classification of urinary bladder cancer

T - Primary tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Non-invasive papillary carcinoma
Tis	Carcinoma *in situ*: 'flat tumour'
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades muscle
T2a	Tumour invades superficial muscle (inner half)
T2b	Tumour invades deep muscle (outer half)
T3	Tumour invades perivesical tissue:
T3a	Microscopically
T3b	Macroscopically (extravesical mass)
T4	Tumour invades any of the following: prostate, uterus, vagina, pelvic wall, abdominal wall
T4a	Tumour invades prostate, uterus or vagina
T4b	Tumour invades pelvic wall or abdominal wall
N - Lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N2	Metastasis in multiple lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N3	Metastasis in common iliac lymph node(s)
M - Distant metastasis	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

4.2 Histological grading of non-muscle-invasive bladder urothelial carcinomas

In 1998, a new classification of non-invasive urothelial tumours was proposed by the World Health Organization (WHO) and the International Society of Urological Pathology (ISUP) (1998 WHO/ISUP classification) and published by the WHO in 2004 (20,21) (Table 4). Its major contribution is a detailed histological description of the various grades, which uses specific cytological and architectural criteria. A website (www.pathology.jhu.edu/bladder) that illustrates examples of various grades has been developed to improve accuracy further in using the system.

Table 4: WHO grading in 1973 and in 2004 (20,21)

1973 WHO grading
Urothelial papilloma
Grade 1: well differentiated
Grade 2: moderately differentiated
Grade 3: poorly differentiated
2004 WHO grading
Flat lesions
Hyperplasia (flat lesion without atypia or papillary aspects)
Reactive atypia (flat lesion with atypia)
Atypia of unknown significance
Urothelial dysplasia
Urothelial CIS
Papillary lesions
Urothelial papilloma (completely benign lesion)
Papillary urothelial neoplasm of low malignant potential (PUNLMP)
Low-grade papillary urothelial carcinoma
High-grade papillary urothelial carcinoma

The 2004 WHO classification of the flat lesions includes urothelial hyperplasia, reactive urothelial atypia, atypia of unknown significance, dysplasia and CIS. Among non-invasive papillary urothelial lesions, the 2004 WHO grading differentiates between PUNLMP and low-grade and high-grade urothelial carcinomas.

Papillary urothelial neoplasm of low malignant potentials are defined as lesions that do not have cytological features of malignancy but show normal urothelial cells in a papillary configuration. Although they have a negligible risk for progression, they are not completely benign and still have a tendency to recur. The intermediate grade (grade 2), which was the subject of controversy in the 1973 WHO classification, has been eliminated (22,23) (Figure 1).

It was shown that the 2004 WHO classification has a better reproducibility than the WHO 1973 classification (24).

The prognostic value of both grading systems (WHO 1973 and 2004) has been confirmed. Attempts to demonstrate better prognostic value of one system over another, however, have yielded controversial results (22-25). The majority of clinical trials published to date on TaT1 bladder tumours have been performed using the 1973 WHO classification, and therefore, the following guidelines are based on this scheme. Until the prognostic role of WHO 2004 is validated by more prospective trials, both classifications can be used.

Figure 1: Stratification of tumours according to grade in the WHO 1973 and 2004 classifications (26)*

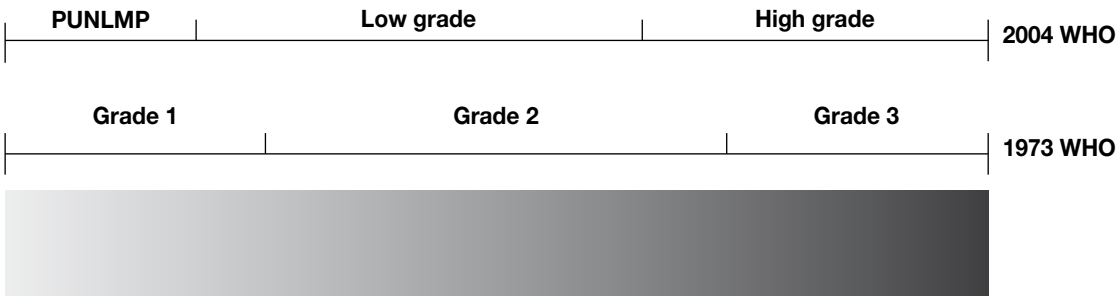

Fig. 1 - Comparison of the 1973 and 2004 WHO grading system. The 1973 WHO grade 1 carcinomas are reassigned, some to the PUNLMP category, and some to the low-grade carcinoma category. Similarly, 1973 WHO grade 2 carcinomas are reassigned, some to the low-grade carcinoma category, and others to the high-grade carcinoma category. All 1973 WHO tumours are assigned to the high-grade carcinoma category. WHO = World Health Organization; PUNLMP = papillary urothelial neoplasm of low malignant potential.

4.3 Controversial definition of non-muscle-invasive ("superficial") tumours

The diagnosis of non-muscle-invasive bladder cancer requires consideration of all transurethral resection (TUR) samples.

A papillary tumour confined to the mucosa is classified as stage Ta according to the TNM system. Tumours that have invaded the lamina propria are classified as stage T1. Ta and T1 tumours can be removed by TUR, and therefore, they are grouped under the heading of non-muscle-invasive bladder cancer for therapeutic purposes. Also included under this heading are flat, high-grade tumours that are confined to the mucosa, and classified as CIS (Tis). However, molecular biology techniques and clinical experience have demonstrated the highly malignant, invasive potential of CIS and T1 lesions. Therefore, the terms non-muscle-invasive and superficial bladder cancer are suboptimal descriptions.

Some promising prognostic factors that are based on pathological examination of resected tissue have been presented:

- In patients with T1 tumours, the depth of invasion into the lamina propria is considered. The depth of invasion is evaluated in relation to the muscularis mucosae layer. T1 tumours are substaged into T1a (tumours that extend into the lamina propria but above the level of the muscularis mucosae) and T1b (tumours that infiltrate into or below the level of the muscularis mucosae). The prognostic value of T1 substaging has been demonstrated by some retrospective cohort studies (27-29) (LE: 3).
- The presence of lymphovascular invasion has been recognised as an unfavourable prognostic factor in T1 tumours (29,30) (LE: 3).
- Detection of the micropapillary variant of urothelial carcinoma represents a poor prognostic factor (31) (LE: 3).

4.4 Inter- and intra-observer variability in staging and grading

Despite well-defined criteria for the diagnosis of urothelial carcinoma, there is significant variability among pathologists for diagnosis of CIS, for which agreement is achieved in only 70-78% of cases (32,33). There is also important inter-observer variability in classification of stage T1 versus Ta tumours, and grading tumours with general conformity between 50 and 60% (24,32-36). The inter-observer variability is less with the 2004 WHO classification compared to the 1973 classification (23,24). However, a review of slides is recommended particularly in T1, CIS and high-grade lesions.

4.5 Specific character of CIS and its clinical classification

Carcinoma *in situ* is a flat, high-grade, non-invasive urothelial carcinoma. The term CIS might suggest that it is a precursor of cancer. Although it might be a precursor of invasive bladder cancer, the histological and cytological aspects of CIS make this an overtly malignant entity in itself.

Macroscopically, CIS can be missed at cystoscopy or be considered as an inflammatory lesion if it is not biopsied. It is often multifocal and can occur in the upper urinary tract and in the prostatic ducts and urethra (37).

Carcinoma *in situ* is classified into one of three different clinical types (38):

- Primary: isolated CIS with no previous or concurrent exophytic tumours;
- Secondary: CIS detected during the follow-up of patients with a previous tumour;
- Concurrent: CIS in the presence of exophytic tumours.

5. DIAGNOSIS

5.1 Symptoms

Haematuria is the most common finding in non-muscle-invasive bladder cancer. TaT1 tumours do not cause bladder pain and rarely present with lower urinary tract symptoms. In patients who do complain of these symptoms, CIS might be suspected.

5.2 Physical examination

Physical examination does not reveal non-muscle-invasive bladder cancer.

5.3 Imaging

5.3.1 Intravenous urography and computed tomography

Intravenous urography (IVU) is used to detect filling defects in the calyces, renal pelvis and ureters, and

hydronephrosis, which can indicate the presence of a ureteral tumour. Large exophytic tumours may be seen as filling defects in the bladder. The necessity to perform routine IVU once a bladder tumour has been detected is now questioned because of the low incidence of significant findings obtained with this method (39-41) (LE: 3). The incidence of upper urinary tract tumours is low (1.8%), but increases to 7.5% in tumours located in the trigone (40). The risk of tumour recurrence in the upper urinary tract during follow-up increases in multiple and high-risk tumours (42).

In many centres, computed tomography (CT) urography is used as an alternative to conventional IVU (43). Especially in muscle-invasive tumours of the bladder and in upper tract tumours, CT urography gives more information than IVU does (including status of lymph nodes and neighbouring organs) (LE: 4). However, CT urography has the disadvantage of higher radiation exposure compared to IVU.

*5.3.2 **Ultrasonography***

Ultrasonography (US) has been used with increasing frequency as the initial tool to assess the urinary tract. This is not only because it avoids the use of contrast agents, but also because sensitive transducers have improved imaging of the upper urinary tract and bladder.

Transabdominal US permits characterisation of renal masses, detection of hydronephrosis and visualisation of intraluminal masses in the bladder. It can be as accurate as IVU for diagnosis of upper urinary tract obstruction (39) (LE: 3). The US is thus a useful tool for investigation in patients with haematuria to detect obstruction, it cannot however exclude the presence of upper tract tumours. Imaging methods (IVU, CT urography or US) have no role in the diagnosis of CIS.

5.4 Urinary cytology

Examination of voided urine or bladder-washing specimens for exfoliated cancer cells has high sensitivity in high-grade tumours but low sensitivity in low-grade tumours (LE: 2b). Due to a loss of cohesion of cells in the epithelial lining of the bladder in CIS, there is a larger number of floating cells in the urine, as well as a high degree of anaplasia. Thanks to these conditions is the sensitivity of cytology in CIS detection > 90%. Cytology is thus useful when a high-grade malignancy or CIS is present. However, urinary cytology often is negative in the presence of low-grade cancer. Positive voided urinary cytology can indicate a urothelial tumour anywhere in the urinary tract, from the calyx to the ureters, bladder and proximal urethra.

Cytological interpretation is user-dependent (44). Evaluation can be hampered by low cellular yield, urinary tract infections, stones or intravesical instillations. In experienced hands however, the specificity exceeds 90% (45) (LE: 2b). Cytology should be performed on fresh urine with adequate fixation. Morning urine is not suitable because of the frequent presence of cytolysis.

5.5 Urinary molecular marker tests

Extensive laboratory research has developed numerous urinary tests for diagnosis of bladder cancer based on detection of soluble or cell-associated markers (45-51).

Numerous reviews of urinary markers have appeared in recent years (45-59). A few of the markers have come into clinical application but none has been accepted as a standard diagnostic procedure in routine urology or in guidelines until now. Three tests are particularly promising: nuclear matrix protein 22 (NMP22), UroVysion®, and ImmunoCyt (49,50,60-64).

The following conclusions can be drawn about the existing tests. The bladder tumour antigen (BTA) test has a very limited role because of its high false-positive rate and low sensitivity for low-grade tumours (65,66). NMP22 similarly suffers from a high false-positive rate but has higher sensitivity than urinary cytology. With careful selection of patients, the specificity of NMP22 can be improved, and because of its high negative predictive volume (NPV), it can potentially be used during follow-up to delay cystoscopy control (60,62,67-69). ImmunoCyt has the highest sensitivity for detection of low-grade tumours and is less affected by other urological diseases. However, with a 60% detection rate for low-grade tumours, the test remains largely inadequate to replace cystoscopy (64,70). UroVysion® adds little to the surveillance of low-grade tumours. However, it can replace cytology for high-grade tumours when experience with urinary cytology is lacking or when its result is inconclusive. Some false-positive results arise because UroVysion® can detect occult disease and thus identify those patients who are more likely to experience recurrence. It might also be useful to predict response to intravesical therapy (63,71,72). Microsatellite analysis is the most promising of the methods listed in Table 5. It can predict recurrence of low-grade tumours in up to 80% of cases, but it still lacks sensitivity (73-75).

The sensitivity of tests can be improved by their combination, as suggested by the International Consensus Panel on Bladder Tumour Markers (45).

Although it is hoped that these tests can soon make the transition from the laboratory to the clinic, it is essential to evaluate their costs to determine whether they can provide a low-cost and reliable alternative to current cystoscopy methods (76).

Table 5 gives an overview of how far the available urinary markers correspond to some of these criteria (52).

Table 5: Summary of main urinary markers

Markers	Overall sensitivity (%)	Overall specificity (%)	Sensitivity for high-grade tumours (%)	Point-of-care test	Interference by BCG instillations and other bladder conditions	Comments
UroVysion®	30-72	63-95	66-70	No	No	Expensive and laborious
Microsatellite analysis	58	73	90	No	No	Expensive and laborious
Gene microarray	80-90	62-65	80	No	No	Expensive and laborious
Immunocyt/ uCyt +™	76-85	63-75	67-92	No	Yes	Good sensitivity in low-grade tumours, affected by BCG
Nuclear matrix protein 22	49-68	85-87.5	75-83	Yes	Yes	Low sensitivity, affected by benign conditions
BTA stat	57-83	68-85	61.5	Yes	Yes	Low sensitivity, affected by benign conditions and BCG
BTA TRAK	53-91	28-83	77	No	Yes	Low sensitivity, affected by benign conditions and BCG
Cytokeratins	12-85	75-97	33-82	No	Yes	Low sensitivity, affected by benign conditions and BCG
Survivin	53-90	88-100	50	No	No	Low sensitivity, expensive and laborious

BCG = Bacillus Calmette-Guérin; BTA = bladder tumour antigen.

5.6 Practical application of urinary cytology and markers

There are specified general requirements for good markers for bladder cancer (45):

- The test must be as simple as possible technically (preferably a point-of-care test, with readily available results, easy to perform, with a short learning curve);
- Low cost;
- Reliable and reproducible results;
- High diagnostic accuracy (high sensitivity and specificity);
- For individual patient populations and clinical situations, the test should have a high positive predictive value to avoid unnecessary workup because of false-positive results, and high NPV to avoid the risk of failing to detect tumours. These parameters vary between populations with different incidences of bladder cancer and cannot be used for general comparison of methods;
- For clinical settings, it is of utmost importance to detect reliably all high-grade tumours before they escape curative treatment.

The following objectives of application of urinary cytology or molecular tests must be considered:

- *Screening of the population at risk of bladder cancer.*
  The application of haematuria dipstick, NMP22 or UroVysion® in bladder cancer screening in high-risk

populations has been reported (60,61). However, concerns about feasibility and cost-effectiveness mean that routine application of screening has not yet been established.

- *Exploration of patients after haematuria or other symptoms that are suggestive of bladder cancer.*
  It is generally accepted that none of the tests can replace cystoscopy. However, urinary cytology or markers can be used as adjunct to cystoscopy to detect invisible tumours, particularly CIS. In this setting, the method should have high sensitivity and specificity for high-grade tumours. Urinary cytology is highly specific and sensitive in this regard. Most commercially available urinary markers are even slightly more sensitive than cytology, the problem is however their lack of specificity.

- *Facilitate surveillance of non-muscle-invasive bladder cancer to reduce the number of cystoscopies (48,52,62,65).*
  To reduce the number of cystoscopies, urinary markers should be able to detect recurrence before the tumours are large and numerous. The limitation of urinary cytology is its low sensitivity for low grade recurrences. Several urinary markers are better but still do not detect half of the low-grade tumours that are detected by cystoscopy. Among the commercially available tests, the best performance for detecting recurrence of low-grade tumours is by immunocytology. Large prospective studies on recurrence of low-grade tumours are still lacking, thus, urinary markers cannot safely replace cystoscopy in this setting.

5.7 Cystoscopy

The diagnosis of bladder cancer ultimately depends on cystoscopic examination of the bladder and histological evaluation of the resected tissue. The diagnosis of CIS is made by a combination of cystoscopy, urine cytology, and histological evaluation of multiple bladder biopsies (77).

Cystoscopy is initially performed in the office, using flexible instruments. If a bladder tumour has been visualised in earlier imaging studies, diagnostic cystoscopy can be omitted because the patient will undergo TUR.

A careful description of the findings is necessary. It should include the site, size, number, and appearance (papillary or solid) of the tumours, as well as a description of mucosal abnormalities. Use of a bladder diagram is recommended.

5.8 Transurethral resection (TUR) of TaT1 bladder tumours

The goal of the TUR in TaT1 bladder tumours is to make the correct diagnosis and remove all visible lesions.

The strategy of resection depends on the size of the lesion. Small tumours (< 1 cm) can be resected *en bloc*, the specimen contains the complete tumour plus a part of the underlying bladder wall. Some experts believe that deep resection is not necessary in small, apparently low-grade lesions with a previous history of TaG1 tumour. Larger tumours should be resected separately in fractions, which include the exophytic part of the tumour, the underlying bladder wall with the detrusor muscle, and the edges of the resection area. The specimens from different fractions must be referred to the pathologist in separate containers to enable him/her to make a correct diagnosis. Cauterisation should be avoided as much as possible during TUR to prevent tissue destruction.

Complete and correct TUR is essential to achieve a good prognosis (78). It has been confirmed that absence of detrusor muscle in the specimen is associated with a significantly higher risk of residual disease and early recurrence (79) (LE: 2).

5.9 Bladder and prostatic urethral biopsies

Carcinoma *in situ* can present as a velvet-like, reddish area that is indistinguishable from inflammation, or it might not be visible at all. It can be present as an isolated lesion without exophytic tumour, or it can accompany TaT1 tumours.

When abnormal areas of urothelium are seen, it is advised to take ‘cold cup’ biopsies or biopsies with a resection loop. Biopsies from normal-looking mucosa, so-called random biopsies (R-biopsies), should be performed in patients with positive urinary cytology and absence of visible tumour in the bladder. It is recommended to take R-biopsies from the trigone, bladder dome and from right, left, anterior and posterior bladder walls.

In patients with TaT1 tumours, R-biopsies are not routinely recommended. The likelihood of detecting CIS, especially in low-risk tumours, is extremely low (< 2%) (80) (LE: 2a). Cold cup biopsies from normal-looking mucosa should be performed when cytology is positive or when exophytic tumour has a non-papillary appearance. Material obtained by random or directed biopsies must be sent for pathological assessment in separate containers. In CIS, the coherence and adherence of epithelial cells is decreased, and this feature often

results in denuded biopsies when taken by cold cup or a resection loop (81).

Involvement of the prostatic urethra and ducts in male patients with non-muscle-invasive bladder cancer has been reported. Although the exact risk of prostatic urethra or ducts involvement is not known, it seems to be higher if the tumour is located on the trigone or bladder neck, in the presence of bladder CIS and multiple tumours (82,83) (LE: 3). In these cases and when cytology is positive, with no evidence of tumour in the bladder, or when abnormalities of prostatic urethra are visible, biopsies of the prostatic urethra are recommended. The biopsy is taken from abnormal areas and from the precollicular area (between 5 and 7 o'clock position) using a resection loop.

5.10 Photodynamic diagnosis (fluorescence cystoscopy)

As a standard procedure, cystoscopy and TUR are performed using white light. However, the use of white light can lead to missing lesions that are present but not visible. Photodynamic diagnosis (PDD) is performed using violet light after intravesical instillation of 5-aminolaevulinic acid (ALA) or hexaminolaevulinic acid (HAL). It has been confirmed that fluorescence-guided biopsy and resection are more sensitive than conventional procedures for detection of malignant tumours, particularly for CIS (84-86) (LE: 2a). The additional detection rate with PDD was 20% for all tumours and 23% for CIS in a cumulative analysis of prospective trials (87). However, false-positivity can be induced by inflammation or recent TUR, and during the first 3 months after BCG instillation (88).

The benefit of ALA fluorescence-guided TUR for recurrence-free survival has been demonstrated in several small, randomised clinical trials (89-91). Cumulative analysis of three trials has shown that the recurrence-free survival was 15.8-27% higher at 12 months and 12-15% higher at 24 months in the fluorescence-guided TUR groups compared to the white light cystoscopy alone groups (87) (LE: 2) However, a large Swedish study could not detect any advantage in using ALA fluorescence-guided TUR routinely in all patients with non-muscle-invasive bladder cancer (92). A recent large, multicentre, prospective randomised trial that compared HAL fluorescence-guided TUR with standard TUR reported an absolute reduction of no more than 9% in the recurrence rate within 9 months in the HAL arm (93) (LE: 1b).

The value of fluorescence cystoscopy for improvement of the outcome in relation to progression rate or survival remains to be demonstrated.

Photodynamic diagnosis is most useful for detection of CIS, and therefore it should be restricted to those patients who are suspected of harbouring a high-grade tumour, e.g. for biopsy guidance in patients with positive cytology or with a history of high-grade tumour. Because of conflicting data on recurrence rate this panel restricts the indication for PDD more than experts in a recently published review (94).

The additional costs of the equipment and instillation for PDD should be taken into account.

5.11 Second resection

The significant risk of residual tumour after initial TUR of TaT1 lesions has been demonstrated (78,95) (LE: 2a). Persistent disease after resection of T1 tumours has been observed in 33-53% of patients (95-100).

Moreover, the tumour is often under-staged by initial resection. The likelihood that a T1 tumour has been under-staged and muscle-invasive disease is detected by second resection ranges from 4 to 25%. This risk has increased up to 50% in some cystectomy series, although these studies have only enrolled selected patients (96,101,102) (LE: 2a). Treatment of a TaT1 high-grade tumour and a T2 tumour is completely different; therefore, correct staging is important.

A second TUR should be considered when the initial resection is incomplete, for example, when multiple and/or large tumours are present, or when the pathologist has reported that the specimen contains no muscle tissue (TaG1 excluded). Furthermore, a second TUR should be performed when a high-grade or T1 tumour has been detected at initial TUR (103). It has been demonstrated that a second TUR can increase the recurrence-free survival (98,99,104) (LE: 2a). There is no consensus about the strategy and timing of second TUR. Most authors recommend resection at 2-6 weeks after initial TUR. The procedure should include resection of the primary tumour site.

5.12 Pathological report

Pathological investigation of the specimen obtained by TUR and biopsies is an essential step in the diagnosis of bladder cancer. The pathological report should specify the grade of the lesion(s) and the depth of tumour invasion into the bladder wall, and should give information about whether the lamina propria and sufficient muscle are present in the specimen (104).

Essential for correct pathological assessment is the high quality of resected tissue. The presence of sufficient muscle is necessary for correct assignment of T-category. Close cooperation between urologists and pathologists is recommended.

5.13 Recommendations for primary assessment of non-muscle-invasive bladder tumours

	GR
The renal and bladder US may be used during initial work-up in patients with haematuria.	C
At the time of initial diagnosis of bladder cancer CT urography or IVU should be performed only in selected cases (e.g. tumours located in the trigone).	B
Cystoscopy is recommended in all patients with symptoms suggestive of bladder cancer. It cannot be replaced by cytology nor by any other non-invasive test.	A
Cystoscopy should describe all macroscopic features of the tumour (site, size, number and appearance) and mucosal abnormalities. A bladder diagram is recommended.	C
Voided urine cytology or urinary markers are advocated to predict high grade tumour before TUR.	C
It is recommended to perform TUR in one piece for small papillary tumours (< 1 cm), including part from the underlying bladder wall.	B
It is recommended to perform TUR in fractions (including muscle tissue) for tumours > 1 cm in diameter.	B
It is recommended to take biopsies from abnormal-looking urothelium. Biopsies from normal-looking mucosa (trigone, bladder dome and from right, left, anterior and posterior bladder walls) are recommended only when cytology is positive or when exophytic tumour has a non-papillary appearance.	C
Biopsy of the prostatic urethra is recommended for cases of bladder neck tumour, when bladder CIS is present or suspected, when there is positive cytology without evidence of tumour in the bladder, or when abnormalities of the prostatic urethra are visible. If biopsy is not performed during the initial procedure, it should be completed at the time of the second resection. The biopsy should be taken from the precollicular area between 5 and 7 o'clock using a resection loop.	C
If equipment is available, fluorescence-guided (PDD) biopsy should be performed when bladder CIS is suspected (e.g. positive cytology, recurrent tumour with previous history of a high-grade lesion).	B
A second TUR should be performed at 2-6 weeks after initial resection when the latter is incomplete (in large and multiple tumours, no muscle in the specimen), or when an exophytic high-grade and/or T1 tumour is detected.	A
The pathological report should specify the grade, depth of tumour invasion, and whether the lamina propria and sufficient muscle are present in the specimen.	A

CIS = carcinoma in situ*; CT = computed tomography; IVU = intravenous urography; PDD = photodynamic diagnosis; TUR = transurethral resection; US = ultrasound.*

6. PREDICTING RECURRENCE AND PROGRESSION

6.1 TaT1 tumours

The classic way to categorise patients with TaT1 tumours is to divide them into risk groups based on prognostic factors derived from multivariate analyses. Using such a technique, it has been proposed to divide patients into low-risk, intermediate-risk and high-risk groups (105). When using these risk groups, however, no distinction is usually drawn between the risk of recurrence and progression. Although prognostic factors indicate a high risk for recurrence, the risk of progression might still be low, and other tumours might have a high risk of recurrence and progression.

In order to predict separately the short-term and long-term risks of recurrence and progression in individual patients, the European Organization for Research and Treatment of Cancer (EORTC) Genitourinary (GU) group has developed a scoring system and risk tables (106). The basis for these tables is the EORTC database, which provides individual patient data for 2,596 patients diagnosed with TaT1 tumours, who were randomised in seven EORTC-GU group trials. Patients with CIS alone are not included. Seventy-eight percent of patients have received intravesical treatment, mostly chemotherapy. However, they have not undergone a second TUR or received maintenance BCG. The scoring system is based on the six most significant clinical and pathological factors:

- number of tumours;
- tumour size;
- prior recurrence rate;
- T-category;
- presence of concurrent CIS;
- tumour grade.

Table 6 illustrates the weights applied to various factors for calculating the total scores for recurrence and progression. Table 7 shows the total scores stratified, as in the original article (106), into four categories that reflect various probabilities of recurrence and progression at 1 and 5 years. By combination of two of the four categories for recurrence and progression, the EAU working group suggests the use of a three-tier system that defines low-, intermediate- and high-risk groups for recurrence and progression, as shown in the rightmost column in Table 7.

Table 6: Weighting used to calculate recurrence and progression scores

Factor	Recurrence	Progression
Number of tumours		
Single	0	0
2-7	3	3
≥ 8	6	3
Tumour diameter		
< 3 cm	0	0
≥ 3 cm	3	3
Prior recurrence rate		
Primary	0	0
≤ 1 recurrence/year	2	2
> 1 recurrence/year	4	2
Category		
Ta	0	0
T1	1	4
Concurrent CIS		
No	0	0
Yes	1	6
Grade (WHO 1973)		
G1	0	0
G2	1	0
G3	2	5
Total score	0-17	0-23

CIS = carcinoma in situ*; WHO = World Health Organization.*

Table 7: Probability of recurrence and progression according to total score

Recurrence score	Probability of recurrence at 1 year		Probability of recurrence at 5 years		Recurrence risk group
	%	(95% CI)	%	(95% CI)	
0	15	(10-19)	31	(24-37)	Low risk
1-4	24	(21-26)	46	(42-49)	Intermediate risk
5-9	38	(35-41)	62	(58-65)	
10-17	61	(55-67)	78	(73-84)	High risk

Progression score	Probability of progression at 1 year		Probability of progression at 5 years		Progression risk group
	%	(95% CI)	%	(95% CI)	
0	0.2	(0-0.7)	0.8	(0-1.7)	Low risk
2-6	1	(0.4-1.6)	6	(5-8)	Intermediate risk
7-13	5	(4-7)	17	(14-20)	High risk
14-23	17	(10-24)	45	(35-55)	

Note: Electronic calculators for Tables 6 and 7 are available at http://www.eortc.be/tools/bladdercalculator/.

The scoring model for BCG-treated patients that predicts the short- and long-term risks of recurrence and progression has recently been presented by the Club Urológico Español de Tratamiento Oncológico (CUETO) (Spanish Urological Oncology Group). It is based on analysis of 1,062 patients from four CUETO trials that compared different intravesical BCG treatments. Patients received 12 instillations during 5-6 months. No immediate postoperative instillation or second TUR were performed in these patients. The scoring system is based on evaluation of seven prognostic parameters:

- patients' sex;
- patients' age;
- recurrence status;
- number of tumours;
- T-category;
- associated CIS;
- tumour grade.

Using these tables, the calculated risk of recurrence is lower than that obtained by the EORTC tables. For progression probabilities, it is lower only in high-risk patients (107). The lower risks in the CUETO tables may be attributed to using a more effective instillation therapy in the individual studies on which the CUETO tables are based. The validation of the EORTC scoring system in an independent patient population with long-term follow-up has confirmed its prognostic value (108).

6.2 Carcinoma *in situ*

Without any treatment, approximately 54% of patients with CIS progress to muscle-invasive disease (109). Unfortunately, there are no reliable prognostic factors that can be used to predict the course of the disease and specify the most dangerous cases. The publications are based on a retrospective analysis of small series of patients and their conclusions are not homogeneous. Some studies have reported worse prognosis in concurrent CIS and T1 tumours compared to primary CIS (110,111) and in extended CIS (112) (LE: 3).

Various publications have shown that the response to intravesical treatment with BCG or chemotherapy is an important prognostic factor for subsequent progression and death caused by bladder cancer (113-116). Approximately 10-20% of complete responders eventually progress to muscle-invasive disease, compared with 66% of non-responders (113-115) (LE: 2).

7. ADJUVANT TREATMENT

7.1 Intravesical chemotherapy

Although state-of-the-art TUR by itself can eradicate a TaT1 tumour completely, these tumours recur in a high percentage of cases and progress to muscle-invasive bladder cancer in a limited number of cases. The high variability in the 3-month recurrence rate indicates that TUR is incomplete or provokes recurrences in a high percentage of patients (78). It is therefore necessary to consider adjuvant therapy in all patients. The absolute risks of recurrence and progression do not always indicate the risk at which a certain therapy is optimal. The choice of therapy may be considered differently according to what risk is acceptable for the individual patient and the urologist.

*7.1.1 **One, immediate, postoperative intravesical instillation of chemotherapy***

In a meta-analysis of seven randomised trials (1,476 patients with a median follow-up of 3.4 years), one immediate instillation of chemotherapy after TUR significantly reduced recurrence rate compared to TUR alone (LE: 1a) (117). In absolute values, the reduction was 11.7% (from 48.4% to 36.7%), which implies a 24.2%

decrease in the corresponding relative risk. The majority of patients (> 80%) in the meta-analysis had a single tumour, but an almost significant and even greater reduction in recurrence was noted among the limited number of patients with multiple tumours. The efficacy of the single instillation has been confirmed also by two recently published studies (118,119). In one of these (119), the benefit was mainly seen in primary and single tumours and was in these tumour categories even greater than the 11.7%. By stratification according to EORTC recurrence scores, the benefit was observed in patients with scores 0-2, but not with scores ≥ 3. However, the study was not sufficiently powered for subgroup analyses. Despite stratification at randomisation, no separate analysis was made for primary or recurrent tumours in the other study (118).

No prospective data are available showing that the single instillation significantly reduces recurrence rates in patients with recurrent tumours. Nevertheless, there is significant evidence from one subgroup analysis that an immediate instillation might have an impact on the repeat instillation regimen for treatment of patients who are at intermediate- and high risk of recurrence (120) (LE: 2a). There are no statistically relevant data that address the role of immediate chemotherapy instillation in tumours at high risk of progression before further BCG intravesical treatment.

In summary, one immediate instillation significantly reduces the risk of recurrence in TaT1 bladder tumours. Further studies are required, however, to determine the definitive role of immediate chemotherapy before BCG or further chemotherapy instillations in intermediate- and high-risk groups.

The effect of early instillation can be explained by the destruction of circulating tumour cells immediately after TUR, or as an ablative effect (chemoresection) of residual tumour cells at the resection site. Prevention of tumour cell implantation should be initiated within the first hours after cell seeding. Within a few hours, the cells are implanted firmly and are covered by extracellular matrix (121-124). In all single instillation studies, the instillation was administered within 24 h. Subgroup analysis of one study has shown that, if the first instillation was not given on the same day as TUR, there was a twofold increase in the relative risk of recurrence (120) (LE: 2a). Moreover, a study in which the instillation was not given strictly on the same day did not find any advantage (125). To maximise the efficacy of the immediate instillation, every effort should be made to create flexible practices that allow the instillation to be given when necessary and as early as possible, that is, in the recovery room or even in the operating theatre.

There is no single drug that is superior with regard to efficacy. Mitomycin C, epirubicin, and doxorubicin have all shown a beneficial effect (117) (LE: 1a). In one study, gemcitabine plus 24 h bladder irrigation with physiological saline was not superior to irrigation with physiological saline alone (126) (LE: 1b).

The guidelines expert panel recommends immediate instillation in tumours at low risk of progression (single, primary, papillary lesions) as the only intravesical treatment and in those presumably at intermediate risk, for which a single instillation is considered as the initial stage of further intravesical therapy. In tumours that are presumably at high risk of progression (solid lesions, positive urinary cytology), immediate instillation is an option because it can have a positive impact on recurrence rate through prevention of tumour cell implantation. However, there is no doubt that subsequent BCG intravesical immunotherapy is essential treatment in these patients (see lower).

The immediate post-operative chemotherapy instillation should be omitted in any case of overt or suspected intra- or extraperitoneal perforation, which is most likely to appear in extensive TUR procedures, and in situations with bleeding requiring bladder irrigation. Severe complications have been reported in patients in whom extravasation of the drug occurs (127).

Clear instructions should be given to the nursing staff to control the free flow of the bladder catheter at the end of the instillation. It has been demonstrated that administration of instillation is possible in the majority of cases (128).

7.1.2 ***Additional adjuvant intravesical chemotherapy instillations***

The need for further adjuvant intravesical therapy depends on the patients' prognosis. In patients with a low risk of tumour recurrence (see Table 7), a single immediate instillation reduces the risk of recurrence and is considered as the standard treatment (117) (LE: 1a). No further treatment should be given in these patients before subsequent recurrence. For other patients, however, a single immediate instillation remains an incomplete treatment because the likelihood of recurrence and/or progression is considerable.

The effect of the immediate instillation of chemotherapy occurs during the first and second year (129,130) (LE: 1b). It has been calculated from the data of five randomised trials (130) that the reduction of recurrence lasts for a period of approximately 500 days.

The choice between further chemotherapy or immunotherapy largely depends on the risk that needs to be reduced: recurrence or progression. A combined analysis of EORTC and Medical Research Council data, comparing intravesical chemotherapy to TUR alone, has demonstrated that chemotherapy prevents recurrence but not progression (131) (LE: 1a). The efficacy of intravesical chemotherapy in reducing the risk of tumour recurrence has been confirmed by two other meta-analyses in primary (132) and recurrent tumours (133).

It is still controversial how long and how frequently instillations of intravesical chemotherapy have to be given. From a systematic review of the literature of randomised clinical trials, which have compared different schedules of intravesical chemotherapy instillations, one can only conclude that the ideal duration and intensity of the schedule remains undefined because of conflicting data (134). Nevertheless, the available evidence does not support any treatment longer than 1 year.

*7.1.3 **Optimising intravesical chemotherapy***

One randomised trial has demonstrated that adapting urinary pH, decreasing urinary excretion, and buffering the intravesical solution reduce the recurrence rate (135) (LE: 1b).

Another randomised trial has documented that concentration is more important than duration of the treatment (136) (LE: 1b). In view of these data, which need confirmation, it seems advisable to ask the patient not to drink on the morning before instillation, and to dissolve the drug in a buffered solution at optimal pH.

7.2 Intravesical Bacillus Calmette-Guérin (BCG) immunotherapy

*7.2.1 **Efficacy of BCG***

Several meta-analyses have addressed important questions concerning the efficacy of BCG in non-muscle-invasive bladder tumours. Four meta-analyses have confirmed that BCG after TUR is superior to TUR alone or TUR and chemotherapy for prevention of recurrence of non-muscle-invasive tumours (137-140) (LE: 1a). Since the publication of these meta-analyses, three randomised studies of intermediate- and high-risk tumours have been presented. In these studies, BCG was compared with the combination of epirubicin and interferon (141), mitomycin C (MMC) (142) or epirubicin (143) alone. All of these studies have confirmed the superiority of BCG for prevention of tumour recurrence. It has been shown that the effect was long lasting (142,143) and was also observed in a separate analysis of patients with tumours at intermediate risk (143).

One recently published meta-analysis (144) has evaluated the individual data from 2,820 patients enrolled in nine randomised studies that have compared MMC versus BCG. In the trials with BCG maintenance, a 32% reduction in the risk of recurrence for BCG compared to MMC was found ($p < 0.0001$), whereas there was a 28% increase in the risk of recurrence ($p = 0.006$) for patients treated with BCG in the trials without BCG maintenance.

Two meta-analyses have demonstrated that BCG therapy prevents, or at least delays, the risk of tumour progression (145,146) (LE: 1a). A meta-analysis carried out by the EORTC-GU group has evaluated data from 4,863 patients enrolled in 24 randomised trials. A total of 3,967 (81.6%) patients had only papillary tumours and 896 (18.4%) had primary or concurrent CIS. Five different BCG strains were used, and in 20 out of the 24 trials, some form of BCG maintenance was used. In four trials only, a 6-week induction course was used. Based on a median follow-up of 2.5 years and a maximum of 15 years, 260 out of 2,658 patients (9.8%) on BCG progressed compared to 304 out of 2,205 (13.8%) in the control groups (TUR alone, TUR plus intravesical chemotherapy, or TUR plus other immunotherapy). This shows a reduction of 27% in the odds of progression with BCG maintenance treatment ($p = 0.0001$). The size of the reduction is similar in patients with TaT1 papillary tumours and in those with CIS (146). A recent randomised study with long-term observation has demonstrated significantly fewer distant metastases and better overall- and disease-specific survival in patients treated with BCG compared to epirubicin (143) (LE: 1b). On the contrary, a meta-analysis of individual patient data was not able to confirm any statistically significant difference between MMC and BCG for progression, survival and cause of death (144). In summary, in spite of these conflicting results, the majority of data was able to show the reduction in the risk of progression in tumours at high and intermediate risk if the BCG including maintenance schedule was used.

Two other meta-analyses have suggested a possible bias in favour of BCG by the inclusion of patients who were previously treated with intravesical chemotherapy (147,148). In the most recent meta-analysis, however, BCG maintenance was more effective than MMC also in patients who were previously treated with chemotherapy (144).

*7.2.2 **Optimal BCG schedule***

For optimal efficacy, BCG must be given in a maintenance schedule (140,144-146) (LE: 1a). In the EORTC-GU group meta-analysis, only patients who received maintenance BCG benefited. In the four trials in which no maintenance was given, no reduction in progression was observed. In the 20 trials in which some form of BCG maintenance was given, a reduction of 37% in the odds of progression was observed ($p = 0.00004$). The meta-analysis was unable to determine which BCG maintenance schedule was the most effective (146). In their meta-analysis, Böhle et al. have concluded that at least 1 year of maintenance BCG is required to obtain the superiority of BCG over MMC for prevention of recurrence or progression (140,145). Although some modifications have been tried, induction BCG instillations are classically given according to the empirical 6-weekly induction schedule that was introduced by Morales in 1976 (149). However, many different maintenance schedules have been used, ranging from a total of 10 instillations given in 18 weeks, to 27

instillations over 3 years (150). The optimal number of induction instillations and the optimal frequency and duration of maintenance instillations remain unknown (151).

7.2.3 ***Optimal dose of BCG***

To reduce BCG toxicity, a number of authors have proposed one-third and one-quarter dose instillations of BCG. Comparing one-third dose to full-dose BCG in 500 patients, CUETO has found no overall difference in efficacy. However, it has been suggested that a full dose of BCG is more effective in multifocal tumours (152,153) (LE: 1b). Although fewer patients have reported toxicity with the reduced dose, the incidence of severe systemic toxicity has been similar in the standard- and reduced-dose groups. The same Spanish group has shown in a prospective randomised trial that one-third of the standard dose of BCG might be the minimum effective dose in intermediate-risk tumours. A further reduction to one-sixth dose resulted in a decrease in efficacy for prevention of recurrence with no decrease in toxicity (154).

7.2.4 ***BCG toxicity***

Assuming that maintenance therapy is necessary for optimal efficacy, the issue of BCG toxicity becomes more relevant. As a result of the more pronounced side effects of BCG compared to intravesical chemotherapy, there is still reluctance about the use of BCG. Deaths due to BCG sepsis and the high frequency of BCG-induced cystitis and allergic reactions have compromised its use (155). However, with increased experience in using BCG, the side effects now appear to be less prominent. Serious side effects are encountered in < 5% of patients and can be effectively treated in virtually all cases (155) (LE: 1b). Major complications can appear after systemic absorption of the drug. Thus, BCG should not be administered during the first 2 weeks after TUR, in patients with macroscopic haematuria or urinary tract infection, or after traumatic catheterisation. It should not be used in immunocompromised patients (immunosuppression, human immunodeficiency virus [HIV]) (156).

The management of side-effects after BCG should reflect their type and grade. Recommendations for individual situations were provided by the International Bladder Cancer Group and by a Spanish group (157,158). Before applying intravesical BCG therapy the urologist should be aware how to treat BCG-induced complications.

7.2.5 ***Indications for BCG***

Although BCG is a very effective treatment, there is a consensus that not all patients with non-muscle-invasive bladder cancer should be treated with BCG due to the risk of toxicity. Ultimately, the choice of treatment depends upon the patients' risk of recurrence and progression (*see* Table 7). The use of BCG does not alter the natural course of tumours at low risk of recurrence (*see* Table 7), and could be considered to be over-treatment for this patient category. In patients with tumours at high risk of progression, for whom cystectomy is not carried out, BCG including at least 1 year maintenance is indicated. In patients at intermediate or high risk of recurrence and intermediate risk of progression, BCG with 1 year maintenance is more effective than chemotherapy for prevention of recurrence; however, it has more side effects than chemotherapy. For this reason both BCG with maintenance and intravesical chemotherapy remain an option. The final choice should reflect the individual patients' risk of recurrence and progression as well as efficacy and side effects of each treatment modality.

7.3 Specific aspects of treatment of CIS

7.3.1 ***Treatment strategy***

If concurrent CIS is found in association with muscle-invasive bladder cancer, therapy is determined according to the invasive tumour. The detection of CIS with TaT1 tumours increases the risk of recurrence and progression of TaT1 tumours (106,107) and further treatment is mandatory. The treatment strategy is generally based on the criteria that are summarised in Sections 7.1, 7.2, 7.4 and Chapter 8.

Carcinoma *in situ* cannot be cured by an endoscopic procedure only. Histological diagnosis of CIS must be followed by further treatment, either intravesical BCG instillations or radical cystectomy (LE: 2). No consensus exists about whether conservative therapy (intravesical BCG instillations) or aggressive therapy (cystectomy) should be done, especially when there are concurrent high-grade papillary tumours. There has been a lack of randomised trials of instillation therapy and early cystectomy as immediate primary treatment. Tumour-specific survival rates after early cystectomy for CIS are excellent, but as many as 40-50% of patients might be over-treated (3).

7.3.2 ***Cohort studies***

In retrospective evaluations of patients with CIS, a complete response rate of 48% was achieved with intravesical chemotherapy and 72-93% with BCG (109-112,159) (LE: 2). Up to 50% of complete responders might eventually show recurrence with a risk of invasion and/or extravesical recurrence (112,150,159,160).

*7.3.3 **Prospective randomised trials***

Unfortunately, there have been few randomised trials in patients with CIS alone. Most trials have included patients with either papillary tumours or CIS, which has resulted in only a small number of CIS patients being entered. Thus, the power to detect differences of treatment results has been low and the reliability of the conclusions is limited (3).

A meta-analysis of clinical trials that has compared intravesical BCG to intravesical chemotherapy (MMC, epirubicin, or adriamycin) in patients with CIS has shown a significantly increased response rate after BCG and a reduction of 59% in the odds of treatment failure with BCG (OR = 0.41, p = 0.0001). In trials that have compared BCG with MMC, the long-term benefit of BCG was smaller, but BCG was superior to MMC in trials with BCG maintenance (OR = 0.57, p = 0.04) (161).

In an EORTC-GU group meta-analysis of tumour progression, in a subgroup of 403 patients with CIS, BCG reduced the risk of progression by 35% as compared to intravesical chemotherapy or different immunotherapy (OR = 0.65, 95% CI = 0.36-1.16, p = 0.10) (146) (LE: 1b). There has been no single trial that has demonstrated superiority of combined BCG and MMC over BCG alone (162) (LE: 1).

In summary, as compared to chemotherapy, treatment of patients with CIS using BCG increases the complete response rate, the overall percentage of patients who remain disease free, and reduces the risk of tumour progression (LE: 1a).

*7.3.4 **Treatment of extravesical CIS***

Patients with CIS are at high risk of extravesical involvement: in the upper urinary tract and in the prostatic urethra. Solsona et al. have found that 87 of 138 patients (63%) with CIS developed extravesical involvement initially or during follow-up (163). Patients with extravesical involvement had worse survival than those with bladder CIS alone (163) (LE: 3).

In the prostate, CIS might be present only in the epithelial lining of the prostatic urethra or in the prostatic ducts (3). These situations should be distinguished from tumour invasion into the stroma of the prostate, which is staged as T4a, and for which immediate cystoprostatectomy is mandatory. Patients with CIS in the epithelial lining of the prostatic urethra can be treated by intravesical instillations of BCG. Transurethral resection of the prostate can improve the contact of BCG with the prostatic urethra (3,164,165) (LE: 3). In patients with prostatic duct involvement, the data are insufficient to provide clear treatment recommendations. As no conclusive results have been attained with regard to the use of conservative therapy, radical surgery should be considered in these patients (165) (LE: 3).

The treatment of CIS that involves the upper urinary tract is discussed in the upper urinary tract guidelines.

7.4 Treatment of failure of intravesical therapy

*7.4.1 **Failure of intravesical chemotherapy***

Patients with non-muscle-invasive recurrence of urothelial bladder carcinoma after intravesical chemotherapy can profit from BCG instillations (147) (LE: 1a).

*7.4.2 **Failure of intravesical BCG immunotherapy***

Treatment with BCG is considered to have failed in following situations:

a. Whenever muscle-invasive tumour is detected during follow-up.
b. If high-grade, non-muscle-invasive tumour is present at both 3 and 6 months (166). In patients with tumour present at 3 months, an additional BCG course can achieve a complete response in > 50% of cases, both in patients with papillary tumours and CIS (37,166), but with increasing risk of progression (167,168).
c. Any worsening of the disease under BCG treatment, such as a higher number of recurrences, higher T- stage or higher grade, or appearance of CIS, in spite of an initial response (LE: 3).

Changing from BCG to intravesical chemotherapy, device-assisted chemotherapy instillations, or additional interferon α-2b immunotherapy can yield responses in selected cases with non-muscle-invasive BCG treatment failure (169-178). However, experience is limited and these strategies are considered experimental. As a result of the high risk of development of muscle-invasive tumour in these patients (166-168) (LE: 3), cystectomy is strongly advocated upon early BCG failure in fit patients.

Patients with a recurrence at > 1 year after completion of BCG therapy can be treated according to the risk classification (*See Tables 6, 7 and 8*) (169).

Table 8: Treatment recommendations in TaT1 tumours according to risk stratification

Risk category	Low	Intermediate	High
Recurrence	One immediate instillation of chemotherapy	One immediate instillation of chemotherapy, followed by further instillations, either chemotherapy or a minimum 1 year of BCG (the final choice is determined by the risk of tumour progression)	One immediate instillation of chemotherapy, followed by further instillations, either chemotherapy or a minimum of 1 year of BCG (the final choice is determined by the risk of tumour progression)
Progression	One immediate instillation of chemotherapy (it can be followed by further chemotherapy instillations if the patients has at the same time an intermediate risk of recurrence)	One immediate instillation of chemotherapy, followed by a minimum of 1 year of BCG or further chemotherapy instillations	Intravesical BCG for at least 1 year, or immediate cystectomy

BCG = bacillus Calmette-Guérin.

7.5 Recommendations for adjuvant therapy in TaT1 tumours and for therapy of CIS

	GR
The type of intravesical therapy should be based on the risk groups shown in Table 7.	A
In patients with TaT1 tumours at low risk of recurrence and progression, one immediate instillation of chemotherapy is recommended as the complete adjuvant treatment.	A
In patients with TaT1 tumours at intermediate or high risk of recurrence and intermediate risk of progression, one immediate instillation of chemotherapy should be followed by a minimum 1 year of BCG treatment, or by further instillations of chemotherapy.	A
If chemotherapy is given, it is advised to use the drug at its optimal pH and to maintain the concentration of the drug during instillation by reducing fluid intake. The optimal schedule and the duration of the chemotherapy instillations remain unclear, but it should be given no more than 12 months.	B
In patients with TaT1 tumours at high risk of progression, intravesical BCG for at least 1 year is indicated.	A
In patients with bladder CIS, intravesical BCG for at least 1 year is indicated.	A
In patients with CIS in the epithelial lining of the prostatic urethra, TUR of the prostate followed by intravesical instillations of BCG could be an option.	C
Immediate radical cystectomy may be offered to patients at highest risk of tumour progression.	C
In patients with BCG failure, cystectomy is indicated.	B

BCG = bacillus Calmette-Guérin; CIS = carcinoma in situ*; TUR = transurethral resection.*

8. CYSTECTOMY FOR NON-MUSCLE-INVASIVE BLADDER CANCER

Some experts consider it is reasonable to propose immediate cystectomy to those patients with non-muscle-invasive tumour who are at high risk of progression. According to the risk tables of the EORTC (*see* Tables 6 and 7) these are:

- multiple recurrent high-grade tumours;
- high-grade T1 tumours;
- high-grade tumours with concurrent CIS.

With these patients, it is recommended to discuss both treatment options: immediate cystectomy and conservative treatment with BCG instillations. Patients should be informed about the benefits and risks of both approaches.

Cystectomy is advocated in patients with non-muscle-invasive tumours with BCG treatment failure, as mentioned above. Delay of cystectomy in these patients might lead to decreased disease-specific survival (179). In patients in whom cystectomy is performed at the time of pathological non-muscle-invasive disease, the 5-year disease-free survival rate exceeds 80% (180-185).

9. FOLLOW-UP OF PATIENTS WITH NON-MUSCLE-INVASIVE BLADDER TUMOURS

As a result of the risk of recurrence and progression, patients with TaT1 bladder tumours need to be followed; however, the frequency and duration of cystoscopy and imaging should reflect the individual patients' degree of risk. Using risk tables (see Tables 6 and 7), we are able to predict the short-term and long-term risks of recurrence and progression in individual patients, and can adapt the follow-up schedule accordingly (106). By planning the follow-up schedule the following aspects should be considered:

a. *The prompt detection of muscle-invasive and high-grade non-muscle-invasive recurrence is crucial because a delay in diagnosis and therapy can be life-threatening to the patient.*

b. *Tumour recurrence in the low-risk group is nearly always low stage and low grade.*
Small, non-invasive (Ta), low-grade papillary recurrence does not present an immediate danger to the patient, and early detection is not essential for successful therapy (186-193) (LE: 2b). In these patients, fulguration of small papillary recurrences on an outpatient basis could be a safe treatment option that reduces the therapeutic burden (194) (LE: 3). Some authors even defend temporary surveillance (192,193,195).

c. *The result of the first cystoscopy after TUR at 3 months is a very important prognostic indicator for recurrence and progression* (106,168,196,197) (LE: 1a). The first cystoscopy should thus **always** be performed 3 months after TUR in all patients with TaT1 bladder tumour.

d. *The risk of upper urinary tract recurrence increases in patients with multiple and high risk tumours* (42) (LE: 3).

As there has not been presented any non-invasive method that could replace endoscopy, the follow-up is based on regular cystoscopies (see 5.5). There has been a lack of randomised studies that have investigated the possibility of safely reducing frequency of follow-up cystoscopies. The following recommendations are therefore based only on retrospective experience.

9.1 Recommendations for follow-up in patients after TUR of non-muscle-invasive bladder cancer

	GR
Patients with TaT1 tumours at low risk of recurrence and progression should have a cystoscopy at 3 months. If negative, the following cystoscopy is advised 9 months later, and then yearly for 5 years.	C
Patients with TaT1 tumours at high risk of progression and those with CIS should have a cystoscopy and urinary cytology at 3 months. If negative, the following cystoscopy and cytology should be repeated every 3 months for a period of 2 years, and every 6 months thereafter until 5 years, and then yearly. Yearly imaging of the upper tract is recommended.	C
Patients with TaT1 tumours at intermediate risk of progression (about one-third of all patients) should have an in-between follow-up scheme using cystoscopy and cytology, which is adapted according to personal and subjective factors.	C
During follow-up in patients with positive cytology and no visible tumour in the bladder, R-biopsies or biopsies with PDD (if equipment is available) and investigation of extravesical locations (CT urography, prostatic urethra biopsy) are recommended.	B

CIS = carcinoma in situ*; PDD = photodynamic diagnosis.*

11. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations.

5-ALA	5-aminolaevulinic acid
ASR	age standardised incidence rate
BCG	bacillus Calmette-Guérin
BTA	bladder tumour antigen
CIS	carcinoma *in situ*
CT	computed tomography
CUETO	Club Urológico Español de Tratamiento Oncológico (Spanish Oncology Group)
EAU	European Association of Urology
EORTC	European Organization for Research and Treatment of Cancer
EORTC-GU	EORTC Genitourinary group
FISH	fluorescence *in situ* hybridisation
GR	grade of recommendation
HAL	hexaminolaevulinic acid
ISUP	International Society of Urological Pathology
IVU	intravenous urography
LE	level of evidence
MMC	mitomycin C
NMIBC	non-muscle-invasive bladder cancer
NVP	negative predictive value
PDD	photodynamic diagnosis
PUNLMP	papillary urothelial neoplasms of low malignant potential
RCT	randomised controlled trial
TCC	transitional cell carcinoma
TNM	tumour, node, metastasis
TUR	transurethral resection
UICC	Union International Contre le Cancer
US	ultrasonography
WHO	World Health Organization

Conflict of interest

All members of the Non-Muscle-Invasive Bladder Cancer guidelines working group have provided disclosure statements of all the relationships that they have and which might be perceived as a potential source of conflict of interest. This information is kept on file in the EAU Central Office database. This guidelines document was developed with the financial support of the EAU. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on

Upper Urinary Tract Urothelial Cell Carcinomas

M. Rouprêt, R. Zigeuner, J. Palou, A. Boehle, E. Kaasinen, R. Sylvester, M. Babjuk, W. Oosterlinck

European Association of Urology

TABLE OF CONTENTS PAGE

1. INTRODUCTION

The most recent summary of the European Association of Urology (EAU) guidelines on upper urinary tract urothelial cell carcinomas (UUT-UCCs) was published in 2004 (1). The EAU Guideline working group for UUT-UCCs has prepared current guidelines to provide evidence-based information for the clinical management of these rare tumours and to help clinicians incorporate these recommendations into their practice. The current update is based on a structured literature search.

2. METHODOLOGY

A Medline search was performed on urothelial malignancies and UUT-UCC management using combinations of the following terms: *urinary tract cancer, urothelial carcinomas, upper urinary tract, carcinoma, transitional cell, renal pelvis, ureter, bladder cancer, chemotherapy, nephroureterectomy, adjuvant treatment, neoadjuvant treatment, recurrence, risk factors,* and *survival*. The publications concerning UUT-UCCs were mostly retrospective, including some large multicentre studies. Due to the scarcity of randomised data, articles were selected for these guidelines based on the following criteria: evolution of concepts, intermediate- and long-term clinical outcomes, study quality, and relevance. Older studies were included selectively if they were historically relevant or if data were scarce in recent publications. To facilitate evaluation of the quality of information provided, levels of evidence (LE) and grades of recommendation (GR) were inserted according to general principles of evidence-based medicine (EBM) (2).

3. EVIDENCE SYNTHESIS

3.1 Epidemiology

Urothelial carcinomas are the fourth most common tumours after prostate (or breast) cancer, lung cancer, and colorectal cancer (3,4). They can be located in the lower urinary tract (bladder and urethra) or the upper urinary tract (pyelocaliceal cavities and ureter). Bladder tumours account for 90-95% of urothelial carcinomas (4) and are the most common malignancy of the urinary tract and the second most common malignancy of the urogenital tract after prostate cancer (5,6). However, UUT-UCCs are uncommon and account for only 5-10% of urothelial carcinomas (3,7-9). The estimated annual incidence of UUT-UCCs in Western countries is about one or two new cases per 100,000 inhabitants. Pyelocaliceal tumours are about twice as common as ureteral tumours. In 8-13% of cases, concurrent bladder cancer is present. Recurrence of disease in the bladder occurs in 30-51% of UUT-UCC patients (10,11), whereas recurrences in the contralateral upper tract are observed in 2-6% (12,13).

The natural history of UUT-UCCs differs from that of bladder cancer: 60% of UUT-UCCs are invasive at diagnosis compared with only 15% of bladder tumours (5,7,9). Upper urinary tract urothelial cell carcinomas have a peak incidence in people in their 70s and 80s, and UUT-UCC is three times more prevalent in men than in women.

There are familial/hereditary cases of UUT-UCCs linked to hereditary nonpolyposis colorectal carcinoma (HNPCC) (14). Among patients with UUT-UCCS, these cases can be detected during a medical interview. Indeed, the cancer is likely to be hereditary if the patient is < 60 yr of age and/or has a personal or family history of an HNPCC-type cancer (15,16). These patients should undergo DNA sequencing to identify hereditary cancers that have been misclassified as sporadic cancers by insufficient clinical data. The presence of other HNPCC-associated cancers should also be evaluated. These patients should be closely monitored, and genetic counselling is advocated (15,16).

3.2 Risk factors

Many environmental factors contribute to the development of UUT-UCCs. Some are similar to those associated with bladder cancer, whereas others are more specific for UUT-UCC. Tobacco and occupational exposure remain the principal exogenous risk factors for developing these tumours. Exposure to tobacco increases the relative risk of developing a UUT-UCC from 2.5 to 7 (17,18). UUT-UCC “amino tumours” are related to occupational exposure to certain aromatic amines. These aromatic hydrocarbons are used in many industries (e.g., dyes, textiles, rubber, chemicals, petrochemicals, and coal). They are responsible for the carcinogenicity of certain chemicals, including benzidine and β-naphthalene. These two chemicals have been banned since

the 1960s in most industrialised countries. In most cases, UUT-UCCs are secondary to an amino tumour of the bladder. The average duration of exposure needed to develop a UUT-UCC is approximately 7 yr, with a latency period of about 20 yr following the termination of exposure. The estimated risk (odds ratio) of developing UCC after exposure to aromatic amines is 8.3 (17,19).

Upper urinary tract tumours resulting from phenacetin consumption almost disappeared (17) after the product was banned in the 1970s.

Although the incidence of Balkan endemic nephropathy is also on the decline (20,21), roles have been proposed for aristolochic acid and the consumption of Chinese herbs in the physiopathology and induction, respectively, of this nephropathy (22-24). Several studies have revealed the carcinogenic potential of aristolochic acid contained in *Aristolochia fangchi* and *Aristolochia clematis* (plants endemic to the Balkans). This acid contains a set of highly toxic nitrophenolate derivatives that exhibit a powerful mutagenic action due to their ability to make up covalent links with cell DNA. The aristolochic acid derivative d-aristolactam causes a specific mutation in the p53 gene at codon 139. This mutation is very rare in the nonexposed population and is predominant in patients with nephropathy due to Chinese herbs or Balkan endemic nephropathy who present with UUT-UCC.

A high incidence of UUT-UCC has also been described in Taiwan, especially in the population of the southwest coast of the island, and represents 20-25% of UCCs in the region (16). The association of UUT-UCC with blackfoot disease and arsenic exposure remains unclear in this patient population (25).

Differences in the ability to counteract carcinogens may contribute to host susceptibility and the risk of developing urothelial carcinomas. Because certain genetic polymorphisms are associated with an increased risk of cancer or faster disease progression, there is variability in interindividual susceptibility to the risk factors just mentioned. Only one polymorphism specific to UUT-UCC has been reported so far. A variant allele, SULT1A1*2, which reduces sulfotransferase activity, enhances the risk of developing UUT-UCC (26). Epidermoid carcinoma of the UUT is associated with chronic inflammatory and infectious disease arising from stones in the UUT (27,28).

3.3 Histology and classification

*3.3.1 **Histologic types***

More than 95% of urothelial carcinomas are derived from the urothelium and correspond to UUT-UCCs or bladder tumours (1,5,28). With regard to UUT-UCCs, morphologic variants have been described that are more often observed in urothelial kidney tumours. These variants always correspond to high-grade tumours, and such urothelial carcinomas are associated with one of the following variants: micropapillary, clear cell, neuroendocrine, and lymphoepithelial (9,27). Collecting-duct carcinoma has similar characteristics to UUT-UCCs because of its common embryologic origin (29).

Upper urinary tract tumours with nonurothelial histology are exceptions (30). Epidermoid carcinomas of the upper urinary tract represent < 10% of pyelocaliceal tumours and are even more rare within the ureter. Other histologic subtypes are adenocarcinomas (< 1%), neuroendocrine carcinomas, and sarcomas.

*3.3.2 **Classification***

The classification and morphology of UUT-UCCs are similar to those of bladder carcinomas (5,28). It is possible to distinguish between noninvasive papillary tumours (papillary urothelial tumours of low malignant potential, low-grade papillary urothelial carcinoma, high-grade papillary urothelial carcinoma), flat lesions (carcinoma *in situ* [CIS]), and invasive carcinomas. All variants of urothelial tumours described in the bladder can also be observed in the upper urinary tract.

3.3.2.1 Tumour Node Metastasis (TNM) staging

Table 1 presents the Union Internationale Contre le Cancer (UICC) 2009 TNM classification used throughout these guidelines (31). According to the TNM classification, the regional lymph nodes that should be considered are the hilar, abdominal para-aortic, and paracaval nodes, and, for the ureter, the intrapelvic nodes. Laterality does not affect the N-classification.

Table 1: TNM classification 2009 for UUT-UCC (31) *

T - Primary tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Non-invasive papillary carcinoma
Tis	Carcinoma *in situ*
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades muscle
T3	(Renal pelvis) Tumour invades beyond muscularis into peripelvic fat or renal parenchyma
	(Ureter) Tumour invades beyond muscularis into periureteric fat
T4	Tumour invades adjacent organs or through the kidney into perinephric fat
N - Regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node 2 cm or less in the greatest dimension
N2	Metastasis in a single lymph node more than 2 cm but not more than 5 cm in the greatest dimension or multiple lymph nodes, none more than 5 cm in greatest dimension
N3	Metastasis in a lymph node more than 5 cm in greatest dimension
M - Distant metastasis	
M0	No distant metastasis
M1	Distant metastasis

**All EAU guidelines advocate the TNM system of tumour classification.*
UUT-UCC = urethelial cell carcinoma of the upper urinary tract.

3.3.2.2 Tumour grade

Until 2004, the most common classification used was the World Health Organization (WHO) classification of 1973, which distinguished only three grades (G1, G2, and G3) (32). In recent years, molecular biologic data have allowed for further distinction between different tumour groups and the development of a new classification system that better reflects the potential growth of these tumours (33). Thus the 2004 WHO classification now takes histologic data into account to distinguish among three groups of noninvasive tumours: papillary urothelial neoplasia of low malignant potential, low-grade carcinomas, and high-grade carcinomas. There are almost no tumours of low malignant potential in the upper urinary tract (9,27,28).

3.4 Symptoms

The diagnosis of a UUT-UCC may be fortuitous or related to the exploration of symptoms (1,6). The symptoms are generally restricted (34). The most common symptom of UUT-UCC is gross or microscopic haematuria (70-80%). Flank pain occurs in up to 20-40% of cases, and a lumbar mass is present in 10-20% of cases (1,7). However, systemic symptoms (altered health condition including anorexia, weight loss, malaise, fatigue, fever, night sweats, or cough) associated with UUT-UCC should prompt consideration of a more rigorous metastatic evaluation or perioperative chemotherapy regimens (34).

3.5 Diagnosis

*3.5.1 **Imaging***

3.5.1.1 Multidetector computed tomographic urography

Multidetector computed tomographic urography (MDCTU) is the gold standard for exploration of the upper urinary tract and has replaced intravenous excretory urography (35-38). It must be conducted under optimal conditions, particularly with acquisition of an excretory phase. Multiple protocols from two helical computed tomography acquisitions (at least millimetric) are necessary before and after the injection of contrast.

The detection rate of UUT-UCC is satisfactory for this type of imaging: 96% sensitivity and 99% specificity for polypoid lesions between 5 and 10 mm. Sensitivity drops to 89% for polypoid lesions < 5 mm and 40% for polypoid lesions < 3 mm (16,17). Multidetector computed tomographic urography can also detect thickening of the wall of the renal pelvis or ureter as a sign of UUT-UCC. The main difficulty remains identifying

flat lesions that are undetectable until they evolve towards a massive infiltration.

Lastly, it was shown that hydronephrosis on preoperative imaging was associated with advanced pathologic disease and poorer oncologic outcomes (39).

3.5.1.2 Magnetic resonance imaging

Magnetic resonance imaging (MRI) urography is indicated in patients who cannot be subjected to an MDCTU (40). The detection rate of MRI is 75% after contrast injection for tumours < 2 cm (41). Magnetic resonance urography with contrast injection, however, remains contraindicated in selected patients with severe renal impairment (< 30 ml/min creatinine clearance) due to the risk of nephrogenic systemic fibrosis. Magnetic resonance urography without contrast is less helpful compared with MDCTU in diagnosing UUT-UCCs.

*3.5.2 **Cystoscopy and urinary cytology***

Positive urine cytology is highly suggestive of UUT-UCC when bladder cystoscopy is normal and if CIS of the bladder or prostatic urethra has been excluded. Cytology is less sensitive for UUT-UCC than for bladder tumours, even for high-grade lesions, and it should ideally be performed *in situ* (i.e. in the renal cavities). A positive cytology may be valuable in staging because it has been associated with muscle-invasive and non-organ-confined disease (42).

The detection of molecular abnormalities by fluorescence *in situ* hybridisation (FISH) is becoming more popular for UCC screening, but results are still preliminary (43,44). The sensitivity of FISH for the identification of UUT-UCCs parallels its performance in bladder cancer; however, the preponderance of low-grade recurrent disease in the population undergoing surveillance and minimally invasive therapy for UUT-UCCs may limit its usefulness (45). In addition, FISH appears to have limited value for upper urinary tract tumour surveillance (46,47).

*3.5.3 **Diagnostic ureteroscopy***

Ureteroscopy is a better approach to diagnose UUT-UCCs (42,48,49). A flexible ureteroscope can explore the ureter macroscopically and reach renal cavities in 95% of cases, and it can assess the aspect of the tumour, obtain tumour biopsy, and determine tumour grade in 90% of cases with a low false-negative rate (50). It also facilitates performing a selective ureteral cytology and a retrograde pyelogram.

Flexible ureteroscopy is especially useful when there is diagnostic uncertainty, when conservative treatment is being considered, or in patients with a solitary kidney. The possible advantages of ureteroscopy should be discussed in the preoperative assessment of any UUT-UCC patient. Combining ureteroscopic biopsy grade, ipsilateral hydronephrosis, and urinary cytology may help decision making on radical nephroureterectomy (RNU) versus endoscopic treatment (42). Table 2 lists the recommendations.

Table 2: Guidelines for the diagnosis of UUT-UCC

Recommendations	GR
Urinary cytology	A
Cystoscopy to rule out a concomitant bladder tumour	A
MDCTU	A

UUT-UCC = urethelial cell carcinoma of the upper urinary tract; MDCTU = multidetector computed tomographic urography.

3.6 Prognostic factors

Upper urinary tract urothelial cell carcinomas that invade the muscle wall usually have a very poor prognosis. The 5-yr specific survival is < 50% for pT2/pT3 and < 10% for pT4 (51,52). This section briefly describes the currently recognised prognostic factors.

*3.6.1 **Tumour stage and grade***

According to the most recent classifications, the primary recognised prognostic factors are tumour stage and grade (8,31,53-55).

*3.6.2 **Age and gender***

The effect of gender on UUT-UCC mortality has been disputed recently and is no longer considered an independent prognostic factor (56-58). Conversely, patient age is still considered an independent prognostic factor because older age at the time of RNU is associated with decreased cancer-specific survival (LE: 3) (59). However, advanced age alone should not be an exclusion criterion for the aggressive treatment of potentially curable UUT-UCC. A large proportion of elderly patients can be cured with RNU (59). This suggests that

chronologic age alone is an inadequate indicator of outcomes in older UUT-UCC patients (59).

*3.6.3 **Tumour location***

According to the most recent findings, the initial location of the tumour within the upper urinary tract (e.g. ureter vs. renal pelvis) is no longer accepted as a prognostic factor (11,60,61), contrary to previously published reports (LE: 3) (62). It seems there is no longer a prognostic impact for tumour location (i.e. ureteral vs. pyelocaliceal tumours) when adjusted for tumour stage (11,63).

*3.6.4 **Lymphovascular invasion***

Lymphovascular invasion is present in approximately 20% of UUT-UCCs and an independent predictor of survival. Lymphovascular invasion status should be included in the pathologic report of RNU specimens (LE: 3) (64-66). However, only in patients with negative lymph nodes does lymphovascular invasion add prognostic information beyond that obtained with standard features (64).

*3.6.5 **Other factors***

Extensive tumour necrosis is an independent predictor of clinical outcomes in patients who undergo RNU. Extensive tumour necrosis can be defined as > 10% of the tumour area (LE: 3) (67,68).
The tumour architecture (e.g., papillary vs. sessile) of UUT-UCCs appears to be associated with prognosis after RNU. A sessile growth pattern is associated with worse outcomes (LE: 3) (8,63,69).

The presence of concomitant CIS in patients with organ-confined UUT-UCC is associated with a higher risk of recurrent disease and cancer-specific mortality (LE: 3) (70). Similar to lower tract urothelial carcinoma, concomitant CIS is an independent predictor of worse outcomes in organ-confined disease (71).

*3.6.6 **Molecular markers***

Several research groups are working on upper urinary tract tumour characteristics and carcinogenesis pathways. Specific markers that could aid in the prognosis of UUT-UCCs have been investigated. Microsatellite instabilities (MSIs) are independent molecular makers used for tumour prognosis (72). In addition, MSIs can help detect germ-line mutations, allowing for the detection of possible hereditary cancers (14,16,72).

E-cadherin has been shown to be a useful independent marker for prognosis, as have hypoxia-inducible factor (HIF)-1α and telomerase RNA component (73). Furthermore, HIF-1α appears to be significantly associated with tumour grade and growth pattern, and the telomerase RNA component could possibly be used for UUT-UCC diagnosis and prognostication. However, to date, none of the markers has been externally validated, and none has fulfilled the clinical and statistical criteria necessary to support its introduction in daily clinical decision making.

3.7 Treatment

*3.7.1 **Localised disease***

3.7.1.1 Radical nephroureterectomy

Radical nephroureterectomy with excision of the bladder cuff is the gold standard treatment for UUT-UCCs, regardless of the location of the tumour in the upper urinary tract (LE: 3) (8). The RNU procedure must comply with oncologic principles, which consist of preventing tumour seeding by avoiding entry into the urinary tract during tumour resection (8,69).

Resection of the distal ureter and its orifice is performed because it is a part of the urinary tract with considerable risk of recurrence. After removal of the proximal part, it is almost impossible to image or approach it by endoscopy during follow-up. Recent publications on survival after nephroureterectomy have concluded that removal of the distal ureter and bladder cuff is beneficial (74-77).

McDonald et al. presented the pluck technique in 1952, but it was not until 1995 (78) that the usefulness of an endoscopic approach to the distal ureter was really emphasised, and then several other alternative techniques were reconsidered to simplify resection of the distal ureter: stripping, transurethral resection of the intramural ureter, and intussusception techniques (12). Apart from ureteral stripping, none of these techniques have demonstrated inferiority to excision of the bladder cuff (LE: 3) (75-77,79). A delay > 45 d between diagnosis and resection of the tumour constitutes a risk for disease progression (LE: 3) (80).

Lymph node dissection associated with RNU is of therapeutic interest and allows for optimal staging of the disease (LE: 3) (81-83). Lymphadenectomy in pN+ allows for reduction of the tumour mass to guide patients towards adjuvant treatments (LE: 3) (82). However, the anatomic sites of lymphadenectomy have not yet been clearly defined. The number of lymph nodes to be removed depends on the tumour location. No trial so far has shown its direct impact on survival (82). Lymphadenectomy appears to be unnecessary in cases of TaT1 UUT-UCCs because it was reported to be retrieved in 2.2% T1 versus 16% pT2-4 tumours (82). In addition, authors have described a continuous increase in the probability of lymph node-positive disease related to pT classification (81). Lastly, lymphadenectomy appears to be a prognostic variable within a model in

patients with histologically confirmed node-negative (pN0) disease (83). However, these data are retrospective; it is not possible to standardise either indication or the extent of lymphadenectomy. Consequently, underreporting of the true rate of node-positive disease is likely.

The safety of laparoscopic RNU has not yet achieved final proof (84,85). In early experience, there were reports of retroperitoneal metastatic dissemination and dissemination along the trocar pathway when large tumours were manipulated in a pneumoperitoneal environment (86,87).

Recent data, however, show a tendency towards equivalent oncologic results between laparoscopic RNU and open surgery. In addition, the laparoscopic approach appears to be superior to open surgery only with regard to functional outcomes (LE: 3) (88-91). Only one prospective randomised study of 80 patients did not provide evidence that laparoscopic RNU is inferior to open RNU for noninvasive UUT-UCC (LE: 2) (92). Several precautions must be taken when operating with a pneumoperitoneum because it may increase tumour spillage:

- Entering the urinary tract should be avoided.
- Direct contact of the instruments with the tumour should be avoided.
- Laparoscopic RNU must take place in a closed system. Morcellation of the tumour should be avoided, and an endobag is necessary to extract the tumour.
- The kidney and ureter must be removed en bloc with the bladder cuff.
- Invasive, large (T3/T4 and/or N+/M+), or multifocal tumours are contraindications for laparoscopic RNU, until proven otherwise.

Recommendations are listed in Table 3.

Table 3: Guidelines for radical management of UUT-UCC: radical nephroureterectomy

Indications for RNU for UUT-UCC	**GR**
Suspicion of infiltrating UUT-UCC on imaging	B
High-grade tumour (urinary cytology)	B
Multifocality (with two functional kidneys)	B
Techniques for RNU in UUT-UCC	
Open and laparoscopic access are equivalent in terms of efficacy	B
Bladder cuff removal is imperative	A
Several techniques for bladder cuff excision are acceptable except stripping	C
Lymphadenectomy is recommended in case of invasive UUT-UCC	C

RNU = radical nephroureterectomy; UUT-UCC = urethelial cell carcinoma of the upper urinary tract.

3.7.1.2 Conservative surgery

Conservative surgery for low-risk UUT-UCCs allows for preservation of the upper urinary renal unit while sparing the patient the morbidity associated with open radical surgery (93,94). Conservative management of UUT-UCCs can be considered in imperative cases (renal insufficiency, solitary functional kidney) or in elective cases (i.e. when the contralateral kidney is functional) for low-grade, low-stage tumours (LE: 3) (76,95). The choice of technique depends on technical constraints, the anatomic location of the tumour, and the experience of the surgeon.

3.7.1.2.1 Ureteroscopy

Endoscopic ablation can be considered in highly selected cases (96,97,98) and in these situations:

- A flexible rather than a rigid ureteroscope, laser generator, and pliers (pluck) for biopsies are available (LE: 3) (96,99).
- The patient is informed of the need for closer, more stringent surveillance.
- A complete resection is advocated.

3.7.1.2.2 Segmental resection

Segmental ureteral resection with wide margins provides adequate pathologic specimens for definitive staging and grade analysis while also preserving the ipsilateral kidney. Segmental resection is possible for the treatment of low- and high-risk tumours of the distal ureter (LE: 3) (100,101). It is necessary, however, to ensure that the area of tissue around the tumour is not invaded. Segmental resection of the iliac and lumbar ureter is associated with a failure rate greater than that for the distal pelvic ureter (100,102).

Open resection of tumours of the renal pelvis or calices has almost disappeared. Resection of

pyelocaliceal tumours is technically difficult, and the recurrence rate is higher than for tumours of the ureter.

3.7.1.2.3 Percutaneous access
Percutaneous management can be considered for low-grade or noninvasive UUT-UCCs in the renal cavities (LE: 3) (97,103,104). This treatment option may be offered to patients with low-grade tumours in the lower caliceal system that are inaccessible or difficult to manage by ureteroscopy. A theoretical risk of seeding exists in the puncture tract and in perforations that may occur during the procedure. This approach, however, is being progressively abandoned due to enhanced materials and advances in distal-tip deflection of recent ureteroscopes.

3.7.1.3 Adjuvant topical agents
The instillation of bacillus Calmette-Guérin or mitomycin C in the urinary tract by percutaneous nephrostomy via a three-valve system open at 20 cm (after complete eradication of the tumour), or even through a ureteric stent (105), is technically feasible after conservative treatment of UUT-UCCs or for the treatment of CIS. The medium-term results are similar to those observed for the treatment of bladder tumours but have not been confirmed in long-term studies (LE: 3) (1,106,107). Table 4 reports the recommendations.

Table 4: Guidelines for conservative management of UUT-UCC

Indications for conservative management of UUT-UCC	**GR**
Unifocal tumour	B
Small tumour	B
Low-grade tumour (cytology or biopsies)	B
No evidence of an infiltrative lesion on MDCTU	B
Understanding of close follow-up	B
Techniques used in conservative management of UUT-UCC	
Laser should be used in case of endoscopic treatment	C
Flexible ureteroscopy is preferable over rigid ureteroscopy	C
Open partial resection is an option for pelvic ureteral tumours	C
A percutaneous approach remains an option in small low-grade caliceal tumours unsuitable for ureteroscopic treatment	C

MDCTU = multidetector computed tomographic urography; UUT-UCC = urethelial cell carcinoma of the upper urinary tract.

3.7.2 ***Advanced disease***
3.7.2.1 Nephroureterectomy
There are no benefits of RNU in metastatic (M+) disease, although it can be considered a palliative option (LE: 3) (8,81).

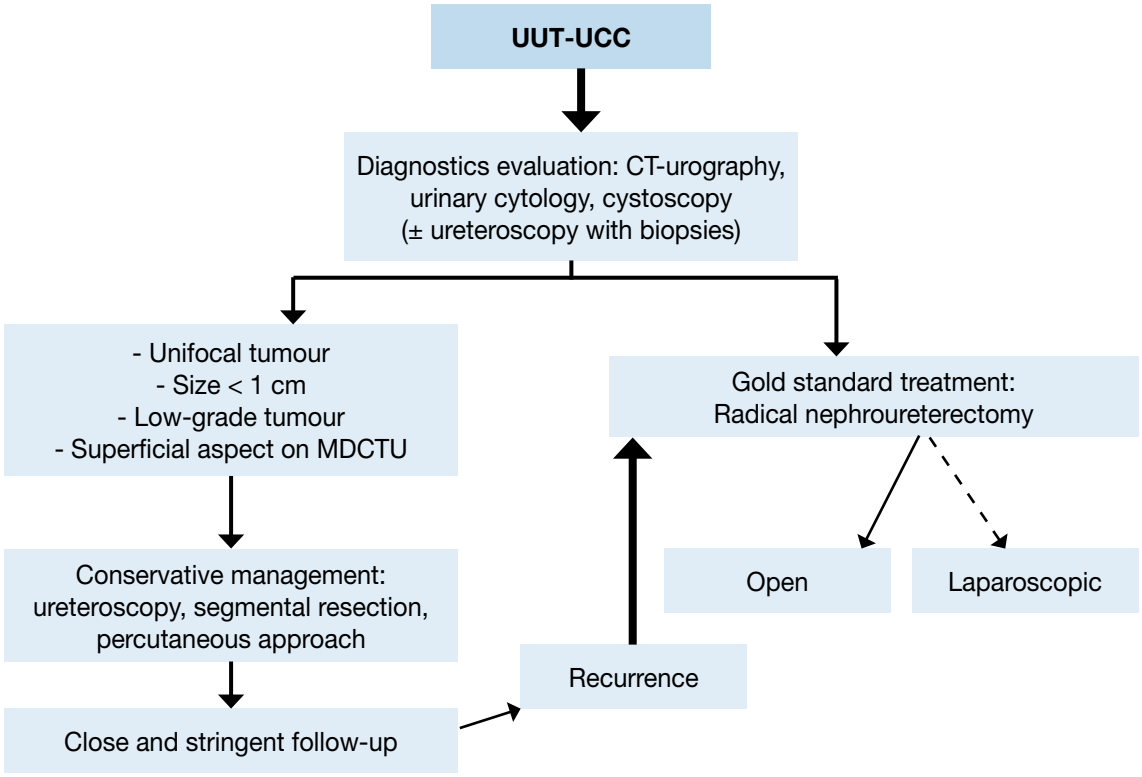
3.7.2.2 Chemotherapy
Because UUT-UCCs are urothelial tumours, platinum-based chemotherapy is expected to produce similar results to those seen in bladder cancer. Several platinum-based chemotherapy regimens have been proposed (108-111).

Only one study has reported the effect of neoadjuvant chemotherapy in contrast to what has been demonstrated in the bladder. While survival data need to mature and longer follow-up is awaited, current preliminary data provide justification for the sustained support of trials using this strategy in UUT-UCCs (112).

Adjuvant chemotherapy achieves a recurrence-free rate of up to 50% but has minimal impact on survival (108-111). Not all the patients receive this treatment because of comorbidities and impaired renal function after radical surgery. Data are currently insufficient to provide any recommendations.

3.7.2.3 Radiation therapy
Adjuvant radiotherapy may improve local control of the disease (113). When given in combination with cisplatinum, it may result in a longer disease-free survival and longer overall survival (114) (LE: 3). Radiation therapy appears to be scarcely relevant nowadays both as a unique therapy and associated with chemotherapy as a tumour adjuvant (Fig. 1).

Fig. 1 Proposed flowchart for the management of UUT-UCC



UUT-UCC = urethelial cell carcinoma of the upper urinary tract; MDCTU = multidetector computed tomographic urography.

3.8 Follow-up

Strict follow-up of UUT-UCC patients after surgical treatment is mandatory to detect metachronous bladder tumours (in all cases), local recurrence, and distant metastases (in the case of invasive tumours).

When RNU is performed, local recurrence is rare, and the risk of distant metastases is directly related to the risk factors listed previously. The reported recurrence rate within the bladder after treatment of a primary UUT-UCC varies considerably from 15% to 50% (10,115,116). Thus the bladder should be observed in all cases. A prior history of bladder cancer and upper tract tumour multifocality are the risk factors most often reported for bladder tumours following UUT-UCCs. The surveillance regimen is based on cystoscopy and urinary cytology for at least 5 yr (10,115,116). A bladder recurrence should not be considered a distant recurrence.

When conservative treatment is performed, the ipsilateral upper urinary tract requires careful follow-up due to the high risk of recurrence. Despite notable improvements in endourologic technology, the follow-up of patients treated with conservative therapy is difficult, and minimally invasive procedures are often necessary (96,98,117,118). Table 5 lists the recommended follow-up schedules.

Table 5: Guidelines for follow-up of UUT-UCC patients after initial treatment

After RNU, over at least 5 yr	**GR**
Noninvasive tumour	
Cystoscopy/urinary cytology at 3 mo and then yearly	C
MDCTU every year	C
Invasive tumour	
Cystoscopy/urinary cytology at 3 mo and then yearly	C
MDCTU every 6 mo over 2 yr and then yearly	C

After conservative management, over at least 5 yr	
Urinary cytology and MDCTU at 3 mo, 6 mo, and then yearly	C
Cystoscopy, ureteroscopy and cytology *in situ* at 3 mo, 6 mo, and then every 6 mo over 2 yr, and then yearly	C

RNU = radical nephroureterectomy; MDCTU = multidetector computed tomographic urography.

4. CONCLUSIONS

These guidelines contain information for the diagnosis and treatment of individual patients according to a current, standardised approach. When determining the optimal treatment regimen for their patients, physicians must take into account each individual patient's specific clinical characteristics with regard to renal function including medical comorbidities; tumour location, grade, and stage; and molecular marker status.

6. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

EBM	evidence based medicine
CIS	carcinoma *in situ*
CT	computed tomography
EAU	European Association of Urology
EBM	evidence-based medicine
FISH	fluorescence *in situ* hybridisation
GR	grade of recommendation
HIF	hypoxia-inducible factor
HNPCC	hereditary nonpolyposis colorectal carcinoma
LE	level of evidence
MDCTU	multidetector computed tomographic urography
MRI	magnetic resonance imaging
MSIs	microsatellite instabilities
RNU	radical nephroureterectomy
TNM	Tumour Node Metastasis
UUT-UCCs	upper urinary tract urothelial cell carcinomas
WHO	World Health Organization

Conflict of interest

All members of the Upper Urinary Tract Urothelial Cell Carcinomas guidelines working group have provided disclosure statements of all relationships which they have and which may be perceived as a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on

Bladder Cancer Muscle-invasive and Metastatic

1. INTRODUCTION

1.1 The guideline

The European Association of Urology (EAU) Guideline Panel for Muscle-invasive and Metastic Bladder Cancer (MIBC) has prepared these guidelines to help urologists assess the evidence-based management of MIBC and to incorporate guideline recommendations into their clinical practice. The EAU Guidelines Panel comprises an international multidisciplinary group of experts from the fields of urology, pathology, radiology and oncology.

It is evident that optimal treatment strategies for MIBC require the involvement of a specialist multidisciplinary team and a model of integrated care to avoid fragmentation of patient care.

The Muscle-invasive and metastatic bladder cancer guidelines are one of three EAU guidelines documents (EAU Guidelines on Non-muscle-invasive (TaT1 and CIS) Bladder Cancer and EAU Guidelines on Upper urinary tract urothelial call carcinomas) which, together, present a comprehensive overview of the management of urothelial neoplasms (1,2).

1.2 Methodology

*1.2.1 **Data identification***

Comprehensive literature searches were designed for each section of the MIBC guideline with the help of an expert external consultant. Following detailed internal discussion, searches were carried out in the Cochrane Library database of Systematic Reviews, the Cochrane Library of Controlled Clinical Trials, and Medline and Embase on the Dialog-Datastar platform. The searches used the controlled terminology of the respective databases. Both MesH and EMTREE were analysed for relevant terms; urinary bladder neoplasms (Medline) and bladder cancer (Embase) were the narrowest single terms available.

Extensive use of free text ensured the sensitivity of the searches, although the subsequent concomitant workload for panel members having to assess the substantial body of literature greatly increased.

Search strategies covered the last 10 years for Medline and for Embase in most cases. Randomised controlled trial (RCT) strategies used were based on Scottish Intercollegiate Guidelines Network (SIGN) and Modified McMaster/Health Information Research Unit (HIRU) filters for RCTs, systematic reviews and practice guidelines on the OVID platform. Results of all searches were scan-read by panel members. In many cases there was a high 'numbers needed to read' due to the sensitivity of the search.

There is clearly a need for continuous re-evaluation of the information presented in the current guideline by an expert panel. It must be emphasised that the current guideline contains information for the treatment of an individual patient according to a standardised approach.

The level of evidence (LE) and grade of recommendation (GR) provided in this guideline follow the listings in Tables 1 and 2 (3). The aim of grading the recommendations is to provide transparency between the underlying evidence and the recommendation given.

It should be noted, however, that when recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of RCTs may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Alternatively, absence of high level evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful for the reader. The quality of the underlying scientific evidence - although a very important factor - has to be balanced against benefits and burdens, values and preferences and cost when a grade is assigned (4-6).

The EAU Guidelines Office, do not perform cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever this data is available, the expert panels will include the information.

*1.2.2 **Publication history***

The EAU published a first guideline on bladder cancer in 2000. This document covered both superficial (non-muscle-invasive) bladder cancer and MIBC. As different treatment strategies are employed for these conditions it was decided to split these topics up, resulting in a first publication of the MIBC guideline in 2004, with subsequent updates in 2007, 2009, 2010, 2011 and this 2012 update. A quick reference document presenting the main findings is also available alongside several scientific publications (7-9).

All texts can be viewed and downloaded for personal use at the EAU website:
http://www.uroweb.org/guidelines/online-guidelines/.

This document was peer-reviewed prior to publication.

1.3 Summary of updated information

For all Sections, the literature has been assessed and the guideline updated whenever relevant information was available.

Of note are changes in sections:

Chapter 2 “Epidemiology and risk factors”;

- Sections 2.2.5 (Bladder Schistosomiasis) and 2.2.6 (Chronic urinary tract infection) have been updated.

Chapter 3 “Classification”;

- Section 3.3.2 (Pathologist’handling of specimens); has been expanded.

Chapter 4 “Diagnosis and staging”;

- Section 4.2.1.1. (MR imaging for local staging of invasive bladder cancer); literature was revisited, resulting in amended recommendations.

Chapter 8 “Non resectable tumours”;

- A new section 8.3 on Supportive care has been included.

Chapter 10 “Bladder-sparing treatments for localised disease”

- Additional supportive evidence for TURB for selected patients has been added.
- Additional supportive evidence for EBRT monotherapy in highly selected patients
- The multimodality bladder-preserving (10.4) treatment section has been expanded; potential benefit will depend on low stage and complete TUR as important prognostic factors.

Chapter 12 “Metastatic disease”;

- Section 12.9 (Treatment of bone metastases - bisphosphonates); new literature has been added, resulting in amended recommendations.
- The available new evidence on quality-of-life (Chapter 13) has been added.

Chapter 14 “Follow up”;

- Additional data included on recurrences and secondary urethral tumours. Also a new follow-up table has been added.

Table 1: Level of evidence*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

**Modified from Sackett, et al. (3).*

Table 2: Grade of recommendation*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett, et al. (3).*

2. EPIDEMIOLOGY AND RISK FACTORS

2.1 Epidemiology

Bladder cancer is the 9th most common cancer diagnosis worldwide, with more than 330,000 new cases each year and more than 130,000 deaths per year, with an estimated male:female ratio of 3.8:1.0 (1). At any point in time 2.7 million people have a history of urinary bladder cancer (1).

At the initial diagnosis of bladder cancer, 70% of cases are diagnosed as non-muscle-invasive bladder cancer (NMIBC) and approximately 30% as muscle-invasive disease. Among patients treated with radical cystectomy because of MIBC, 57% had muscle invasion at presentation, while 43% had been initially diagnosed with NMIBC that progressed despite organ-preserving treatment (2). Approximately one-third of patients diagnosed with MIBC have undetected metastasis at the time of treatment of the primary tumour (3), while 25% of patients subjected to radical cystectomy present with lymph node involvement at the time of surgery.

2.2 Risk factors for bladder cancer

*2.2.1 **Tobacco smoking***

Tobacco smoking is the most well-established risk factor for bladder cancer, causing 50-65% of male cases and 20-30% of female cases (4). A casual relationship has been established between exposure to tobacco and cancer in studies in which chance, bias and confounding can be ruled out with reasonable confidence (5). The alleged carcinogenic constituents of tobacco smoke include arylamines, particularly the potent carcinogen 4-aminobiphenyl (4-ABP), polycyclic aromatic hydrocarbons (PAHs), N-nitroso compounds, heterocyclic amines, and various epoxides.

The incidence of bladder cancer is directly related to the duration of smoking and number of cigarettes smoked per day (6). The risk of bladder cancer is also higher in those who start smoking at a young age or who are exposed to environmental tobacco smoke during childhood (7). A recent meta-analysis looked at 216 observational studies on cigarette smoking and cancer from 1961 to 2003, with reported estimates for current and/or former smokers. The pooled risk estimates for bladder cancer demonstrated a significant association for both current and former smokers. In an analysis of 21 studies, the overall relative risk calculated for current smokers was 2.77 (95% confidence interval [CI]: 2.17-3.54), while an analysis of 15 studies showed that the

overall relative risk calculated for former smokers was 1.72 (95% CI: 1.46-2.04) (8). An immediate decrease in the risk of bladder cancer was observed in those who stopped smoking. The reduction was about 40% within 1-4 years of quitting smoking and 60% after 25 years of cessation (6). The promotion of smoking cessation would result in the incidence of bladder cancer decreasing equally in men and women.

2.2.2 ***Occupational exposure to chemicals***

Occupational exposure is the second most important risk factor for bladder cancer. Work-related cases accounted for 20-25% of all bladder cancer cases in several series. The substances involved in chemical exposure have been benzene derivatives and arylamines (2-naphthylamine, 4-ABP, 4,4'-methylenedianiline and o-toluidine), and it is likely to occur in occupations in which dyes, rubbers, textiles, paints, leathers and chemicals are used (9). The risk of bladder cancer due to occupational exposure to carcinogenic aromatic amines is significantly higher after 10 years, or more; the mean latency period usually exceeds 30 years (10,11). These chemicals have contributed minimally to the current incidence of bladder cancer in Western countries because of strict regulations. In fact, there has been a trend towards a decrease in bladder cancer due to occupational exposure, as indicated by a pooled analysis of 11 European case-control studies on bladder cancer between 1976 and 1996 (12).

An example of occupational exposure is that of aromatic amines. These established carcinogens for urothelium can be inactivated by a metabolic acetylation pathway. The presence of an NAT2 slow-acetylation genotype has been associated with a higher risk of bladder cancer (13), suggesting that patients who are slow acetylators may be more susceptible to bladder cancer than rapid acetylators.

Other risk factors include phenacetin, which was included in 1987 among proven human carcinogens by the International Agency for Research on Cancer (IARC). Some studies have suggested that the risk of bladder cancer due to phenacetin is dose dependent; however, the data concerning its metabolite acetaminophen are controversial (14).

2.2.3 ***Radiation therapy***

Increased rates of secondary bladder malignancies have been reported after external beam radiation therapy (EBRT) for gynaecological malignancies, with relative risks of 2 to 4 (15). A recent population cohort study identified 243,082 men treated for prostate cancer between 1988 and 2003 in the Surveillance, Epidemiology and End Results database (SEER) in the USA. The standardised incidence ratios for bladder cancer developing after radical prostatectomy (RP), EBRT, brachytherapy (BT), and EBRT-BT were 0.99, 1.42, 1.10 and 1.39, respectively, compared with the general US population. The increased risk of bladder cancer in patients undergoing ERBT, BT or ERBT-BT should be taken into account during follow-up although the likelihood of mortality was described as very low in a recent study (16). As bladder cancer requires a long time to develop, patients treated with radiation and a long life-expectancy are at highest risk and should be followed up closely (17).

2.2.4 ***Dietary factors***

Several dietary factors had been believed to be related to bladder cancer; however, a link remains controversial. Currently, there is limited evidence of a causal relationship between bladder cancer and dietary factors. A meta-analysis of 38 articles reporting data on diet and bladder cancer supported the hypothesis that vegetable and fruit intake reduced the risk of bladder cancer (18). For bladder cancer, there seems to be no association between dietary transfatty acid (TFA) intake and an increased risk, as observed for prostate cancer (19).

2.2.5 ***Bladder schistosomiasis***

Bladder schistosomiasis (bilharzia) is the second most common parasitic infection after malaria, with about 600 million people exposed to infection in Africa, Asia, South America, and the Caribbean (20). Although there is a well-established relationship between squamous cell carcinoma of the bladder and schistosomiasis, the trends are changing for bladder cancer in endemic zones, such as Egypt. Data from the National Cancer Institute (NCI) Cairo, the largest tertiary cancer hospital in Egypt, showed that patients diagnosed in 2005 had a six-fold higher chance of developing transitional cell carcinoma (TCC) compared with patients diagnosed in 1980 (21). This shift from squamous cell carcinoma to TCC is attributed to a decline in the detection of bilharzia eggs in urine samples, probably due to better control of the disease in rural populations (22,23).

2.2.6 ***Chronic urinary tract infection***

Muscle-invasive bladder cancer, particularly invasive squamous cell carcinoma, has been linked to the presence of chronic urinary tract infection (UTI) different from schistosomiasis. A direct association between bladder cancer and UTIs has been observed in several case–control studies, reporting a twofold increased risk of bladder cancer in patients with recurrent UTIs in some series. However, some of these results may be attributed to recall bias (24). Furthermore, to date, no clear relationship between any bacterial or viral infection

and bladder cancer has been established in prospective studies (25).
However, an increased risk of bladder cancer has been described in patients with long-term indwelling catheters (26).

2.2.7 ***Chemotherapy***

The use of cyclophosphamide, an alkylating agent used for treatment of lymphoproliferative diseases and other non-neoplastic diseases, has been correlated with posterior development of MIBC with a period of latency of 6-13 years. Acrolein is a metabolite of cyclophosphamide and is responsible for the increase in the incidence of bladder cancer. This effect occurs independently of the association of haemorrhagic cystitis with the same treatment (27,28) and was counteracted with concomitant application of mercaptoethanesulfonate (mesna) (29).

2.2.8 ***Synchronous and metachronous upper urinary tract tumours***

In some cases, there is an association between upper urinary tract tumours (UUTT) and bladder cancer. The incidence of UUTT after diagnosis of NMIBC has been reported to be between 1.7% and 26%. Although synchronous UUTT and NMIBC are uncommon, 46% are invasive.

In a retrospective review of 1,529 patients with primary non-muscle-invasive bladder carcinoma who underwent initial examination of the upper urinary tract with excretory urography, those with a tumour in the bladder trigone were almost 6 times more likely to develop a synchronous tumour in the upper urinary tract (30). Examination of the upper urinary tract only in patients with a tumour in the trigone or with multiple bladder tumours could diagnose 41% or 69% of UUTT, respectively. In multiple and high-risk tumours, there is an increased risk of tumour recurrence in the UUT.

In addition, the overall incidence of bladder cancer development after treatment of UUTT has been reported in the literature as 15-50%. No level 1 evidence from prospective randomised trials is available, as yet. Intraluminal tumour seeding and pan-urothelial field change effects have both been proposed to explain intravesical recurrences. In most cases, bladder cancer arises in the first 2 years after upper urinary tract urothelial cell carcinoma (UUT-UCC) management. However the risk is life-long and repeat episodes are common. No variables can be used to predict future bladder cancer recurrence in UUT-UCC patients reliably. A history of bladder cancer prior to UUT-UCC management and upper tract tumour multifocality are the only commonly reported clinical risk factors in the current literature (31).

2.2.9 ***Gender***

In a retrospective study of patients who underwent radical cystectomy, it was demonstrated that women were more likely to be diagnosed with primary muscle-invasive disease than men (85% vs 51%) (2). It has been proposed that women are more likely to be older than men when diagnosed, with a direct effect on their survival. In addition, delayed diagnosis is more likely in women after haematuria is observed, because the differential diagnosis in women includes diseases more prevalent than bladder cancer (32).

Differences in the gender prevalence of bladder cancer may be due to other factors besides tobacco and chemical exposure. In a large prospective cohort study, post-menopausal status was associated with an increase in bladder cancer risk even after adjusting for smoking status. This result suggests that the differences in oestrogen and androgen levels between men and women could be responsible for some of the difference in the gender prevalence of bladder cancer (33-35). Recently a study in Egyptian women was conducted and younger age at menopause (< 45y) was a factor associated with increasing risk of bladder cancer, while multiple pregnancies and use of oral contraceptives were associated with decreased odds of having bladder cancer. The magnitude of associations was higher in the urothelial carcinoma group (36). A recent publication mentions that female gender has a significant negative impact on CSS in patients younger of age and with positive LVI status, possibly suggesting different clinical phenotypes (37).

2.2.10 ***Race and socio-economic status***

Limited data exists on this topic, but a study based on 13,234 cases diagnosed in the SEER database in the period 1979-2003 showed that survival time from diagnosis was significantly decreased among cancer cases in patients with low socioeconomic status (SES) compared with those with higher SES. Hazard ratios for all causes and cancer-specific mortality among blacks compared to whites for eight of the most common types of cancers combined, lost statistical significance after adjusting for SES factors and treatments. But blacks still had unfavourable prognoses compared with whites even after adjustment for SES and treatment for tumours such as breast-, colorectal-, and urinary bladder cancer (38).

2.3 Conclusions and recommendations for epidemiology and risk factors

Conclusions	LE
The incidence of muscle-invasive disease has not changed for 5 years.	
Active and passive tobacco smoking continues to be the main risk factor, while exposure-related incidence is decreasing.	2a
The increased risk of developing bladder cancer in patients submitted to external beam radiation therapy, brachytherapy or a combination of external beam radiation therapy and brachytherapy must be taken into account during patient follow-up. As bladder cancer requires time to develop, patients treated with radiation at a young age are at the greatest risk and should be followed up closely.	3
The estimated male-to-female ratio for bladder cancer is 3.8:1.0. Women are more likely to be diagnosed with primary muscle-invasive disease than men.	
Currently, treatment decisions cannot be based on molecular markers.	

Recommendations	GR
The principle preventable risk factor for muscle-invasive bladder cancer is active and passive smoking.	B
Notwithstanding stricter regulations, workers should be informed about the potential carcinogenic effects of a number of recognised substances, duration of exposure, and latency periods. Protective measures should be recommended.	A

3. CLASSIFICATION

3.1 Tumour, Node, Metastasis classification

The Tumour, Node, Metastasis (TNM) Classification of Malignant Tumours is the method most widely used to classify the extent of cancer spread. Recently a seventh edition was published, effective as of 2010 (1). There are no significant modifications to this for bladder cancer compared with the previous (2002) edition.

Table 3: 2009 TNM classification of urinary bladder cancer

T - Primary tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Non-invasive papillary carcinoma
Tis	Carcinoma *in situ*: 'flat tumour'
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades muscle
T2a	Tumour invades superficial muscle (inner half)
T2b	Tumour invades deep muscle (outer half)
T3	Tumour invades perivesical tissue
T3a	Microscopically
T3b	Macroscopically (extravesical mass)
T4	Tumour invades any of the following: prostate, uterus, vagina, pelvic wall, abdominal wall
T4a	Tumour invades prostate, uterus or vagina
T4b	Tumour invades pelvic wall or abdominal wall

N - Lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N2	Metastasis in multiple lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N3	Metastasis in common iliac lymph node(s)
M - Distant metastasis	
M0	No distant metastasis
M1	Distant metastasis

3.2 Histological grading of non-muscle-invasive bladder tumours

In 1998, a new classification of non-invasive urothelial tumours was proposed by the World Health Organization (WHO) and the International Society of Urological Pathology (ISUP). It was published by the WHO in 2004 (2,3) (Table 4). Its major contribution is a detailed histological description of the various grades using specific cytological and architectural criteria. A website (http://www.pathology.jhu.edu/bladder) illustrating examples of various grades was developed to improve accuracy in using the system.

Table 4: WHO grading in 1973 and 2004 (2,3)

1973 WHO grading	
Urothelial papilloma	
Grade 1:	well differentiated
Grade 2:	moderately differentiated
Grade 3:	poorly differentiated
2004 WHO grading	
Urothelial papilloma	
Papillary urothelial neoplasm of low malignant potential (PUNLMP)	
Low-grade papillary urothelial carcinoma	
High-grade papillary urothelial carcinoma	

*3.2.1 **WHO grading***

The 2004 WHO grading differentiates between papilloma, papillary urothelial neoplasms of low malignant potential (PUNLMP), and low-grade and high-grade urothelial carcinomas.

The papilloma is composed of a delicate fibrovascular core covered by normal urothelium. A PUNLMP is defined as a papillary fibrovascular growth covered by proliferated urothelium exceeding the normal thickness. Although PUNLMPs have a negligible risk of progression, they are not completely benign and have a tendency to recur. The low-grade papillary urothelial carcinoma group includes all former grade 1 (WHO 1973) cases and some former grade 2 cases (if a variation of architectural and cytological features exist at high magnification).

Use of the 2004 WHO classification is recommended as this should result in a uniform diagnosis of tumours better classified according to risk potential. However, until the 2004 WHO classification has been validated by more clinical trials, tumours should be graded using both the 1973 and the 2004 WHO classifications (4).

Most clinical trials published so far on bladder tumours have been performed using the 1973 WHO classification, so this is used in the 2012 edition of the guidelines.

3.3 Pathology

*3.3.1 **Urologist handling of specimens***

In transurethral resection (TUR) specimens, the superficial and deep areas of the tumour must be sent to the pathology laboratory separately. If random biopsies of the flat mucosa have been carried out, each biopsy of the flat mucosa must also be sent separately.

In radical cystectomy the bladder fixation must be carried out as soon as possible. The pathologist must open the specimen from the urethra to the bladder dome and fix the specimen in formalin. In some circumstances this procedure can also be performed by the urologist. In a female cystectomy specimen,

the length of the urethral segment removed en bloc with the specimen should be checked, preferably by the urological surgeon (5).

3.3.2 ***Pathologist handling of specimens***

Specimen handling should follow the general rules as published by a collaborative group of pathologists and urologists (6). It must be stressed that it may be very difficult to confirm the presence of a neoplastic lesion using gross examination of the cystectomy specimen after TUR or chemotherapy, so the entire retracted or ulcerated area must be included.

It is compulsory to study the urethra, the ureter, the prostate in men and the radial margins (7). In urethra-sparing cystectomy, the level of urethral dissection, completeness of the prostate specifically at the apex (in men), and the inclusion of the entire bladder neck and amount of adjacent urethra (in women) should be documented.

All lymph node specimens should be provided in their totality, in clearly labelled containers. In case of doubt, or adipous differentiation of the lymph node, the entire specimen is to be included.

Lymph nodes should be counted and measured on slides, capsular effraction and percentage of lymph node invasion should be reported as well as vascular embols. In case of metastatic spread in the perivesical fat without real lymph node structures (capsule, subcapsular sinus), this localisation should nevertheless be considered as N+.

Fresh frozen sections are helpful to determine treatment strategy. A recent study confirmed reliability of fresh frozen sections of obturator lymph nodes, but similar studies are warranted to confirm these results (8). As yet, the use of fresh frozen section is generally used within a clinical study setting.

3.3.3 ***Pathology of muscle-invasive bladder cancer***

In muscle-invasive bladder cancer there are usually no cases of PUNLMP and low-grade carcinoma. All cases are high-grade urothelial carcinomas (grade II or grade III). For this reason, no more prognostic information can be provided by grading muscle-invasive bladder cancer (9). However, some morphological subtypes can be important for helping with prognosis and treatment decisions. Currently the following differentiation is used:

1. urothelial carcinoma (more than 90% of all cases)
2. urothelial carcinomas with squamous and/or glandular partial differentiation (10,11);
3. micropapillary urothelial carcinoma;
4. small-cell carcinomas (12);
5. some urothelial carcinomas with trophoblastic differentiation;
6. nested carcinoma (13):
7. spindle cell carcinomas.

For staging, TNM 2002/2009 (6^{th} or 7^{th} edition) is recommended (both editions are identical for bladder cancer). The pattern of muscular invasion can provide some prognostic information. Most cases show nodular or cordonal growth, but about 44% have an infiltrative pattern. According to some authors (9), the median survival time of a patient with an infiltrative pattern is lower than that for an individual with other pattern types ($p = 0.06$). Blood vessel invasion and lymph node infiltration have an independent prognostic significance (14). It seems that the pN category is closely related to the number of lymph nodes studied by the pathologist (15). For this reason, some authors have observed that more than nine lymph nodes have to be investigated to reflect pN0 appropriately (16).

New prognostic markers are under study (17). Currently, insufficient evidence exists to recommend the standard use of the prognostic marker p53 in high-risk muscle-invasive disease, as it will not yield sufficient data upon which to base treatment in an individual patient.

3.3.4 ***Recommendations for the assessment of tumour specimens***

Mandatory evaluations
Depth of invasion (categories pT2 vs pT3a, pT3b or pT4);
Margins with special attention paid to the radial margin, prostate, ureter, urethra and peritoneal fat;
Histological subtype, if it has clinical implications;
Extensive lymph node representation (more than nine);
Optional evaluations
Bladder wall blood vessel invasion;
Pattern of muscle invasion.

4. DIAGNOSIS AND STAGING

4.1 Primary diagnosis

4.1.1 Symptoms

Painless haematuria is a common finding. In addition, some patients complain of urgency, dysuria, increased frequency and pelvic pain. Pelvic pain and all the symptoms related to urinary tract obstruction are found in more advanced tumours.

4.1.2 Physical examination

Physical examination should include rectal and vaginal bimanual palpation. A palpable pelvic mass can be found in patients with locally advanced tumours. In addition, bimanual examination should be carried out before and after TUR to assess whether there is a palpable mass or if the tumour is fixed to the pelvic wall (1,2).

4.1.3 Bladder imaging

A bladder mass identified by diagnostic imaging such as ultrasonography (US), intravenous urography (IVU), computed tomography (CT) or magnetic resonance (MR) imaging should be confirmed with cystoscopy and histology.

4.1.4 Urinary cytology and urinary markers

Examination of a voided urine or bladder-washing specimen for exfoliated cancer cells has high sensitivity in high-grade tumours (LE: 3). It is therefore useful when a high-grade malignancy or carcinoma *in situ* (CIS) is suspected.

Positive urinary cytology may indicate a urothelial tumour anywhere in the urinary tract from the calix, through the ureters, into the bladder and proximal urethra. Cytological interpretation is user dependent (3). The evaluation can be hampered by low cellular yield, urinary tract infections, stones or intravesical instillations. In experienced hands, however, specificity exceeds 90% (4) (LE: 2b). Cytology should be performed on fresh urine with adequate fixation. Morning urine is not suitable as cytolysis may often be present. No urinary marker is registered specifically for the diagnosis of invasive bladder cancer. However, as most invasive tumours are of high grade the positive predictive value of markers may be greater in this setting (5).

4.1.5 Cystoscopy

The diagnosis of bladder cancer ultimately depends on cystoscopic examination of the bladder and histological evaluation of the resected tissue. In general, cystoscopy is initially performed in the office, using flexible instruments. If a bladder tumour has been visualised unequivocally in earlier imaging studies, such as CT, MR imaging, or US, a diagnostic cystoscopy may be omitted as the patient will undergo TUR for a histological diagnosis.

A careful description of the finding is necessary. It should include documentation of the site, size, number, and appearance (papillary or solid) of the tumours as well as a description of mucosal abnormalities. Use of a bladder diagram is recommended.

The use of Photodynamic Diagnosis could be considered, especially if a T1 high grade tumour is present, in order to find associated CIS. The additional presence of a CIS could lead to a more aggressive treatment plan (*see* also section 5.1). Photodynamic Diagnosis has proven a great sensitivity for the detection of CIS and in experienced hands the rate of false positives may not be higher than seen in regular white light cystoscopy (6).

4.1.6 Transurethral resection (TUR) of invasive bladder tumours

The goal of TUR is to enable a correct diagnosis by the pathologist, which means including bladder muscle in the adequately sized resection biopsies.

The strategy of resection depends on the size of the lesion. Small tumours (less than 1 cm) can be resected en bloc, where the specimen contains the complete tumour plus a part of the underlying bladder wall including bladder muscle. Larger tumours have to be resected separately in fractions, which include the exophytic part of the tumour, the underlying bladder wall with the detrusor muscle and the edges of the resection area. At least the deeper part of the resection specimen must be referred to the pathologist in a separate labelled container to enable him to make a correct diagnosis. Cauterisation has to be avoided as much as possible during the resection to prevent tissue destruction. In case Photodynamic Diagnosis is used, fluorescing areas should be biopsied in order to detect primary or associated CIS lesions. Fluorescence endoscopy should not be used in the first 6 weeks after any instillation therapy due to a higher rate of false positive results.

*4.1.7 **Random bladder and (prostatic) urethral biopsy***

Bladder tumours are often multifocal. Moreover tumours can be accompanied by CIS or dysplasia. These lesions may present themselves as velvet-like, reddish areas, indistinguishable from inflammation, or may be not visible at all.

The biopsies from normal-looking mucosa in patients with invasive bladder tumours, so-called random biopsies (R-biopsies) show a low yield (7). Fluorescence cystoscopy is performed using filtered blue light after intravesical instillation of a photosensitiser initially experimentally 5-aminolevulinic acid (5-ALA) and lately after approval by the EMA hexaminolaevulinate (HAL). It has been confirmed that fluorescence-guided biopsy and resection are more sensitive than conventional procedures in detecting malignant tumours, particularly CIS (8-11) (LE: 2a). However, false-positive results may be induced by inflammation, recent TUR or intravesical instillation therapy. A recent multicentre, prospective, international trial showed that in experienced hands the rate of false positives is not higher than seen in regular white light cystoscopy (6). Material obtained by random or directed biopsies must be sent for pathological assessment in separate containers.

The involvement of the prostatic urethra and ducts in male patients with bladder tumours has been reported. Although the exact risk is not known, it seems to be higher if the tumour is located on the trigone or bladder neck, in the presence of bladder CIS and in multiple tumours (12,13) (LE: 3). Identification of involvement of the prostatic urethra can be determined either at the time of primary TUR or by frozen section during the cystoprostatectomy procedure. Although a frozen section has a higher negative predictive value and is more accurate, neither technique is 100% sensitive (14-16).

*4.1.8 **Second resection***

There is a significant risk of residual tumour after the initial TUR (17,18) (LE: 1). Persistent disease was observed in 33-53% of patients (18-24). Moreover, the tumour may be understaged by the initial resection. There is a 4-25% probability that tumours initially staged as being of a lower stage are in fact muscle-invasive (19,20). Correct staging is extremely important since it will directly affect the treatment modality. A second TUR should always be performed when the initial resection has been incomplete, e.g. when multiple and/or large tumours are present, or when the pathologist has reported that the specimen contained no muscle tissue. Furthermore, a second TUR should be performed when a high-grade, non-muscle-invasive tumour or a T1 tumour has been detected at the initial TUR. There is no consensus about the strategy and timing of a second TUR. Most authors recommend resection at 2-6 weeks after the initial TUR. The procedure should include a resection of the primary tumour site.

*4.1.9 **Concomitant prostate cancer***

Ruling out progressive prostate cancer should be considered since 25-46% of patients submitted to cystectomy for bladder cancer (25,26) appear to have prostate cancer on final pathology. Unless the entire prostate is to be removed during cystectomy, any type of prostate cancer should be excluded.

*4.1.10 **Specific recommendations for primary assessment of presumably invasive bladder tumours***

(For general information on the assessment of bladder tumours, see EAU Guidelines on Non-muscle-invasive Bladder cancer)

Recommendations	GR
Cystoscopy should describe all macroscopic features of the tumour (site, size, number and appearance) and mucosal abnormalities. A bladder diagram is recommended.	C
Biopsy of the prostatic urethra is recommended for cases of bladder neck tumour, when bladder CIS is present or suspected, when there is positive cytology without evidence of tumour in the bladder, or when abnormalities of the prostatic urethra are visible. If biopsy is not performed during the initial procedure, it should be completed at the time of the second resection.	C
In women undergoing a subsequent orthotopic neobladder, procedure information is required (including a histological evaluation) of the bladder neck and urethral margin, either prior to, or at the time of cystoscopy.	C
The pathological report should specify the grade, the depth of tumour invasion and whether the lamina propria and muscle tissue are present in the specimen.	C

4.2 Imaging for staging in verified bladder tumours

Imaging is indicated only if there is a clinical consequence. The treatment and prognosis for invasive bladder cancer is determined by tumour stage and grade (27). Tumour staging must be accurate for selecting the

correct treatment in clinical practice. The use of CT and MR imaging has largely replaced other imaging modalities for staging of invasive bladder cancer.

The purpose of imaging for staging invasive bladder cancer is to:

- Assess the extent of local tumour invasion;
- Detect tumour spread to lymph nodes;
- Detect tumour spread to the upper urinary tract and other distant organs (liver, lung, bones, peritoneum, pleura, adrenal gland and others).

*4.2.1 **Local staging of invasive bladder cancer***

Both CT and MR imaging may be used for assessment of local invasion but they are unable to detect microscopic invasion of perivesical fat (T3a) (28). The aim of CT and MR imaging is therefore to detect T3b disease, or higher.

4.2.1.1 MR imaging for local staging of invasive bladder cancer

Magnetic resonance imaging has superior soft tissue contrast resolution compared with CT, but poorer spatial resolution. In studies performed before the availability of CT imaging, MR imaging was reported to be more accurate for local assessment. The accuracy of MR imaging for primary tumour staging varies from 73% to 96% (mean 85%). These values were 10-33% (mean 19%) higher than those obtained with CT (29).

Fast dynamic contrast-enhanced MR imaging helps to differentiate bladder tumour from surrounding tissues because enhancement of the tumour occurs earlier than the normal bladder wall due to neovascularisation (30,31). Fast dynamic MR imaging with images acquired at one image per second helps to distinguish tumour from post-biopsy reaction (30).

In 2006 a link between gadolinium-based contrast agents (Gd-CA) and nephrogenic systemic fibrosis (NSF) was established. NSF may result in a fatal or debilitating systemic fibrosis. Patients with impaired renal function are at risk of developing NSF. For this group of patients, non-ionic linear Gd-CAs should be avoided (gadodiamide, gadopentetate dimeglumine, and gadoversetamide) and a stable macrocyclic contrast agent used (gadobutrol, gadoterate meglumine, or gadoteridol). Alternatively, contrast enhanced CT could be performed using iodinated contrast media (32) (LE: 4).

4.2.1.2 CT imaging for local staging of invasive bladder cancer

The advantages of CT include shorter acquisition time, wider coverage in a single breath hold, and lower susceptibility to various patient factors.

Computed tomography imaging is unable to differentiate between stages Ta to T3a, but it is useful clinically for detecting invasion into the perivesical fat (T3b) and adjacent organs. The accuracy of CT in determining extravesical tumour extension varies from 55% to 92% (33) and increases with more advanced disease (34).

*4.2.2 **Imaging of nodal involvement***

The assessment of nodal status based simply on size is limited by the inability of both CT and MR imaging to identify metastases in normal sized or minimally enlarged nodes. Sensitivities for detection of lymph node metastases are low, ranging from 48% to 87%. Specificities are also low as nodal enlargement may be due to benign pathology. Overall, the results of CT and MR imaging for detection of lymph node metastases in a variety of primary pelvic tumours are similar (35-40). Pelvic nodes greater than 8 mm and abdominal nodes greater than 10 mm in maximum short axis diameter (MSAD) should be regarded as enlarged on CT and MR imaging (41,42).

Currently there is no evidence supporting routine use of positron emission tomography (PET) CT in nodal staging of bladder cancer, although the method has been evaluated with varying results in small prospective trials (43,44).

*4.2.3 **Extravesical urothelial carcinoma***

Computed tomography urography is the preferred imaging modality for the diagnosis and staging of upper urinary tract and bladder cancer (45,46). Computed tomography urography has a higher diagnostic accuracy for urothelial cancers compared to IVU (LE: 2b). For UUT-UCC detected by CT urography, a biopsy for histopathological confirmation of diagnosis is recommended to eliminate false-positive results. (47-50).

*4.2.4 **Distant metastases other than lymph nodes***

Prior to any treatment aimed at cure, it is essential to evaluate the presence of distant metastases. CT and

MR imaging are the diagnostic tools of choice to detect metastases to lung and liver. Metastases to bones or brain at presentation of invasive bladder cancer are rare. Bone scan and additional brain imaging are therefore not routinely indicated unless the patient has specific symptoms or signs to suggest bone or brain metastases (51,52. MR imaging is more sensitive and specific for diagnosing bone metastases than bone scintigraphy (53,54) (LE: 2b).

*4.2.5 **Conclusions and recommendations for staging of verified bladder tumour***

Conclusions	**LE**
Imaging is used for formal staging only if it will make a difference to the selection of treatment options.	
Magnetic resonance (MR) imaging has some advantages over computed tomography (CT) for local staging, without being able to guide future treatment in most cases.	
If the patient is evaluated for radical treatment, multidetector computed tomography (CT) due to its higher specificity may be equivalent to magnetic resonance (MR) imaging regarding local staging.	
A positron emission tomography computed tomography (PET/CT) examination does not offer additional information but this is still under investigation.	

Recommendations	**GR**
Computed tomography or magnetic resonance imaging is recommended if there is suspicion of locally advanced or metastatic disease precluding radical treatment.	
In patients considered eligible for radical treatment, for optimal T-staging, either MR imaging with fast dynamic contrast-enhancement or multidetector computed tomography (CT) with contrast enhancement are recommended.	B
In patients with confirmed muscle-invasive bladder cancer, computed tomography (CT) of the chest, abdomen and pelvis is the optimal form of staging, including CT urography for complete examination of the upper urinary tracts. If CT is not available, lesser alternatives are excretory urography and a chest X-ray.	B
In patients with a verified muscle invasive lesion (TUR), abdominal pelvis and chest imaging is mandatory. MR imaging and CT are equivalent in diagnosing local and distant abdominal metastases.	C
Computed tomography (CT) is preferred to magnetic resonance (MR) imaging for the detection of pulmonary metastases.	C

5. TREATMENT FAILURE OF NON-MUSCLE INVASIVE BLADDER CANCER

5.1 High-risk non-muscle-invasive urothelial carcinoma

The recurrence and progression rate of NMIBC is strongly associated with tumour grade and invasion into the lamina propria. The progression to T2 tumours varies from 6% to 25% in Ta and from 27% to 48% in T1 tumours of all grades. Inter- and intra-observer varying abilities in grading as well as staging and completeness of TUR are key variables confounding the results of present long-term studies of TUR, with or without intravesical therapy.

The understaging error in TaT1 tumours of 35% to 62% presented in large cystectomy series is due to the presence of recurrent tumours of largely unknown pre-cystectomy therapy and the lack of a second TUR (1-3) (LE: 3). The latter identifies 24% to 49% T2 tumours diagnosed initially as non-muscle-invasive tumours (4,5) (LE: 3). However, in spite of these disadvantages, recent meta-analyses have shown that intravesical therapy with Bacillus Calmette-Guérin (BCG) maintenance therapy prevents recurrence (6,7), but not progression. So far, no significant overall- or disease-specific survival advantages have been proven compared to no intravesical therapy (8-10) (LE: 1).

The disease progression rate is low in patients with small tumours (< 3 cm) and without associated CIS. Twenty per cent of patients progress within 5 years, with approximately 90% of patients keeping their intact bladder during follow-up of up to 10 years (11) (LE: 2). However, in a recently published prospective multicentre trial, the progression rate was significantly lower than previously reported, even when the presence of concomitant CIS was considered. This was probably due to the combination of a second resection prior to inclusion in the trial and maintenance treatment as part of the protocol (12) (LE: 1b).

Initial cystectomy can be considered based on tumour multiplicity, size, concomitant *in situ* cancer, and urothelial tumour of the prostatic urethra (13) (GR: C). Although the percentage of patients with primary TaT1 tumours and the indication for cystectomy in TaT1 tumours is not specified in large cystectomy series, the 10-year recurrence-free survival is approximately 80% and similar to TUR and BCG maintenance therapy (1,3,14,15) (LE: 3). In case of recurrent TaT1, mostly associated with CIS, the understaging at time of cystectomy is 34%, but the 10-year survival is not significantly different for patients with pT1 and pT2 tumours (16) (LE: 3). This is in contrast to an earlier report indicating a significant worse outcome for patients with previous TUR(s) (17) (LE: 3).

Undoubtedly, patients with muscle-invasive recurrence are best treated with radical cystectomy. However, the outcome in terms of presence of lymph node metastases and cancer-free survival may be inferior to patients with the same tumour stage, but who receive radical cystectomy at first presentation (18) (LE: 3).

There is uncertainty about the treatment of patients who develop tumour recurrence in spite of BCG therapy because of different BCG therapy schedules and the absence of a uniform definition of BCG failure. It has been indicated that the recurrence (persistence) of tumour at 9 months in spite of BCG therapy is associated with a 30% chance of invasive tumours and death due to metastatic disease (19) (LE: 3). Solsona, et al. demonstrated that 80% of patients who had persistent disease at 3 months progressed to muscle invasive disease (20) (LE: 3). In addition, adequate tissue sampling from the prostatic urethra is an essential factor in considering the outcome of conservative treatment, since urethral tumours are associated with a significant decrease in tumour-free survival (21) (LE: 3). However, with careful selection and surveillance a durable complete response can be achieved also in patients diagnosed with superficial bladder transitional cell carcinoma involving the prostatic urethra (22). Based on these findings, cystectomy should be performed in appropriate patients at least at 9 months, because additional BCG therapy yields a response rate of only 27% to 51% and of unknown duration (23,24) (GR: C). Salvage chemotherapy is associated with limited response and should not be offered (25,26) (LE: 3).

Patients with disease recurring within 2 years of initial TUR plus BCG therapy have a better outcome than patients who already have muscle-invasive disease indicating that cystectomy should be performed at first recurrence, even in case of non-muscle-invasive disease (18) (LE: 3; GR: C).

5.2 Carcinoma *in situ*

Primary CIS confined to the bladder is treated with intravesical BCG, yielding a complete response rate of 83-93% (27,28) (LE: 2). CIS associated with TaT1 is treated according to the overt tumour.

Approximately 50% of patients develop recurrent disease with muscle invasion or extravesical tumour (27,29) (LE: 2). Between 11% and 21% die of the disease within 5-7 years after an initial complete response (27,30) (LE: 2). Non-responders or incomplete responders have a significant risk of tumour progression of 33% to 67% (20,31) (LE: 2).

The current guidelines on non-muscle-invasive bladder cancer define BCG failure as:

a. Whenever muscle-invasive tumour is detected during follow-up.
b. If high-grade, non-muscle-invasive tumour is present at both 3 and 6 months.

In patients with tumour present at 3 months, an additional BCG course can achieve a complete response in > 50% of cases, both in patients with papillary tumours and CIS but with increasing risk of progression.

5.3 Recommendations for treatment failure of non-muscle-invasive bladder cancer

Recommendations	GR
In all T1 tumours at high risk of progression (i.e. high grade, multifocality, carcinoma *in situ*, and tumour size, as outlined in the EAU guidelines for Non-muscle-invasive bladder cancer [32]), immediate radical cystectomy is an option.	B
In all T1 patients failing intravesical therapy, cystectomy should be performed.	B

6. NEOADJUVANT CHEMOTHERAPY

The standard treatment for patients with muscle-invasive bladder cancer is radical cystectomy. However, this 'gold standard' only provides 5-year survival in about 50% of patients (1-5). In order to improve these unsatisfactory results, the use of peri-operative chemotherapy has been explored since the 1980s. There are many advantages of neoadjuvant chemotherapy, i.e. administering chemotherapy to patients with operable urothelial carcinoma of the urinary bladder before the planned definitive surgery (or radiation), including:

- Chemotherapy is delivered at the earliest time-point, when the burden of micrometastatic disease is expected to be low;
- Potential reflection of in vivo chemosensitivity;
- Tolerability of chemotherapy is expected to be better before cystectomy rather than after;
- Hypothetically patients with micrometastatic disease might respond to neoadjuvant therapy and reveal favourable pathological status determined mainly by negative lymph node status and negative surgical margins.

The disadvantages of neoadjuvant chemotherapy include:

- For clinical staging with CT or MR imaging, over- and under-staging is likely to happen with a staging accuracy of only 70% (6,7). Overtreatment is the possible negative consequence;
- Delayed cystectomy might compromise the outcome in patients not sensitive to chemotherapy (8,9).

The side-effects of neoadjuvant chemotherapy affecting outcome of surgical morbidity need to be considered. In one randomised trial (10), the same distribution of post-operative complications grade 3-4 was seen in both trial arms (10). However, generally, pre-operative anaemia and neuropathy was more common in the chemotherapy group. In the combined Nordic trials NCS1+NCS2, (n = 620), neoadjuvant chemotherapy did not have any major adverse effect on the percentage of performable cystectomies. In the intention-to-treat analysis, the cystectomy-frequency was 86% in the experimental arm and 87% in the control arm. Still, in crude figures, 218 of 306 experimental and cystectomised patients received all 3 chemotherapy cycles (71%). Further 23 patients 1 or 2 cycles and 3 patients with greater than 25% dose reduction of cisplatin, translating into 78% receiving any neoadjuvant treatment (11).

Several randomised phase III trials investigated the question of whether or not neoadjuvant chemotherapy improved survival, with conflicting results (12-28). Most patients were ≤ 70 years old, had a performance status (PS) of 0-1 and a creatinine clearance of > 50-60 mL/minute, due to the kind of chemotherapy (single-agent cisplatin or cisplatin combination chemotherapy) scheduled.

Differences in trial design were mainly the type of chemotherapy (i.e. single-agent cisplatin or combination chemotherapy) and the number of cycles planned. From the statistical point of view, the studies differed in size, patient characteristics (e.g. clinical T-stages included), and the kind of definitive treatment allowed (cystectomy or radiotherapy or both).

Because of the lack of clarity, even though a considerable number of randomised trials had been performed, three meta-analyses were undertaken to answer the very important question of whether or not neoadjuvant chemotherapy prolongs survival (29-31).

- The first meta-analysis, published in 2003 (29), included 10 randomised trials (except for results of the INT 0080-study [20]) and showed a 13% reduction in the risk of death, equivalent to 5% absolute benefit at 5 years (increased overall survival from 45% to 50%).
- The second meta-analysis, published in 2004 (30), included 11 of 16 randomised trials with overall survival data of 2,605 patients. A statistically significant decrease in the risk of death (10%) was seen, corresponding to an absolute improvement in overall survival of 5% (from 50% to 55%).
- In the most recent meta-analysis, published in 2005 (32), with updated independent patient data of 11 randomised trials (3,005 patients), a statistically significant survival benefit in favour of neoadjuvant chemotherapy was also seen. The results of this analysis confirmed the previously published data and showed 5% absolute improvement in survival at 5 years. The Nordic combined trial showed an absolute benefit of 8% in survival at 5 years and 11% in the clinical T3 subgroup, translating into nine patients needed to treat (11). Of note, only cisplatin combination chemotherapy with at least one additional chemotherapeutic agent resulted in a meaningful benefit (29,31); the regimens tested were MVA(E)C, CMV, CM, cisplatin/adriamycin, cisplatin/5-fluorouracil (5-FU), and CarboMV. To date, it is unknown if more modern chemotherapy regimens are as effective.

The presence of micrometastases is postulated to be lower in smaller tumours (T2) compared to more extensive tumours (T3b-T4b). T4 stage tumours are prone to a higher degree of clinical understaging because macrometastic nodal deposits are detected more often in post-cystectomy specimens of these extensive tumours (32). Further data is in support of neoadjuvant chemotherapy in the subgroup of T2b-T3b tumours (former classification T3), which has been shown to provide a modest but substantial improvement in long-term survival and significant downstaging.

6.1 Conclusions and recommendations for neoadjuvant chemotherapy

Conclusions	LE
Neoadjuvant cisplatin-containing combination chemotherapy improves overall survival, irrespective of the type of definitive treatment used.	1a
Neoadjuvant chemotherapy has its limitations regarding patient selection, current development of surgical technique, and current chemotherapy combinations.	

Recommendations	GR
Neoadjuvant chemotherapy should always be cisplatinum based.	A
Neoadjuvant chemotherapy is not recommended in patients with PS $\geq$ 2 and/or impaired renal function.	B

7. RADICAL SURGERY AND URINARY DIVERSION

7.1 Removal of the tumour-bearing bladder

*7.1.1 **Background***

Radical cystectomy is the standard treatment for localised muscle-invasive bladder cancer in most countries of the Western Hemisphere (1,2). New interest in quality-of-life issues has increased the trend toward bladder preservation treatment modalities, like radio- and/or chemotherapy (*see* Chapters 9 and 10). Performance status and age influence the choice of primary therapy, as well as type of urinary diversion with cystectomy being reserved for younger patients without concomitant disease and better performance status. The value of assessing overall health before recommending and proceeding with surgery was emphasised in a recent multivariate analysis, which demonstrated an association between co-morbid disease and adverse pathological and survival outcome following radical cystectomy (3).

There is still controversy about age, radical cystectomy and the type of urinary diversion. Cystectomy is associated with the greatest risk reduction in disease-related and non-disease related death in patients older than 80 years (3). The largest retrospective single-institution study on cystectomy to date demonstrated that patients above 80 years did have an increased postoperative morbidity but not an increased mortality. Some patients even successfully underwent a neobladder procedure in this group, but the majority of patients were treated with an ileal conduit diversion (4).

*7.1.2 **Timing and delay of cystectomy***

In a retrospective series of 153 patients with a clear indication for radical surgery of locally advanced bladder cancer, a delay of treatment beyond 90 days of primary diagnosis caused a significant increase in extravesical disease (81 vs 52%) (5).

The delay of cystectomy not only affects the outcome but also the type of urinary diversion. In organ-confined urothelial cancer of the bladder the average time from the primary diagnosis to cystectomy was 12.2

months in neobladder and 19.1 months in ileal conduit patients. It was even more striking for those patients who had an organ-confined invasive cancer diagnosed; in neobladder patients the average time to surgery was 3.1 and in ileal conduit patients 15.1 months (6). Similar results have been observed in a series of 247 patients where superior recurrence-free survival and overall survival was significantly better in those treated within the 90 day period compared to others who were treated after a longer period (7).

7.1.3 ***Indications***

Traditionally radical cystectomy is recommended for patients with muscle-invasive bladder cancer T2-T4a, N0-Nx, M0 (1). Other indications include high-risk and recurrent superficial tumours, BCG-resistant Tis, T1G3 (*see* Chapter 5), as well as extensive papillary disease that cannot be controlled with TUR and intravesical therapy alone.

Salvage cystectomy is indicated for non-responders to conservative therapy, recurrences after bladder sparing treatments, non-urothelial carcinomas (these tumours respond poorly to chemo- and radiotherapy) and as a purely palliative intervention for e.g. fistula formation, pain or recurrent macrohaematuria (*see* Section 8.1 Palliative cystectomy).

7.1.4 ***Technique and extent***

Radical cystectomy includes the removal of the bladder and adjacent organs, that is prostate and seminal vesicles in men, and uterus and adnexa in women (8). The inclusion of the entire prostate in male patients, and the extent of urethrectomy and vaginal resection in female patients, however, has recently been questioned (9,10).

Various techniques of partial prostate-sparing cystoprostatectomy in male patients with localized tumours have been proposed and results of series with a longer follow-up have been published (11-13). A randomised study comparing patients with and without remnant portions of the prostate is lacking and will be difficult to perform. Autopsy studies as well as studies looking at the unsuspected incidence of prostate cancer in cystoprostatectomy specimens suggest that in approximately 23-54% of patients a prostate cancer is found in the cystoprostatectomy specimen. Up to twenty-nine percent of these cancers may be clinically significant, locally recurrent or even metastatic in patients with prostatic tissue preserving radical cystectomy (14-16).

Furthermore urothelial cancer in the prostate was detected in 32 and 33% (69/240 cases and 77/235 cases, resp.) of patients undergoing radical cystoprostatectomy (15,17). In another study 50/121 of the cystoprostatectomy specimens (41%) removed for urothelial cancer had unsuspected prostate cancer. Twenty-four of these 50 tumours (48%) were clinically significant. In the same study 58/121 patients (48%) had urothelial carcinoma in the prostate of which 19 (33%) had apical involvement (18). Overall in the above mentioned series only 26 to 33% of the patients undergoing cystoprostatectomy for bladder cancer had neither prostate cancer nor prostatic urothelial cancer in the specimen.

However, by individualising the indication to spare seminal vesicles and the prostatic capsule in a group of 31 patients the oncological risk was small with a high probability of preserving potency (19).

Radical cystectomy also includes the dissection of regional lymph nodes. There is substantial data on the extent of lymphadenectomy. However, controversies in evaluating the clinical significant of lymphadenectomy relates to two main aspects of nodal dissection; postulated therapeutic procedure and/or staging instrument.

More recently, it has been attempted to categorize the extent of lymphadenectomy. A standard lymphadenectomy in bladder cancer patients involves the removal of all nodal tissue cranially up to, and including, the common iliac bifurcation with the ureter being the medial border and including the internal iliac, presacral, obturator fossa and external iliac nodes (20). An extended lymphadenectomy includes all lymph nodes in the region of the aortic bifurcation and common iliac vessels medially to the crossing ureters. The lateral boarders are the genitofemoral nerves, caudally the circumflex iliac vein, the ligamentum lacunare and the lymph node of Cloquet in addition to the area described in the standard lymphadenectomy (21-23).

A recent study comparing the results of a high volume centre performing mainly a standard lymphadenectomy vs. a high volume centre performing an extended pelvic lymph node dissection in patients undergoing radical cystectomy revealed that there was no difference with regards to overall survival and recurrence (24) although the mean number of lymph nodes was 22 in one institution and 38 in the other institution. In another study looking at the SEER data did show a survival benefit in patients with the removal of more than 10 lymph nodes in patients with lymph node metastasis (25). It seems clear, however, that a more limited field of lymph node dissection in the pelvis than the standard lymphadenectomy as outlined above is associated with suboptimal staging and also with a poorer outcome for patients both with node positive and node negative disease (26,27).

There are several localisation studies with regards to lymphadenectomy (28-33) which demonstrated both

retrospectively and prospectively that metastatic lymph nodes in bladder cancer patients are not found outside the pelvis if the pelvic lymph nodes are free of tumour.

An accurate anatomic assignment of removed lymph nodes is sometimes difficult and varies with different surgeons.

In the only autopsy investigation yet performed, it was shown that in 215 patients with nodal dissemination, the frequency of metastasis was 92% in regional (perivesical or pelvic), 72% in retroperitoneal, and 35% in abdominal lymph nodes. There was also a significant correlation between nodal metastases and concomitant distant metastases ($p < 0.0001$). Approximately 47% of the patients had both nodal metastases and distant dissemination and only 12% of the patients had nodal dissemination as sole metastatic manifestation (34). It has been suggested that progression free survival as well as overall survival might be correlated with the amount of lymph nodes removed during surgery. Removal of more than 10-15 lymph nodes has been postulated to be both sufficient for the evaluation of the lymph node status as well as being beneficial for overall survival in retrospective studies (25,33,35). No evidence exists of a minimum number of lymph nodes on the contrary to other cancers. Nevertheless the probability of survival increases with the number of dissected lymph nodes (36).

Inter-individual differences in the number of pelvic and retroperitoneal lymph nodes and difficulties in processing of the removed tissue by pathologists were not taken into account in these studies (37-39).

A distal ureteral segment (length not specified) should be resected and in case of bladder CIS a frozen section for evaluation of the surgical margins should be performed (8,40). Urethrectomy is recommended if there are positive margins at the level of urethral dissection, positive margins anywhere on the bladder specimen (in both sexes), if the primary tumour is located at the bladder neck or in the urethra (in women), or if tumour extensively infiltrates the prostate (1,41,42).

*7.1.5 **Laparoscopic/robotic-assisted laparoscopic cystectomy (RALC)***

Laparoscopic cystectomy and RALC have been shown to be feasible both in male and female patients (43,44). Both cystectomy and lymphadenectomy have been done in small series, according to the same principles used in cystectomy and anterior exenteration for several decades now (45). However, these techniques are still experimental because of the limited number of cases reported, an absence of long-term oncological and functional outcome data, and a possible selection bias (46,47).

Laparoscopic intracorporeal construction of urinary diversion with or without robotic assistance has been tested in small series only (46,48,49). It is a challenging and lengthy procedure with the current technical equipment available and must therefore be regarded as experimental. Laparoscopic cystectomy and pelvic lymphadenectomy (with or without robotic assistance), with extracorporeal construction of urinary diversion, is an option for surgical treatment (LE: 3).

7.2 Urinary diversion after radical cystectomy

From an anatomical standpoint three alternatives are presently used after cystectomy:

- Abdominal diversion such as uretherocutaneostomy, ileal or colonic conduit, and various forms of a continent pouch.
- Urethral diversion which includes various forms of gastrointestinal pouches attached to the urethra as a continent, orthotopic urinary diversion (neobladder, orthotopic bladder substitution).
- Rectosigmoid diversions, such as uretero(ileo-)rectostomy.

Different types of segments of the intestinal tract have been used to reconstruct the urinary tract, including the stomach, ileum, colon, and the appendix (50). Several studies have compared certain aspects of health-related quality of life, such as sexual function, urinary continence and body image, in patient cohorts with different types of urinary diversion. However, further research is needed on pre-operative tumour stage and functional situation, socio-economic status, time interval to primary surgery, etc.

*7.2.1 **Preparations for surgery***

For cystectomy, general preparations are necessary as for any other major pelvic and abdominal surgery. If the urinary diversion is constructed from gastrointestinal segments, the length or size of the respective segments and their pathophysiology when storing urine must be considered (51). Despite the necessary interruption and re-anastomosis of bowel, a formal bowel preparation may not be necessary (52). Furthermore, bowel recovery time has been reduced by the use of early mobilisation, early oralisation and gastrointestinal stimulation with metoclopramide and chewing gum (53).

Patients undergoing continent urinary diversion have to be motivated both to learn about their diversion and

to be manually skilful in manipulating their diversion. Contra-indications to more complex forms of urinary diversion include:

- Debilitating neurological and psychiatric illnesses.
- Limited life expectancy.
- Impaired liver or renal function.
- Transitional cell carcinoma of the urethral margin or other surgical margins.

Relative contraindications specific for an orthotopic neobladder are high-dose preoperative radiation therapy, complex urethral stricture disease, and severe urethral sphincter-related incontinence (54-56).

7.2.2 ***Ureterocutaneostomy***

Ureteral diversion to the abdominal wall is the simplest form of cutaneous diversion. It is considered as a safe procedure. It is therefore preferred in older, or otherwise compromised, patients, who need a supravesical diversion (57,58). However, others have demonstrated that, in carefully selected elderly patients, all other forms of wet and dry urinary diversions, including orthotopic bladder substitutions, are possible (4).

Technically either one ureter to which the other shorter one is attached end-to-side is connected to the skin (transuretero-ureterocutaneostomy) or both ureters are directly anastomosed to the skin. Due to the smaller diameter of the ureters, stoma stenosis has been observed more often than in intestinal stomas (57).

In a recent retrospective comparison with short or median follow-up of 16 months the diversion-related complication rate was considerably lower for ureterocutaneostomy compared to an ileal or colon conduit (59). Despite the limited comparative data available it has to be taken into consideration however, that older data and clinical experience suggest stricturing on skin level and ascending urinary tract infection are more frequent complications as compared to ileal conduit. In a retrospective study comparing various forms of intestinal diversion, ileal conduits had fewer late complications than continent abdominal pouches or orthotopic neobladders (60).

7.2.3 ***Ileal conduit***

The ileal conduit is still an established option with well-known/predictable results. However, up to 48% of the patients develop early complications including urinary tract infections, pyelonephritis, uretero-ileal leakage and stenosis (60). The main complications in long-term follow-up studies are stomal complications in up to 24% of cases and functional and/or morphological changes of the upper urinary tract in up to 30% (61-63). An increase in complications was seen with increased follow-up in the Berne series of 131 patients followed for a minimum of 5 years (median follow-up 98 months) (61): the rate of complications increased from 45% at 5 years to 94% in those surviving longer than 15 years. In the latter group, 50% and 38% of the patients developed upper urinary tract changes and urolithiasis, respectively.

7.2.4 ***Continent cutaneous urinary diversion***

A low-pressure detubularised ileal reservoir can be used as a continent cutaneous urinary diversion for selfcatheterisation; gastric, ileocecal and sigma pouches have also been described (64-66). Different antireflux techniques can be used (8). Most patients have a well-functioning reservoir with daytime and night time continence approaching 93% (67). A stomal stenosis in 23.5% of patients with appendix stoma and 15% with an efferent intussuscepted ileal nipple was observed in a study reviewing retrospectively the results of more than 800 patients. Stone formation in the pouch occurred in 10% of patients (67-69). In a small series of previously irradiated female patients incontinence and stomal stenosis was 18% (8/44 patients) (70).

7.2.5 ***Ureterocolonic diversion***

The oldest and most common form was primarily a refluxive and later an antirefluxive connection of ureters into the intact rectosigmoideum (uretero[recto]sigmoidostomy) (71,72). Most of the indications for this procedure have become obsolete due to a high incidence of upper urinary tract infections and the long-term risk of developing colon cancer (73,74). Bowel frequency and urge incontinence were additional side-effects of this type of urinary diversion. However, it may be possible to circumvent the above-mentioned problems by interposing a segment of ileum between ureters and rectum or sigmoid in order to augment capacity and to avoid a direct interaction between urothelium, colonic mucosa, together with faeces and urine (75).

7.2.6 ***Orthotopic neobladder***

An orthotopic bladder substitution to the urethra is now commonly used both in men and women. Contemporary reports document the safety and long-term reliability of this procedure. In several large centres, this has become the diversion of choice for most patients undergoing cystectomy (1,56,76). In elderly patients

(> 80 years), however, it is very rarely performed, even in high-volume expert centres (77,78).

The terminal ileum is the gastrointestinal segment most often used for bladder substitution and there is less experience with ascending colon, including caecum, and the sigmoid (1). The emptying of the reservoir anastomosed to the urethra requires abdominal straining, intestinal peristalsis and sphincter relaxation. Early and late morbidity in up to 22% of the patients is reported (79,80). Long-term complications include diurnal (8-10%) and nocturnal incontinence (20-30%), ureterointestinal stenosis (3-18%), urinary retention (4-12%) both in males and female patients, metabolic disorders and vitamin B12 deficiency in series with 1,054 and more than 1,300 patients (56,81). In a recent study, which compared cancer control and patterns of disease recurrence in neobladder and conduit patients, no cancer-specific survival difference could be identified between the two groups when adjusting for pathological stage (82). Urethral recurrence in neobladder patients seems rare (1.5-7% for both male and female patients) (56,83). These results indicate that the choice of a neobladder both in male and female patients does not compromise the oncological outcome of cystectomy. It remains debatable whether a neobladder is better for quality of life compared to a non-continent urinary diversion (84-86).

Various forms of upper tract reflux protection, including a simple isoperistaltic tunnel, an ileal intussusception, a tapered ileal prolongation implanted subserosally, and a direct (sub)mucosal or subserosal ureteral implantation, have been described (69,80). According to the reported long-term results, the upper urinary tract is protected sufficiently by either method.

In conclusion, standard radical cystectomy in male patients with bladder neoplasms includes removal of the entire bladder, prostate, seminal vesicles, distal ureters (length of the segment undefined), and corresponding lymph nodes (extent undefined) (LE: 2b). Currently, it is not possible to recommend a particular type of urinary diversion. However, most institutions will prefer ileal orthotopic neobladders and ileal conduits based on clinical experience (9,87). In selected patients, ureterocutaneostomy is surgically the least-burdensome type of diversion (LE: 3). Recommendations related to radical cystectomy and urinary diversions are listed in section 7.6.2.

7.3 Morbidity and mortality

In a recent comprehensive long-term study (n = 1054), peri-operative mortality was reported in 3% of cases, and early complications, defined as any complication within 3 months of surgery, in 28% (76,81). Late morbidity is usually due to the type of urinary diversion (see above). Early morbidity associated with radical cystectomy for NMIBC (at high risk for disease progression) is similar and not less than that associated with muscle-invasive tumours (88). In general, a lower morbidity and mortality has been observed by surgeons and by hospitals with a higher case load and therefore more experience (89).

7.4 Survival

Research findings have demonstrated good survival outcomes:

- According to a multi-institutional database of 888 consecutive patients undergoing cystectomy and lymphadenectomy for bladder cancer, the outcome at 5 years was 58% for a mean recurrence-free survival and 66% for bladder cancer-specific survival (90).
- The recurrence-free and overall survival in a large single centre study of 1,054 male and female patients was 68% and 66% at 5 years and 60% and 43%, at 10 years, respectively (2).
- In node-positive patients, 10-year disease-specific and overall survival rates in another study have been reported to be 27.7% and 20.9%, respectively (91). In this cohort, 10-year disease-specific and overall survival rates were 72.9% versus 49.1% for organ-confined disease (defined as ≤ pT3a), and 33.3% versus 22.8% for non-organ-confined disease (91).
- In another study, 5-year recurrence-free survival was 76% in patients with pT1 tumours, 74% for pT2, 52% in pT3, and 36% in pT4 tumours (92). Tumour stage and nodal involvement are the only independent predictors of survival (93).

7.5 Conclusions on urinary diversion after radical cystectomy

Conclusions	LE
For muscle-invasive bladder cancer radical cystectomy is the curative treatment of choice.	3
A higher case load reduces morbidity and mortality of cystectomy.	3
Radical cystectomy includes removal of regional lymph nodes, the anatomical extent of which has not been sufficiently defined.	3
Radical cystectomy in both sexes must not include the removal of the entire urethra in all cases, which may then serve as outlet for an orthotopic bladder substitution.	3
Terminal ileum and colon are the intestinal segments of choice for urinary diversion.	3
The type of urinary diversion does not affect oncological outcome.	3
Laparoscopic and robotic-assisted laparoscopic cystectomy is feasible but still investigational.	3
In patients with invasive bladder cancer older than 80 years cystectomy is an option.	3
Co-morbidity, age, previous treatment for bladder cancer or other pelvic diseases, surgeon and hospital volume of cystectomy, and type of urinary diversion influence surgical outcome.	2
Surgical complications of cystectomy and urinary diversion should be reported in a uniform grading system. Currently, the best-adapted, graded system for cystectomy is the Clavien grading system.	2

7.6 Recommendations for radical cystectomy and urinary diversion

*7.6.1 **Recommendations for radical cystectomy***

Recommendations	GR
Radical cystectomy is recommended in T2-T4a, N0 M0, and high risk non-muscle-invasive BC (as outlined above).	A*
Do not delay cystectomy more than 3 months since it increases the risk of progression and cancer-specific death.	B
Pre-operative radiotherapy is not recommended in case of subsequent cystectomy with urinary diversion.	A
Lymph node dissection should be an integral part of cystectomy, but the extent of the dissection has not been established.	B
The urethra can be preserved if margins are negative. If no bladder substitution is attached, the urethra must be checked regularly.	B
Laparoscopic and robot-assisted laparoscopic cystectomy are both options. However, current data have not sufficiently proven the advantages or disadvantages for both oncological and functional outcomes of laparoscopic and robotic-assisted laparoscopic cystectomy.	C
Before cystectomy, the patient should be fully informed about the benefits and potential risks of all possible alternatives, and the final decision should be based on a balanced discussion between patient and surgeon.	B
Pre-operative bowel preparation is not mandatory, ‘fast track’ measurements may reduce the time of bowel recovery.	C
An orthotopic bladder substitute should be offered to male and female patients lacking any contraindications and who have no tumour in the urethra and at the level of urethral dissection.	B

8. NON-RESECTABLE TUMOURS

8.1 Palliative cystectomy for muscle-invasive bladder carcinoma

For patients with inoperable locally advanced tumours (T4b, invading the pelvic or abdominal wall), radical cystectomy is not usually a therapeutic option (1). Treatment of these patients remains a clinical challenge. These patients are candidates for palliative treatments, such as palliative radiotherapy.

Inoperable locally advanced tumours may be accompanied by several debilitating symptoms, including bleeding, pain, dysuria and urinary obstruction. There are several treatment options for patients with these symptoms. In advanced bladder cancer complicated by bleeding, cystectomy with urinary diversion is the most invasive treatment. It carries the greatest morbidity and should be considered only if there are no other options (1).

In patients with locally advanced pelvic cancer and urinary bladder involvement, palliative radical cystectomy with urinary diversion using intestinal segments is usually performed for the relief of symptoms such as pain, recurrent bleeding, urgency and fistula formation (2).

Zebic, et al. (2005) (3) retrospectively analysed patients aged ≥ 75 years, who had received radical

cystectomies with either curative or palliative intent. The indications for palliative cystectomy were advanced pelvic malignancy with severe irritating voiding symptoms, severe pain and recurrent macrohaematuria requiring blood transfusions (3). Zebic, et al. (2005) concluded that elderly people have a greater risk of peri-operative morbidity and mortality, especially those with very advanced pelvic malignancies, who have undergone palliative cystectomy (3).

Advanced MIBC can be associated with ureteral obstruction. In invasive tumours, the mechanism of ureteral obstruction is probably caused by a combination of mechanical blockage by the tumour and invasion of ureteral orifices by tumour cells interfering with ureteral peristalsis. Bilateral ureteral obstruction, or unilateral obstruction to a solitary functioning kidney, can result in uraemia. Treatment of such patients is still a dilemma. El-Tabey et al. retrospectively reviewed the records of patients who presented with bladder cancer and obstructive uraemia (4). Patients with inoperable locally advanced bladder tumours (23 patients, 37.7%) were treated with permanent nephrostomy tubes to relieve obstruction; radical cystectomy was not an option. Ten patients underwent surgery (26.3%); palliative cystectomy without lymphadenectomy was carried out for advanced nodal involvement in four patients and for locally advanced disease infiltrating the pelvic wall in six patients. In all 10 patients, local pelvic recurrence was reported within the first year of follow-up (4).

In another study, post-operative outcome was reported for primary radical cystectomy in 20 T4 bladder cancer patients (of which seven cases were T4b). The authors concluded that primary cystectomy for T4 bladder cancer was technically feasible and had a very tolerable therapy-related morbidity and mortality (5).

8.2 Conclusions and recommendations for non-resectable tumours

Conclusions
Primary radical cystectomy in T4b bladder cancer is not a curative option.
If there are symptoms, radical cystectomy may be a therapeutic/palliative option.
Intestinal or non-intestinal forms of urinary diversion can be used with or without palliative cystectomy.

Recommendations	LE	GR
In patients with inoperable locally advanced tumours (T4b), primary radical cystectomy is a palliatative option and cannot be offered as curative treatment.		B
In patients with symptoms palliative cystectomy may be offered.		
Prior to any further interventions, surgery-related morbidity and quality-of-life should be fully discussed with the patient.	3	B

8.3 Supportive care

Severe, localized problems can occur in patients with invasive, non-operable bladder cancer and those in whom cystectomy has not been performed because of metastatic disease. These problems include pain, bleeding, voiding problems and obstruction of the upper urinary tract (UUT).

Obstruction of the UUT

Unilateral (best kidney) or bilateral nephrostomy tubes provide the easiest solution for UUT obstruction, but patients find the tubes are inconvenient and prefer ureteral stenting. However, stenting can be difficult to achieve and stents must be regularly replaced. There is also the risk of stent obstruction or displacement. Another possible solution is the possibility of a urinary diversion with, or without, a palliative cystectomy.

Bleeding and pain

In the case of bleeding, first screen the patient for coagulation disorders or review the patient's use of anticoagulant drugs. Transurethral (laser) coagulation may be difficult in a bladder full of tumour or with a bleeding tumour. Intravesical rinsing of the bladder with 1% silver nitrate or 1–2% alum can be effective (12), and can usually be done without any form of anaesthesia. The instillation of formalin (2.5–4% during 30 minutes) is a more aggressive and more painful procedure, requiring general or regional anesthesia. Formalin instillation also has a higher risk of side effects, e.g. bladder fibrosis, but is more likely to control the bleeding (13). Vesicoureteral reflux should be excluded to prevent renal complications.

Radiation therapy is another common strategy for control of bleeding, which is also used to control pain. In an older report, haematuria and pain control were 59% and 73%, respectively (14). Irritative bladder and bowel complaints due to irradiation are possible but are usually mild.

Non-conservative options are embolization of specific arteries in the small pelvis, with success rates as high as 90% (15). Radical surgery is a last resort and includes cystectomy and diversion.

9. NEOADJUVANT / ADJUVANT RADIOTHERAPY IN MUSCLE-INVASIVE BLADDER CANCER

Contrary to literature addressing radiotherapy prior to surgical intervention for muscle-invasive bladder cancer, data discussing findings for adjuvant radiotherapy after radical cystectomy are extremely scarce and outdated and relate mostly to non-urothelial cancer only (1). Possibly also due to late gastero-intestinal complications, post-operative radiotherapy has never been widely used. With the availability of equipment allowing for more precise targeting resulting in less damage to surrounding tissue, there may be reason to revisit this option in the future (2,3).

9.1 Pre-operative radiotherapy

*9.1.1 **Retrospective studies***

Several retrospective studies have looked at the effect of pre-operative radiotherapy in patients with bladder cancer.

- The largest retrospective series (n = 526) showed that pre-operative radiotherapy at a dose of 50 Gy resulted in down-staging in 73% of cT3 patients versus 29% of patients who were not given preoperative radiotherapy (4,5). Local control improved from 72% to 91% in pT3b patients (n = 91), but not in pT2 or pT3a patients, while overall survival improved from 40% to 52%.
- The results of a non-randomised study comparing 40 Gy versus 5-20 Gy versus no radiotherapy showed that only 40 Gy pre-operative radiotherapy reduced the risk of local recurrence from 27% to 11% and improved survival from 21% to 63% (6).
- Overall, nearly all retrospective studies of pre-operative radiotherapy at doses of 40-50 Gy, followed after 4-6 weeks by cystectomy, showed (4-12):
  - down-staging of the tumour stage (40-65% of patients)
  - lower risk of local recurrence (10-42%)
  - improved survival (11-12%).
- Some studies showed that an improvement in local control was highest for T3b tumours (5-7).
- Other studies showed that achievement of a pathological complete remission (pCR) was a prognostic factor for survival (6-8).
- One retrospective study (8) found no significant increase in toxicity due to pre-operative radiotherapy (10% versus 3%).

*9.1.2 **Randomised studies***

There have been six published randomised studies investigating pre-operative radiotherapy.

- The largest randomised trial (n = 234 evaluable patients) administered pre-operative radiotherapy at a dose of 45 Gy in fractions of 1.8-2.2 Gy in muscle-invasive tumours. The results showed a significant increase in pCR (9% to 34%) in favour of pre-operative radiotherapy and no significant increase in 5-year survival of 33% to 45% (13). In patients not given adjuvant chemotherapy, survival was significantly better than in patients given pre-operative radiotherapy (25-52%). pCR was a prognostic factor for better survival. A major limitation was the exclusion from the analysis of almost 50% of patients because they did not receive the planned treatment.
- The Southwest Oncology Group (SWOG) trial (n = 124), which used a pre-operative dose of 5 x 4 Gy, did not show a survival advantage (14).
- An Egyptian study in patients with bladder cancer caused by bilharzia (predominantly squamous cell carcinoma, n = 92) showed a significant survival advantage for > T3 tumours, but a marginal and nonsignificant difference for the whole group (15).
- A small, randomised study of 44 patients (16) showed a significant increase in pCR (18-55%) and a small increase in 5-year survival (61-72%, not significant), but the results were limited by a small patient population and differing radiotherapy schedules (32-54 Gy).
- In another small, three-armed study (n = 72), patients were randomised between surgery, surgery with pre-operative radiotherapy (45 Gy in 4-5 weeks) and radiotherapy alone (50-60 Gy in 4-6 weeks) (17). Pre-operative radiotherapy resulted in 24% of patients achieving pCR. There were no significant differences in survival or toxicity between the three arms.
- There was no reported increase in toxicity due to pre-operative radiotherapy in any of the above-mentioned studies.
- The effect on the local recurrence rate was not specifically documented in any of the studies.
- Three of the randomised studies looked at down-staging and found an increase in pCR following preoperative radiotherapy from 9% to 34% (10), 0% to 24% (14) and from 18% to 55% (16).
- Local recurrences were not reported (13,17), nor were they similar in any of the randomised studies (16).

- All five randomised studies looked at survival. The largest study found a significant survival advantage from 25% to 52% in those patients who did not receive adjuvant chemotherapy (13). The Egyptian study found a survival advantage only for T3 patients or higher (15). No study found a significant survival advantage for the whole group.
- A meta-analysis of the randomised trials on the value of pre-operative radiotherapy showed an odds ratio for the difference in 5-year survival of 0.71 (95% CI: 0.48-1.06). However, the meta-analysis was potentially biased by the many patients in the largest trial, who did not receive the planned treatment. When the results of the largest trial were excluded, the odds ratio became 0.95 (95% CI: 0.57-1.55), indicating that improved survival with pre-operative radiotherapy had not been proven (18,19).
- The sixth RCT was not included in the meta-analysis (18) since its findings deviated from all the others. Furthermore, the follow-up period was only two years (20).

*9.1.3 **Effect of pre-treating patients with neoadjuvant radiotherapy before cystectomy***

A recent study compared the long-term outcome of pre-treating patients before cystectomy with neoadjuvant radiotherapy (n = 90) versus not pre-treating with radiotherapy (n = 97). The clinical stage of tumours was T1-3. Down-staging to T0 after cystectomy occurred in 7% (7/97) without radiotherapy versus 57% (51/90) with radiotherapy. In cT3 tumours, these results were 0% (0/16) versus 59% (19/34), respectively. Down-staging resulted in a longer PFS. In cT3 tumours, there was also a significant longer disease-specific survival. However, the results are limited by the small patient numbers and the retrospective nature of the study.

Another recent retrospective study on neoadjuvant radiotherapy also found a survival advantage, though the results were also limited (21).

9.2 Conclusions and recommendations for pre-operative radiotherapy

Conclusions	LE
No data exist to support that pre-operative radiotherapy for operable muscle-invasive bladder cancer increases survival.	2
Pre-operative radiotherapy for operable muscle-invasive bladder cancer, using a dose of 45-50 Gy in fractions of 1.8-2 Gy results in down-staging after 4-6 weeks.	2
Pre-operative radiotherapy with a dose of 45-50 Gy in fractions of 1.8-2 Gy does not significantly increase toxicity after surgery.	3
There are suggestions in older literature that pre-operative radiotherapy decreases local recurrence of muscle-invasive bladder cancer.	3

Recommendations	GR
Pre-operative radiotherapy is not recommended to improve survival.	B
Pre-operative radiotherapy for operable muscle-invasive bladder cancer results in tumour downstaging after 4-6 weeks.	C

10. BLADDER-SPARING TREATMENTS FOR LOCALISED DISEASE

10.1 Transurethral resection of bladder tumour (TURB)

When patients with an initially invasive bladder cancer, presenting with pT0 or pT1 status at second resection, are selected for transurethral resection of bladder tumour (TURB) alone, about half of them will have to undergo radical cystectomy for recurrent muscle-invasive cancer, with a disease-specific death rate ranging up to 47% within this group (1,2).

A disease-free status at re-staging TUR appears to be crucial in making the decision not to perform radical cystectomy (3,4). A prospective study by Solsona et al. (3) included 133 patients with a radical TUR and negative biopsies, and recently reported 15 year follow-up (5). Patients had regular cystoscopy and biopsies, and were treated additionally according to their findings. In all, only 6.7% were understaged during the initial TURBT, 30% had recurrent NMIBC and went on to intravesical therapy, and 30% (n=40) progressed, of which 27 died of bladder cancer. This results in a CSS of 81.9%, 79.5% and 76.7%, and a PFS with intact bladder of 75.5%, 64.9%, 57.8%, after 5, 10 and 15 years respectively.

TUR alone is only possible as a therapeutic option if tumour growth is limited to the superficial muscle layer and if re-staging biopsies are negative for residual tumour (6). TUR alone should only be considered as a therapeutic option when the patient is unfit for cystectomy or a multimodality bladder-preserving approach, or refuses open surgery (7).

*10.1.1 **Conclusion and recommendation for TURB***

Conclusion and recommendation	LE	GR
Transurethral resection of bladder tumour (TURB) alone is not a curative treatment option in most patients.	2a	B

10.2 External beam radiotherapy (EBRT)

The target field usually comprises the bladder only, with a safety margin of 1.5-2 cm to allow for unavoidable organ movements (1-4). Any beneficial effect with larger pelvic fields has not been demonstrated. The target dose for curative radiotherapy for bladder cancer is 60-66 Gy, with a subsequent boost using external radiotherapy or interstitial brachytherapy. The daily dose is usually 1.8-2 Gy, and the course of radiotherapy should not extend beyond 6-7 weeks to minimise the repopulation of cancer cells. The use of modern standard

radiotherapy techniques results in major, related, late morbidity of the urinary bladder or bowel in less than 5% of tumour-free patients (5-9). As well as the response to radiotherapy, important prognostic factors for outcome include:

- tumour size;
- hydronephrosis;
- completeness of the initial TURB.

Overall, 5-year survival rates in patients with MIBC range between 30% and 60%, depending on whether they have a complete response (CR) following radiotherapy. Cancer-specific survival rates are between 20% and 50% (10-14).

Prognostic factors for success were investigated in an Italian single institution series of 459 irradiated patients, including approximately 30% of unfit T1 patients, with 4.4 years average follow-up. Significant factors were found in a multivariate survival analysis to be:

- age;
- T category (for all end points);
- tumour dose (only for failure-free survival) (15).

Based on available trials, a Cochrane analysis has demonstrated that radical cystectomy has an overall survival benefit compared to radiotherapy (16).

External radiotherapy can be an alternative treatment in patients unfit for radical surgery, as demonstrated in a group of 92 elderly or disabled patients with T2-4 N0-1 M0 bladder cancer and a median age of 79 years. The total dose given was 55 Gy in 4 weeks. The cystoscopic complete remission rate at 3 months was 78%, 3-year local control rate 56%, and 3-year overall survival 36%. Pre-treatment bladder capacity was demonstrated in 81% of patients (17).

Similar long term results were reported by Chung et al (18). 340 patients with MIBC were treated with EBRT alone, EBRT with concurrent chemotherapy, or neoadjuvant chemotherapy followed by EBRT. The overall CR was 55% and the 10 year DSS and OS were 35% and 19% respectively. CR was 64%, 79%, and 52% after EBRT alone, concurrent chemotherapy (n=36), and neoadjuvant chemotherapy (n=57) respectively, although in this last group most patients had T3 and T4 tumours. Younger age, lower tumour stage and absence of CIS were associated with a significant improvement in survival. For example, in the T2 group, 5 year OS was 44% and DSS was 58%. A relapse within 2 to 3 years was a bad prognostic sign. The authors concluded that EBRT monotherapy was an option only in highly selected patients.

10.2.1 ***Conclusions and recommendation for external beam radiotherapy***

Conclusions	**LE**
External beam radiotherapy alone should only be considered as a therapeutic option when the patient is unfit for cystectomy or a multimodality bladder-preserving approach.	3
Radiotherapy can also be used to stop bleeding from the tumour when local control cannot be achieved by transurethral manipulation because of extensive local tumour growth.	3

Recommendation	**GR**
Surgical intervention or multimodality treatment are the preferred curative therapeutic approaches since they are more effective than radiotherapy alone.	B

10.3 Chemotherapy

Chemotherapy alone rarely produces durable complete responses. In general, a clinical complete response rate of up to 56%, as reported in some series, must be weighed against a staging error of > 60% (1-2). Response to chemotherapy is a prognostic factor for treatment outcome and eventual survival (3), though it may be confounded by patient selection.

Several groups have reported the effect of chemotherapy on resectable tumours (neoadjuvant approach), as well as unresectable primary tumours (4-7). Neoadjuvant chemotherapy with 2-3 cycles of methotrexate,

vinblastine, adriamycin plus cisplatin (MVAC) or cisplatin, methotrexate plus vinblastine (CMV) has led to a downstaging of the primary tumour in different prospective series (4-6). Pathological complete responses of bladder primary tumours were reached in 12-50% of patients after MVAC and in 12-22% of patients after gemcitabine/ cisplatin (GC) in phase II and phase III trials (4-6,8-16). Contemporary series with GC followed by radical cystectomy reported inferior pT0 rates, which may have been related to a lack of dose density and inappropriate delay of surgery (17).
As for bladder preservation, response is evaluated by cystoscopy and CT-imaging only, followed by close surveillance. This approach is prone to an imminent staging error, which can put the patient at risk for local recurrence and/or consecutive metastatic disease.

For very selected patients, a bladder-conserving strategy with TUR of the bladder and systemic cisplatin-based chemotherapy, preferably with MVAC, may allow long-term survival with intact bladder (18). However, this approach cannot be recommended for routine use.

10.3.1 ***Conclusion and recommendation for chemotherapy for muscle-invasive bladder tumours***

Conclusion	**LE**
With cisplatin-based chemotherapy as primary therapy for locally advanced tumours in highly selected patients, complete and partial local responses have been reported.	2b

Recommendation	**GR**
Chemotherapy alone is not recommended as primary therapy for localised bladder cancer.	A

10.4 Multimodality bladder-preserving treatment

Recent organ-preservation strategies combine TURB, chemotherapy and radiation (1,2). The rationale for performing TURB and radiation is to achieve local tumour control. Application of systemic chemotherapy, most commonly as methotrexate, cisplatin and vinblastine (MCV), aims at the eradication of micrometastasis. Many protocols use cisplatin and/or 5-FU and, recently, gemcitabine with radiation, because of their established role as radiosensitisers. Cisplatin-based chemotherapy in combination with radiotherapy, following TURB, results in a complete response rate of 60-80%.

In a recent, small, phase 1-2 study the value of gemcitabine in multimodality treatment was emphasised, with a 5 year OS of 70.1% and DSS of 78.9% (3).

Another recent study with a mean follow up of 42 months compared TURBT + radiochemotherapy (n=331) with TURBT + radiotherapy (n=142) (4). The overall CR was high (70.4%). However, the radiochemotherapy group had a clear survival advantage (median survival 70 months) compared to the radiotherapy group (median survival 28.5 months). Long term results were dependent on stage, lymphatic invasion (LVI), residual tumour status and initial response at restaging TUR.

The importance of the radicality of the initial TUR was also confirmed in a recent Japanese study with 82 patients treated with TURBT and chemoradiotherapy (5). Initial pCR rate was relatively low (39%) in the absence of a radical initial TURBT. Still, clinical CR (84%) and survival data were high (5 year OS 77.7%, 5 year PFS 64.5%), although this included salvage treatment. Primary cT2 patients showed a significant improvement in survival compared to cT3-4 and recurrent cases.

Several other smaller recent series confirm the potential of multimodality protocols (6-9). Five year OS rates around 70% are reported. However, protocols differ for each study, as does patient selection. Recurring patients usually do badly, and so do patients with tumours progressing from NMIBC to MIBC. Low stage and complete TUR remain important prognostic variables.

It is recommended that early cystectomy is performed in individuals who do not achieve a complete response following combination therapy. About 40-45% of these patients may survive with an intact bladder at 4-5 years (2).

A comparable long-term survival rate of 50-60% at 5 year follow-up is reported by both multimodality bladder-

preserving trials and cystectomy series. However, these therapeutic approaches have never been directly compared and patients in multimodality series are highly selected (2,10-12).

A bladder-preserving multimodality strategy requires very close multidisciplinary co-operation and a high level of patient compliance. Even if a patient has shown a complete response to a multimodality bladder-preserving strategy, the bladder remains a potential source of recurrence. About half of patients can be expected to survive with their native bladder intact. A T0 status at repeat TUR after the initial transurethral resection of the primary tumour, followed by chemotherapy in combination with radiotherapy, was identified as a prognostically important variable. However, even the latter patients are at a life-long risk of developing intravesical tumour recurrences and need meticulous surveillance and multiple invasive procedures. It has been postulated that a delay in radical cystectomy due to an initial bladder-preserving approach increases the risk of lymph node metastases to a lymph-node positive rate of 26% when cystectomy becomes necessary due to treatment failure.

*10.4.1 **Conclusions and recommendations for multimodality treatment in muscle-invasive bladder cancer***

Conclusions	**LE**
In a highly selected patient population, long-term survival rates of multimodality treatment are comparable to those of early cystectomy.	3
Delay in surgical therapy can compromise survival rates.	2b

Recommendations	**GR**
Transurethral resection of bladder tumour (TURB) alone cannot be offered as a standard curative treatment option in most patients.	B
Radiotherapy alone is less effective than surgery and is only recommended as a therapeutic option when the patient is unfit for cystectomy or a multimodality bladder-preserving approach.	B
Chemotherapy alone is not recommended as primary therapy for muscle-invasive bladder cancer.	A
Surgical intervention or multimodality treatment are the preferred curative therapeutic approaches since they are more effective than radiotherapy alone.	B
Multimodality treatment could be offered as an alternative in selected, well-informed, well selected and compliant patients, especially for whom cystectomy is not an option.	B

11. ADJUVANT CHEMOTHERAPY

Adjuvant chemotherapy for patients after radical cystectomy with pT3/4 and/or lymph node positive (N+) disease without clinically detectable metastases (M0) is under debate (1,2). The benefits of chemotherapy in the adjuvant setting include:

- Chemotherapy is administered after accurate pathological staging.
- Overtreatment in patients at low risk for micrometastases is avoided.
- No delay in definitive surgical treatment, especially in patients not sensitive to chemotherapy.

The drawbacks of adjuvant chemotherapy are:

- Assessment of in vivo chemosensitivity of the tumour is not possible.
- Delay or intolerability of chemotherapy, due to post-operative morbidity.

There is not enough evidence in favour of the routine use of adjuvant chemotherapy (2,8). To date, there have been only five published randomised trials of adjuvant chemotherapy (3-7) and one meta-analysis (8), with updated individual patient data from six trials and a total of only 491 patients for survival analysis. Furthermore, all these trials were suboptimal with serious deficiencies, including low sample size (underpowered), substandard chemotherapy, early stopping of patient entry, and flaws in design and statistical analysis, including irrelevant endpoints or a lack of recommendations concerning salvage chemotherapy for relapse or metastases (2). The data are not convincing enough to give an unequivocal recommendation for the use of adjuvant chemotherapy.

From the evidence so far available, it is unclear whether immediate adjuvant chemotherapy or chemotherapy at the time of relapse is superior or if the two approaches are equivalent with respect to the endpoint overall survival. In recent trial updates, cisplatin-based combination chemotherapy was able to produce long-term disease-free survival, even in metastatic disease, albeit mainly in patients with lymph node metastases only, and with a good performance status (9-11).

Patients with extravesical and/or node positive disease following cystectomy should be enrolled in clinical trials whenever possible. In non-protocol-eligible patients, adjuvant cisplatin-based chemotherapy is an option provided the patient is well informed about the scarce data available.

Published trials of randomised adjuvant chemotherapy have used three to four cycles of CMV (cisplatin, methotrexate, vinblastine), CISCA (cisplatin, cyclophosphamide, and adriamycine), MVA(E)C (methotrexate, vinblastine, adriamycine or epirubicine, and cisplatin) and CM (cisplatin, methotrexate) (12). There is no evidence that more modern or carboplatin-containing chemotherapy combinations are as effective. Patients ineligible for cisplatin should not receive adjuvant chemotherapy.

11.1 Conclusion and recommendation for adjuvant chemotherapy

Conclusion	LE
Adjuvant chemotherapy is under debate. Neither randomised trials nor a meta-analysis have provided sufficient data to support the routine use of adjuvant chemotherapy.	1a

Recommendation	GR
Adjuvant chemotherapy is advised within clinical trials, but not as a routine therapeutic option.	A

12. METASTATIC DISEASE

Approximately 30% of patients with urothelial cancer present with muscle-invasive disease; about half will relapse after radical cystectomy depending on the pathological stage of the primary tumour and the nodal status. Local recurrence accounts for about 30% of relapses, whereas distant metastases are more common. About 10-15% of patients are already metastatic at diagnosis (1). Before the development of effective chemotherapy, patients with metastatic urothelial cancer rarely exceeded the median survival of 3-6 months (2).

12.1 Prognostic factors and treatment decisions

Bladder cancer is a chemosensitive tumour. Response rates differ with respect to patient-related factors and pre-treatment disease. Prognostic factors for response and survival have been established. In a multivariate analysis, Karnofsky PS of 80% or less and the presence of visceral metastases were independently prognostic of poor survival after treatment with MVAC (methotrexate, vinblastine, adriamycine and cisplatin). These so-called 'Bajorin' prognostic factors (3) have also been validated for newer combination chemotherapies (4,5) and are crucial for assessing phase II study results and stratifying phase III trials (6,7). Additional data on the prognostic value of elevated alkaline phosphatase and the number of disease sites (more or less than three) were generated prospectively (8). A retrospective analysis showed that, in elderly patients, an ECOG (Eastern Cooperative Oncology Group) PS 2-3 and a haemoglobin level of < 10 mg/dL were independent predictors of poor survival (9). Age itself has no impact on response or toxic events (9).

For patients refractory to platinum or progressing shortly after platinum based combination chemotherapy, four prognostic groups have been established, based on three adverse factors that had been developed in a vinflunine treated patient population and validated in an independent data set: Hb < 10 g/dL, the presence of liver metastases and ECOG PS >1 (10).

*12.1.1 **Comorbidity in metastatic disease***

Comorbidity is defined as „the presence of one or more diseases in addition to an index disease". Patients with a history of cancer have an average of three co-morbid conditions and co-morbidity is the rule, rather than the exception. Incidence and prevalence of co-morbidity increase with age. However, despite the importance of co-morbidity in clinical practice, it has not gained a considerable role in clinical trials, medical statistics and clinical practice (11). Co-morbidities are an important predictor of clinical outcome (12).

In multiple publications, co-mobidities proved predictive in 1-5 year mortality rates, which was true only in part for age and sex.

Source	N	Comorbidity	Predictive capacity
Charlson[13]	218	+	5-year mortality
Inouye[14]	318	+	2-year mortality
Lee[15]	8009	+	4-year mortality
Walter[16]	1427	+	1-year mortality

Comorbidity increases with age. However, chronologic age does not necessarily correlate with functional impairment. Physiologic impairment varies substantially between individuals. A number of definitions exist trying to establish how to select patients better as potentially "fit" or "unfit" candidates for chemotherapy. Age itself is not among them.

The EORTC conducted the first randomized phase II/III trial for „unfit" urothelial carcinoma patients (17). Their definition of „fit" and „unfit" for cisplatin is:

- „fit": GFR ≥ 60 ml/min and PS 0-1
- „unfit": GFR < 60 ml/min and /or PS 2

Furthermore and based on an expert survey; eligibility criteria for clinical trials enrolling patients with metastastatic UC "unfit" for cisplatin-based chemotherapy are: grade ≥ 2 audiometric loss and peripheral neuropathy and NYHA class III heart failure (18).

For urothelial cancer, more than 50% of patients are not eligible for cisplatin based chemotherapy (19-22).

Patient selection for systemic chemotherapy is key. There are a number of tools, which, so far, have not been able to solve this dilemma. Performance status is not accurate enough, particular in patients > 75 years of age. For measuring functional status, the comprehensive geriatric assessment (CGA) has proven to be more sensitive than the mere estimate of the physician (23). The CGA would most likely be helpful but, as yet,

has not been validated for urothelial cancer patients.
As for comorbidity, the Charlson score is not used as a standard. Renal function assessment is of utmost importance in the urothelial cancer population. Calculated creatinine clearance (crcl) with current formulas tends to under-estimate crcl in pts > 65 years compared to measured crcl (19,24).

The CGA includes: functional status, co-morbidities, socio- economic circumstances, cognition, emotional perception, co-medication, nutrition and geriatric syndrome (25).

Notwithstanding the clear advantages of this tool (description of physiologic aging, detection of reversible problems and issues, cognitive function assessment) the drawbacks preventing its widespread use in clinical practice is the fact that it is a resource intensive activity (both for time and staff involvement). This tool could potentially be the basis of a more user-friendly, accurate, questionnaire. However, validation in studies will be needed before standard use can be recommended.

12.2 Single-agent chemotherapy

Varying response rates of single-agent first-line chemotherapy have been reported with only 12% for cisplatin compared to MVAC (7), 12% for carboplatin (26), 42% for paclitaxel (27), 31% for docetaxel (28), 29% for methotrexate, 19% for adriamycin, 15% for epirubicin, 13% for mitomycin C, 35% for 5-FU, 14% for vinblastine, 29% for ifosfamide and 8% for cyclophosphamide (29,30). The most robust single-agent data is a response rate of about 25% for gemcitabine for first- and second-line use in several, larger-sized, phase II trials (31-38).

Responses with single agents are usually short-lived and complete responses are rare. Of note, no long-term disease-free survival has been reported with single-agent chemotherapy. The median survival in such patients is only about 6-9 months. Patients with PS WHO 3-4, with or without additional negative prognostic factors, are not expected to benefit from combination chemotherapy. The most appropriate approach for this patient group is best supportive care or, at most, single-agent chemotherapy.

12.3 Standard first-line chemotherapy for 'fit' patients

Cisplatin-containing combination chemotherapy has been the standard of care since the late 1980s. MVAC has been proven superior to cisplatin monotherapy and CISCA (cisplatin, cyclophosphamide and adriamycine) (7,39) and, more recently, to cisplatin/docetaxel (40). MVAC and gemcitabine/cisplatin (GC) have prolonged survival up to 14.8 and 13.8 months, respectively (41-43). The lower toxicity of GC (43), however, has resulted in GC increasingly becoming a new standard regimen (44).

Neither of the two combinations was proven to be superior over the other, but equivalence was not tested, with response rates of 46% and 49% for MVAC and GC, respectively. The long-term survival results confirmed the anticipated equivalence of the two regimens (8). The major difference between the above-mentioned combinations was toxicity, with GC being less toxic (43). MVAC is better tolerated with the use of GCSF (40,44).

High-dose intensity MVAC (HD-MVAC) with GCSF is less toxic and more efficacious than standard MVAC in terms of dose density, complete response and 2-year survival rate. However, there is no significant difference in median survival between the two regimens (45,46).

All disease sites have been shown to respond to cisplatin-based combination chemotherapy, but have been reported most often in lymph nodes. A response rate of 66% and 77% with MVAC and HD-MVAC, respectively, has been reported in retroperitoneal lymph nodes versus 29% and 33% at extranodal sites (45). The sites of disease also have an impact on long-term survival. In lymph-node-only disease, 20.9% of patients were alive at 5 years compared to only 6.8% of patients with visceral metastases (8).

Further intensification of treatment using new triplets, dose-dense schedules or adding targeted therapies is still being investigated. These approaches should be reserved for clinical trials and are not suitable for routine use (47,48).

12.4 Carboplatin-containing chemotherapy in 'fit' patients

Carboplatin-containing chemotherapy is not proven to be equivalent to cisplatin combinations. However, it is probably inferior and therefore should not be considered interchangeable or standard. The only randomised phase III study of carboplatin-containing chemotherapy had a disappointing response rate of only 28.2% in the investigational arm (paclitaxel/carboplatin) compared to MVAC and had to be closed down early because of a low accrual rate. There is therefore no evidence that this doublet might have adequate efficacy for first-line use (49).

Various carboplatin versus cisplatin combination chemotherapies in randomised phase II trials have produced lower complete response rates and a shorter overall survival for the carboplatin arms (50-52).

12.5 Non-platinum combination chemotherapy

Gemcitabine and paclitaxel combinations in different schedules have been studied as both first- and second-line treatments. Apart from severe pulmonary toxicity with a weekly schedule of both drugs, this combination has been well tolerated and produced response rates between 38% and 60% in both lines. As there has not been a randomised comparison to standard cisplatin chemotherapy, non-platinum combination-chemotherapy is not recommended for first-line use in patients who are fit enough (38,53-59).

12.6 Chemotherapy in patients 'unfit' for cisplatin

Up to 50% of patients are ineligible for cisplatin-containing chemotherapy, either because of a poor PS and/or impaired renal function, or because of co-morbidity preventing high-volume hydration (60,61). The first randomised phase II/III trial in this setting was conducted by the European Organisation for Research and Treatment of Cancer and compared methotrexate/carboplatin/vinblastine (M-CAVI) and carboplatin/gemcitabine (Carbo/Gem) in patients unfit for cisplatin. Both regimens were active. Severe acute toxicity (SAT) was 13.6% in patients given Carbo/Gem versus 23% on M-CAVI, while the overall response rate was 42% on Carbo/Gem and 30% on M-CAVI. Further analysis showed that in patients with PS 2 and impaired renal function, combination chemotherapy provides limited benefit (62). The overall response rate and SAT were both 26% for the former group, and 20% and 24%, respectively, for the latter group (62). Recent phase III data has confirmed these results (63).

12.7 Second-line treatment

Second-line chemotherapy data are highly variable and prognostic factors are unclear in this setting. Suggested prognostic factors include the choice of first-line chemotherapy (peri-operative/metastatic), prior chemosensitivity, duration of response to first-line treatment, presence of visceral metastases, PS and the 'Bajorin'-prognostic factors. Until recently, there was no defined chemotherapy standard in this setting. A reasonable strategy may be to offer selected patients who initially responded to platinum-containing regimens, another course 12 months, or more, after the initial treatment.

Second-line response rates of paclitaxel (weekly), docetaxel, oxaliplatin, ifosfamide, topotecan, lapatinib, gefitinib and bortezomib range between 0% and 13% in small phase II trials (64-72). Although gemcitabine has also shown excellent response rates in second-line use (31,35-38), most patients already receive this drug as part of their front-line treatment.

In a phase II trial, pemetrexed 500 mg/m^2, given every 3 weeks, showed a promising response rate of 28% and manageable toxicity with the addition of vitamin B12 and folinic acid supplementation and dexamethasone prophylaxis (73). The excellent response rate could not be confirmed by a second, smaller sized trial (74).

Paclitaxel/gemcitabine showed response rates of 38-60%, depending on pre-treatment response and indication of prior chemotherapy. Unfortunately, no adequate randomised phase III trial has been conducted to assess the true value of this second-line combination (2,54,58).

Vinflunine, a novel third-generation vinca alkaloid, has shown objective response rates of 18% and disease control in 67% (75). A phase III trial of vinflunine plus best supportive care (BSC) randomised against BSC alone in patients progressing after first-line treatment with platinum-containing combination chemotherapy for metastatic disease was published recently (763). The results showed modest activity (overall response rate, 8.6%), a clinical benefit with a favourable safety profile and, most importantly, a survival benefit in favour of vinflunine, which was statistically significant in the eligible patient population (not in the ITT population). For second-line treatment in advanced or metastatic urothelial cancer, this trial reached the highest level of evidence ever reported. Currently, vinflunine is the only approved second-line treatment; any other treatment should take place in the context of clinical trials.

12.8 Low-volume disease and post-chemotherapy surgery

With cisplatin-containing combination chemotherapy, excellent response rates may be obtained in patients with lymph node metastases only, good PS and an adequate renal function, including a high degree of complete responses, with up to 20% of patients achieving long-term disease-free survival (8,46,77,78). Stage migration may play a role in this positive prognostic development. A retrospective study of post-chemotherapy surgery after a partial or complete response indicated that post-chemotherapy surgery may contribute to long-term disease-free survival in selected patients (79-81).

12.9 Treatment of bone metastases

The prevalence of metastatic bone disease (MBD) in patients with advanced/metastatic urothelial cancer has been reported to be 30-40% (82). Skeletal complications due to MBD have a detrimental effect on pain and quality of life and are also associated with increased mortality (83). Bisphosphonates reduce and delay skeletal-related events (SRE) due to bone metastases by inhibiting bone resorption. In a small pilot study in patients with bladder cancer, SRE of bone metastases could be delayed (84). Denosumab is a fully human monoclonal antibody that binds to, and neutralizes, the receptor activator of nuclear factor kappa-B ligand (RANKL), thereby inhibiting osteoclast function and preventing generalized bone resorption and local bone destruction. Denosumab was noninferior to zoledronic acid (ZA) in preventing or delaying first on-study SRE in patients with advanced cancer metastatic to bone, including also a few urothelial carcinoma patients (85). Denosumab has been recently approved by the European Medicines Agency (EMA) for the treatment of patients with bone metastases of solid tumors. Patients with MBD, irrespective of the cancer type, should be considered for bone targeted treatment (83).

Patients treated with either zoledronic acid or denosumab should be informed about possible side effects and prophylactic management of osteonecrosis of the jaw and hypocalcemia, which is more common in denosumab treated patients. Aggressive calcium and vitamin D supplementation is recommended. Dosing regimens of ZA should follow respective regulatory recommendations and should be adjusted according to pre-existing medical conditions (86). With the use of denosumab, no follow up of renal function is required because the agent has no potential nephrotoxicity and no dose adjustments are required.

12.10 Conclusions and recommendations for metastatic disease

Conclusion	LE
Performance status and the presence or absence of visceral metastases are independent prognostic factors for survival. These factors are at least as important as the type of chemotherapy administered.	3
Cisplatin-containing combination chemotherapy is able to achieve a median survival of up to 14 months, with long-term disease-free survival reported in about 15% of patients with nodal disease and good performance status.	1b
Single-agent chemotherapy provides low response rates of usually short duration.	2a
Carboplatin-combination chemotherapy is less effective than cisplatin-based chemotherapy in terms of complete response and survival.	2a
Non-platinum combination chemotherapy has produced substantial responses in first- and second-line use, but has not been tested against standard chemotherapy in fit patients or in a purely unfit patient group.	2a
To date, there is no defined standard chemotherapy for 'unfit' patients with advanced or metastatic urothelial cancer.	2b
Vinflunine reached the highest level of evidence ever reported for second-line use.	1b
Post-chemotherapy surgery after a partial or complete response may contribute to long-term disease-free survival.	3
Zoledronic acid and denusomab have been studied and approved for all cancer types including urothelial cancer, as they have been shown to reduce and delay skeletal-related events in metastatic bone disease.	1

Recommendations	GR
The selection of treatment should be guided by prognostic factors.	B
First-line treatment for "fit" patients:	
Use cisplatin-containing combination chemotherapy with GC, MVAC, preferably with GCSF, or HD-MVAC with GCSF.	A
Carboplatin and non-platinum combination chemotherapy are not recommended.	B
First-line treatment in patients ineligible ('unfit") for cisplatin:	
Use carboplatin combination chemotherapy or single agents.	C

For cisplatin-ineligible patients ('unfit') with either PS 2 or impaired renal function, or with 0-1 poor Bajorin prognostic factors, first-line treatment is carboplatin-containing combination chemotherapy, preferably with gemcitabine/carboplatin.	A
Second-line treatment:	
In patients progressing after platinum-based combination chemotherapy for metastatic disease, vinflunine should be offered. Alternatively, treatment within a clinical trial setting may be offered.	A*
Zoledronic acid or denosumab, are recommended for the treatment of bone metastases.	B

** Grade A recommendation is weakened by a problem of statistical significance.*
BSC = best supportive care; GC = gemcitabine plus cisplatin; GCSF = granulocyte colony stimulating factor; GFR = glomular filtration rate; MVAC = methotrexate, vinblastine, adriamycin plus cisplatin; HD MVAC = high-dose methotrexate, vinblastine, adriamycin plus cisplatin; PS = performance status

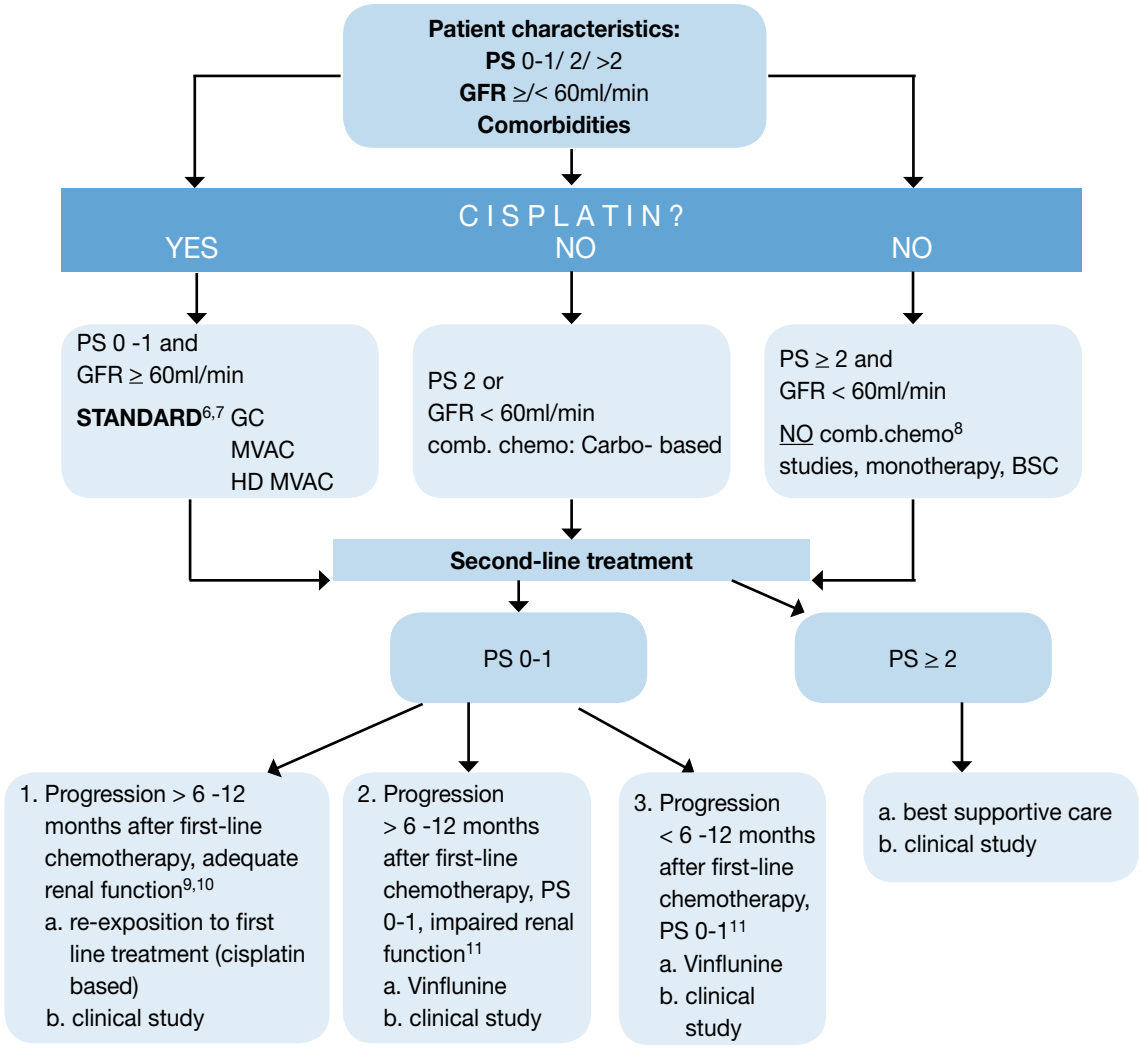
12.11 Biomarkers

Statistically relatively modest, disease control rates, but sporadically, remarkable responses in some patients with urothelial bladder cancer have led to the investigation of biomarkers for the assessment of prognosis after surgery and the potential value of perioperative chemotherapy, and as a predictor for response to chemotherapy or for its monitoring. Most of the biomarkers were associated with tumour angiogenesis. To date, small studies, usually retrospective, have investigated microvessel density, altered p53 tumour expression (87), serum vascular endothelial growth factor (88), urinary and tissue basic fibroblast growth factor (89), urinary (wild type and mutant) and tissue fibroblast growth factor receptor-3 (90), and more recently thrombospondin-1 (91), the detection of circulating tumour cells (92,93) and multi-drug resistance gene expression (94). Although a few biomarkers have shown potential, none has sufficient evidence to support their clinical routine use (LE: 3).

Recommendation on the use of biomarkers	**GR**
Currently, no biomarkers can be recommended in daily clinical practice since they have no impact on predicting outcome, treatment decisions or monitoring therapy in muscle-invasive bladder cancer.	A*

**Upgraded following panel consensus.*

Figure 2: Flowchart for the management of metastatic urothelial cancer



BSC = best supportive care; GC = gemcitabine plus cisplatin; GFR = glomular filtration rate; MVAC = methotrexate, vinblastine, adriamycin plus cisplatin; HD MVAC = high-dose methotrexate, vinblastine, adriamycin plus cisplatin; PS = performance status

13. QUALITY OF LIFE

13.1 Introduction

The evaluation of health-related quality of life (HRQoL) considers physical, psychological, emotional and social functioning.

Several questionnaires have been validated for assessing HRQoL in patients with bladder cancer, including FACT (Functional Assessment of Cancer Therapy)-G (1), EORTC QLQ-C30 (2), EORTC QLQ-BLM (muscle invasive bladder cancer module) (3), and SF (Short Form)-36 (4,5) and recently the BCI questionnaire specifically designed and validated for bladder cancer patients (6).

A psychometric test, such as the FACT-BL, should be used for recording bladder cancer morbidity. New intensive interviewing techniques have added valuable information to our knowledge of HRQoL, which greatly depends on patients' individual preferences in life (7).

Unfortunately, most retrospective studies do not evaluate the association between HRQoL and bladder cancer-specific issues after cystectomy, such as day and night-time incontinence or potency. Furthermore, important co-variables, such as a patient's age, mental status, coping ability and gender, have only rarely been considered (8,9). It remains difficult to predict the impact of post-therapeutic symptoms because of individual differences in symptom tolerance.

13.2 Choice of urinary diversion

There is controversy about which type of urinary diversion is best for a patient's HRQoL (10). Some studies have not demonstrated any difference in HRQoL (9,11,12). Nevertheless, most patients stated that, given a choice, they would still opt for an orthotopic diversion rather than an ileal conduit (13). Another recent study has shown that, although urinary function is better in conduit patients, the urinary bother is the same in both diversion groups, resulting in the same HRQoL evaluation (14).

Due to improved surgical techniques in orthotopic bladder substitution, some recent studies are supportive of continent bladder substitutes (3,15-18). Two studies have shown a statistically significant difference in HRQoL in favour of neo-bladders (18,19). Patients with an orthotopic substitution had significantly better physical function and a more active lifestyle compared to patients with an ileal conduit. It is important to note that HRQoL parameters are independent prognostic factors for overall survival (20). Patients with a continent bladder-substitute generally score more favourably than those with an incontinent diversion, as judged by body image, social activity and physical function (14,15,21).

13.3 Non-curative or metastatic bladder cancer

In non-curative or metastatic bladder cancer, HRQoL is reduced because of associated micturition problems, bleeding, pain and therefore disturbance of social and sexual life (22). There is limited literature describing HRQoL in bladder cancer patients receiving palliative care (23), but there are reports of bladder-related symptoms relieved by palliative surgery (24), radiotherapy (25), and/or chemotherapy (26).

Alternative definitive treatments of muscle-invasive bladder cancer, e.g. trimodality bladder-sparing procedures, have shown similar survival times compared to cystectomy. However, the impact on HRQoL has been controversial (26-31).

13.4 Conclusions and recommendations for health-related quality-of-life (HRQoL)

Conclusions	LE
No randomised, prospective HRQoL study has evaluated the different forms of definitive treatment for muscle-invasive bladder cancer.	
In most patient groups studied, the overall HRQoL after cystectomy remains good, irrespective of the type of urinary diversion used. The suggestion that continent diversions are associated with a higher HRQoL, has not been sufficiently substantiated.	2b
Important determinants of (subjective) quality of life are a patient's personality, coping style and social support.	

Recommendations	GR
The use of validated questionnaires is recommended to assess HRQoL in patients with muscle-invasive bladder cancer	B
Unless a patient's co-morbidities, tumour variables and coping abilities present clear contra-indications, a continent urinary diversion should be offered.	C
Pre-operative patient information, patient selection, surgical techniques, and careful post-operative follow-up are the cornerstones for achieving good long-term results.	C
Patient should be encouraged to take active part in the decision-making process. Clear and exhaustive information on all potential benefits and side-effects should be provided, allowing them to make informed decisions.	C

14. FOLLOW-UP

An appropriate schedule for disease monitoring should be based on:
- natural timing of disease recurrence;
- probability of disease recurrence;
- possibilities of treatment of a recurrence (1);
- functional deterioration at particular sites.

Nomograms on cancer-specific survival following radical cystectomy have been developed and externally validated, however, their wider use cannot be recommended prior to the availability of further data (2-4).

Local pelvic recurrences after urothelial bladder cancer occur in 7-12%. For male and female patients, in contemporary series with bladder substitution, secondary and primary urethral tumours are found in 4-6% and 1,4-4%, respectively. Upper tract recurrences vary between 2,4-17% (5-8). Most recurrences manifest during the first 24 months, often within 6-18 months after surgery. However, late recurrences have also occurred up to 5 years after cystectomy. Pelvic recurrence can be predicted by pathological stage of the primary tumour (pTN) and pathological nodal status (pN).

Patients have a poor prognosis after pelvic recurrence. Even with treatment, median survival ranges from 4-8

months following diagnosis. Definitive therapy can sometimes provide prolonged survival, but in most cases provides only palliation of symptoms. Treatment options include systemic chemotherapy, local surgery or radiotherapy.

14.1 Site of recurrence

14.1.1 ***Distant recurrences***

Distant recurrences are seen in up to 50% of patients treated with cystectomy. Most recurrences occur in the first 24 months, although progression has been observed after more than 10 years (9). Again, pT and pN were risk factors (10).

The most likely sites for distant recurrences are the lungs, liver and bones (11). Upper urinary tract recurrence is rarely seen (2-7%). However, when it develops, it usually does so within 22-40 months after cystectomy (1,11-13). Surveillance regimens often fail to detect tumours before symptoms develop. Radical nephro-ureterectomy can provide prolonged survival (12).

The relationship between follow-up, recurrences and outcome in neobladder patients was recently addressed by retrospective studies in two high volume centres (14,15), but their results were inconclusive with respect to the impact of follow-up on patient outcomes or survival. The first reported on 479 patients after neobladder surgery, who were prospectively followed up for a median of 4.3 years. Of 174 patients with a recurrence, 87 were found on routine follow-up (median time to recurrence 1 year), compared to 87 patients found with symptoms (median time to recurrence of 0.7 years) (14). Most patients (> 70%) had distant recurrences. Secondary urothelial tumours were in the UUT (14 patients, 8%) or urethra (24 patients, 13.8%, of which 21 were detected with cytology). Patients with asymptomatic recurrences had higher OS and CSS, suggesting some benefit of surveillance.

The second study reported on 1,207 patients after cystectomy, who were followed up for 59 months (15). Of 444 patients with a tumour recurrence, 154 were found after routine follow-up (mean time to recurrence 20 months), whilst 290 had symptomatic recurrence (mean time to recurrence 17.5 months). Only 12 (2.7%) had a urethral recurrence. One of the most important findings was that no difference in survival was demonstrated between symptomatic and asymptomatic recurrences.

14.1.2 ***Secondary urethral tumours***

The incidence of secondary urethral tumours is 5-17%, and they are most likely to occur 1-3 years after surgery. Prophylactic urethrectomy at the time of cystectomy is no longer justified in most patients. In men, the most important risk factor for development of urethral recurrence is prostatic stromal invasion (21-64%) (16-18).

In women, the main risk factor is disease at the bladder neck (19). Many studies have demonstrated that the risk of urethral recurrence after orthotopic diversion (0.9-4%) (16,20-22) is significantly lower than after non-orthotopic diversion (6.4-11.1%) (16,21).

Recently, Boorjan et al. specifically addressed urethral recurrences after cystectomy (23). This retrospective study included 1,506 patients with a follow-up of 13.5 years. A neobladder was only constructed after negative urethral frozen section. Only 5.6% of patients experienced a recurrence, of which 55% were symptomatic and 45% asymptomatic. The majority of asymptomatic recurrences were detected with cytology. The 5 year CSS of symptomatic patients (41%) was much lower than in asymptomatic patients (80%). Risk variables for urethral recurrence were prostatic urethral involvement (HR 4.89), bladder tumour focality (HR 2.34) and orthotopic neobladder construction (HR 0.34).

Little data or agreement exist about urethral follow-up, with some recommending routine surveillance to include urethral wash cytology and urine cytology (18), and others doubting the need for routine urethral surveillance at all (20, 24-26). Urethral washes and urine cytology do not appear to have any effect on survival (24,27,28).

Treatment is influenced by the local stage and grade of a urethral recurrence:

- In CIS of the urethra, BCG instillations have shown success rates of 83% (20).
- In invasive disease, urethrectomy should be performed if the urethra is the only site of disease.
- In distant disease, systemic chemotherapy is indicated (11).

Table 5: Suggestions for general follow-up based on the stage of initial tumour after cystectomy

Procedure	Months after cystectomy								
<pT1	3	6	12	18	24	30	36	48	60
Ultrasound kidneys	x								
CT/MRI thor/abd plus UUT*			x		x		x	x	x
Lab,** sed, culture and cytology	x	x	x		x		x	x	x
pT2									
Ultrasound kidneys	x								
CT/MRI thor/abd, plus UUT*		X***	x	X***	x		x	x	x
Lab, sed, culture and cytology	x	x	x		x		x	x	x
>PT3 of N+									
Ultrasound kidneys	x								
CT/MRI thor/abd, plus UUT*	x	x	x	x	x	x	x	x	x
Lab, sed, culture and cytology	x	x	x		x	x	x	x	x

CT = computed tomography scan; MRI = magnetic resonance imaging; thor = thoracic; abd = abdominal; lab = laboratory investigations; sed = urine sediment analysis; UUT = upper urinary tract.
** If UUT is abnormal at CT or there is positive cytology, recurrent primary sampling should be performed.*
*** Blood chemistry, including serum creatinine, or renal function and blood gas analysis.*
****T2a,N0M0 tumours and/or Karnofsky <100%.*

14.1.3 Conclusions and recommendations for specific recurrence sites

Site of recurrence	Conclusion	LE	Recommendation	GR
Secondary urethral tumour	Staging and treatment should be done as for primary urethral tumour	3	Local conservative treatment is possible for non-invasive tumour.	C
			In isolated invasive disease, urethrectomy should be performed.	B
			Urethral washes and cytology are not recommended.	A
Pelvic recurrence	Poor prognosis Treatment should be individualised depending on the local extent of tumour	2b	Radiotherapy, chemotherapy and possibly surgery are options for treatment, either alone or in combination.	C
Upper urinary tract			Specific upper urinary tract imaging is only indicated in case of clinical symptoms.	
			Radical nephrectomy can provide prolonged survival.	

Imaging for urothelial carcinoma with, or without, cystectomy*

Radiological procedure	Rating scale[1]	Comments	Relative radiation level*
X-ray chest	4		Minimum
CT urography	8		High
X-ray abdomen loopogram	5	In patients with an ileal loop postcystectomy	Medium
X-ray intravenous urography	5	Utilisation of intravenous urography has continued to decline with the increasingly widespread use of CT urography	Medium
MR imaging abdomen and pelvis without and with contrast	7	See ESUR guidelines on contrast media version 7.0 (29)	None
CT abdomen and pelvis with contrast	1	Appropriate if CT urography is not available. Visceral/nodal status evaluated during CT urography	High
CT chest with contrast	5	Performed if chest X-ray is equivocal	Medium
US pelvis (bladder)	3		None
FDG-PET whole body indicated for suspected or nodal metastasis	2	Indicated for suspected nodal or distant metastasis	High
After 5 years of follow-up, oncological surveillance can be stopped and surveillance continued with functional surveillance			

[1]1 is least appropriate; 9 is most appropriate

** Adapted 2011 from: American College of Radiology. Follow-up Imaging of Bladder Carcinoma. Date of origin: 1996; Last review date: 2009 (30).*

CT = computed tomography; FDG-PET = fluorodeoxyglucose positron emission tomography; MR = magnetic resonance; US = ultrasound

15. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

ARCO	accelerated radiotherapy with carbogen
ARCON	accelerated radiotherapy with carbogen nicotinamide
ASCO	American Society of Clinical Oncology
5-ALA	5-aminolaevulinic acid
4-ABP	4-aminobiphenyl
BC	bladder cancer
BT	brachytherapy
BCG	Bacille Calmette-Guérin
CGA	comprehensive geriatric assessment
CI	confidence interval
CIS	carcinoma *in situ*
CISCA	cisplatin, cyclophosphamide plus adriamycin
CM	cisplatin, methotrexate
CMV	cisplatin, methotrexate plus vinblastine
CT	multidetector computed tomography
EAU	European Association of Urology
EBRT	external beam radiation therapy
ECOG	Eastern Cooperative Oncology Group
EORTC	European Organization for Research and Treatment of Cancer
FACT	Functional Assessment of Cancer Therapy
FDG-PET	fluorodeoxyglucose positron emission tomography
5-FU	5-Fluorouracil
GC	gemcitabine plus cisplatin
GFR	glomerular filtration rate
GCSF	granulocyte colony stimulating factor
HAL	hexaminolaevulinate
HD-MVAC	high-dose methotrexate, vinblastine, adriamycin plus cisplatin
HIRU	Health Information Research Unit
HRQL	health-related quality of life
IARC	International Agency for Research on Cancer
IPD	independent patient data
ISUP	International Society of Urological Pathology
IVU	Intravenous urography
MCV	methrotrexate, cisplatin and vinblastine
MDCT	multidetector computed tomography
MiM-BC	Muscle-invasive and metastatic bladder cancer
MRC	Medical Research Council (UK)
MR(I)	magnetic resonance (imaging)
MVAC	methotrexate, vinblastine, adriamycin plus cisplatin
MVA(E)C	methotrexate, vinblastine, adriamycine or epirubicine, and cisplatin
NAT	N-acetyltransferase
NMIBC	non-muscle-invasive bladder cancer
NSF	nephrogenic systemic fibrosis
OS	overall survival
PAHs	polycyclic aromatic hydrocarbons
pCR	pathological complete remission
PDD	photodynamic diagnosis
PET	positron emission tomography
PS	performance status
PUNLMP	papillary urothelial neoplasms of low malignant potential
RALC	robotic-assisted laparoscopic cystectomy
R-biopsies	random biopsies
RCT	randomised controlled trial
SEER	Surveillance Epidemiology and End Results
SES	socio-economic status
SF-36	Short Form-36
SIGN	Scottish Intercollegiate Guidelines Network

SWOG	Southwest Oncology Group
TCC	transitional cell carcinoma
TNM	Tumour, Node, Metastasis
TUR	transurethral resection
TURB	transurethral resection of bladder tumour
UICC	Union International Contre le Cancer
UC	urethrocystoscopy
US	ultrasonography
UUTT	upper urinary tract tumours
UUT-UCC	upper urinary tract-urothelial cell carcinoma (UUT-UCC)
WHO	World Health Organization

Conflict of interest
All members of the Muscle-Invasive and Metastatic Bladder Cancer guidelines working group have provided disclosure statements of all relationships which they have and which may be perceived as a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

1. INTRODUCTION

1.1 Introduction

The European Association of Urology (EAU) Guidelines Group for Prostate Cancer have prepared this guidelines document to assist medical professionals assess the evidence-based management of prostate cancer. The multidisciplinary panel of experts include urologists, radiation oncologists, a medical oncologist, and a pathologist specialized in prostate cancer.

1.2 Data identification and evidence sources

The recommendations provided in the current guidelines are based on a systemic literature search performed by the panel members (1). MedLine, Embase, and Web of Science databases were searched to identify original articles, review articles and editorials addressing “epidemiology”, “risk factors”, “diagnosis”,“staging” and “treatment” of prostate cancer. The controlled vocabulary of the Medical Subject Headings(MeSH) database was used alongside a “free-text” protocol, combining “prostate cancer” with the terms“diagnosis”, “screening”, “staging”, “active surveillance”, “radical prostatectomy”, “external beam radiation”,“brachytherapy”, “androgen deprivation”, “chemotherapy”, “relapse”, “salvage treatment”, and “follow-up” to ensure sensitivity of the searches.

All articles published between January 2010 (previous update) and November 2011 were considered for review. The expert panel reviewed these records to select the articles with the highest evidence, according to a rating schedule adapted from the Oxford Centre for Evidence-based Medicine Levels of Evidence (1).

Additionally, publications from the major urological (EAU, AUA) and oncological meetings (ASCO, ESMO, ASTRO) have been considered.Where possible, abstracts will be replaced by the full scientific publications when these become available. Also no major recommendations can be based on evidence from abstract only.

It must be emphasised that clinical guidelines present the best evidence available but following the recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, also taking individual circumstances and patient preferences into account.

1.3 Level of evidence and grade of recommendation

The level of evidence (LE) and grade of recommendation (GR) provided in this guideline follow the listings in Tables 1 and 2. The aim of grading the recommendations is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

**Modified from Sackett, et al. (1).*

It should be noted that when recommendations are graded, there is not an automatic relationship between the level of evidence and the grade of recommendation. The availability of RCTs may not necessarily translate into a grade A recommendation if there are methodological limitations or disparities in the published results. Conversely, an absence of high-level evidence does not necessarily preclude a grade A recommendation if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations in which corroborating studies cannot be performed, perhaps for ethical or other reasons. In this case, unequivocal recommendations are considered helpful for the reader. Whenever this occurs, it has been clearly indicated in the text with an asterisk as ‘upgraded based on panel consensus’. The quality of the underlying scientific evidence is a very important factor, but it has to be balanced against benefits and burdens, values and preferences and costs when a grade is assigned (2-4).

The EAU Guidelines Office does not perform cost assessments, nor can they address local/national preferences in a systematic fashion. However, whenever such data are available, the expert panels will include the information.

Table 2: Grade of recommendation*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett, et al. (1).*

1.4 Publication history

The Prostate Cancer Guidelines were first published in 2001, with partial updates achieved in 2003 and 2007, followed by a full text update in 2009. Also in 2011 a considerable number of sections of the PCa guidelines were revised. This 2012 publication includes updated chapters and sections as detailed below. The literature for all chapters has been revisited and, where available, new literature has been included.

The 2012 PCa guidelines publication underwent a blinded peer-review process before publication.

Standard procedure for EAU publications includes an annual assessment of newly published literature in this field, guiding future updates. An ultra-short reference document is being published alongside this publication. All documents are available with free access through the EAU website Uroweb (http://www.uroweb.org/guidelines/online-guidelines/).

Summary of updated and new information

Chapter 6 “Diagnosis”:

- All literature has been revisited, new data has been added;
- Most notably in sections 6.2.3 (PCA3 marker), 6.4.8 (Antibiotics prior to biopsy), 6.4.11 (Complications), 6.5 (Pathology of prostate needle biopsies) and 6.6.2.3 (Definition of extraprostatic extension).
- In section 6.4.8 (Antibiotics prior to biopsy), the quinolones resistance related to infectious complications after biopsy.

Chapter 8 “Watchful waiting/active surveillance”:

- Additional data on the impact of radical prostatectomy compared to watchful waiting (WW) has been added.
- Data have been added supporting that comorbidity status is the leading cause of death at ten years, especially for Charlson score ≥ 2, irrespective of age, even for those with an aggressive tumour.
- Active surveillance as appropriate for highly selected, low risk patients only. Early re-biopsy plays as an increasingly important role in the patient’s selection process.
- In general, repeat biopsies are a major tool for patient follow-up.

Chapter 9 “Treatment: Radical prostatectomy”;

- Additional data have been included in section 9.1 (Introduction) on robot-assisted laparoscopic prostatectomy (RALP)
- Added emphasis is given to the need for a multidisciplinary approach in the treatment of high-risk localised disease Section 9.4 (High-risk localised PCa).

Chapter 10 “Treatment: Definitive radiation therapy”;

- Additional data has been added on the various hormonal therapy options, section 10.8 (Locally advanced PCa: T3-4, N0M0).

Chapter 11 “Experimental local treatment of prostate cancer”;

- Additional data has been added on oncological outcomes and treatment-associated complications (Section 11.3 -HIFU of the prostate).
- Additional data on salvage radical prostatectomy versus CSAP has been included (Section 16.6.2 - Salvage cryosurgical ablation of the prostate for radiation failures).
- A new section has been added on salvage high-intensity focused ultrasound (HIFU).

Chapter 12 “Hormonal treatment”;

- Data from the largest randomised controlled trial on PCa patients relapsing after radiotherapy has been incorporated, showing that intermittent androgen-deprivation therapy (ADT) proved to be as effective as continuous ADT.

- Additional data regarding bone protection and the potential role of denosumab in delaying secondary bone metastases. However, denosumab does not impact overall survival or cancer-specific survival.
- Further data on androgen deprivation therapy (ADT) was included. ADT is associated with increased cardiac morbidity, not an increase in cardiac mortality. The presence of a congestive heart failure or myocardial infarction increases the mortality risk

Chapter 15 “Follow up after hormonal treatment”;

- The literature has been revisited. The importance of bone- and testosterone monitoring is reinforced.

Chapter 16 “Treatment of biochemical failure after treatment with curative intent”

- In section 16.4 (Evaluation of PSA progression), additional data has been added on the role of choline PET/CT in the diagnosis of men with rising PSA following radical prostatectomy.

Chapter 17 “Castration resistant prostate cancer”;

- For section 17.4 (Recommendations for assessing therapeutic response), new literature has been incorporated and recommendations have changed;
- 17.8.5.2 (Abiraterone acetate), new information has been added;
- 17.9.10 (Specific bone targets), information from the ENTHUSE study has been included.

New topics included in this 2012 print

- Quality of life of patients with localised prostate cancer
- Chapter 16, A section has been added on salvage high-intensity focused ultrasound (HIFU)
- Chapter 17, Section 17.10.4 RANK ligand inhibitors

1.5 Potential conflict of interest statement

The expert panel have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guidelines/online-guidelines/.

2. BACKGROUND

Cancer of the prostate (PCa) is now recognised as one of the most important medical problems facing the male population. In Europe, PCa is the most common solid neoplasm, with an incidence rate of 214 cases per 1000 men, outnumbering lung and colorectal cancer (1). Furthermore, PCa is currently the second most common cause of cancer death in men (2). In addition, since 1985, there has been a slight increase in most countries in the number of deaths from PCa, even in countries or regions where PCa is not common (3).

Prostate cancer affects elderly men more often than young men. It is therefore a bigger health concern in developed countries with their greater proportion of elderly men. Thus, about 15% of male cancers are PCa in developed countries compared to 4% of male cancers in undeveloped countries (4). It is worth mentioning that there are large regional differences in incidence rates of PCa. For example, in Sweden, where there is a long life expectancy and mortality from smoking-related diseases is relatively modest, PCa is the most common malignancy in males, accounting for 37% of all new cases of cancer in 2004 (5).

3. CLASSIFICATION

The 2009 TNM (Tumour Node Metastasis) classification for PCa is shown in Table 3 (1).

Table 3: Tumour Node Metastasis (TNM) classification of PCa*

T - Primary tumour		
TX	Primary tumour cannot be assessed	
T0	No evidence of primary tumour	
T1	Clinically inapparent tumour not palpable or visible by imaging	
	T1a	Tumour incidental histological finding in 5% or less of tissue resected
	T1b	Tumour incidental histological finding in more than 5% of tissue resected
	T1c	Tumour identified by needle biopsy (e.g. because of elevated prostate-specific antigen [PSA] level)
T2	Tumour confined within the prostate[1]	
	T2a	Tumour involves one half of one lobe or less
	T2b	Tumour involves more than half of one lobe, but not both lobes
	T2c	Tumour involves both lobes
T3	Tumour extends through the prostatic capsule[2]	
	T3a	Extracapsular extension (unilateral or bilateral) including microscopic bladder neck involvement
	T3b	Tumour invades seminal vesicle(s)
T4	Tumour is fixed or invades adjacent structures other than seminal vesicles: external sphincter, rectum,levator muscles, and/or pelvic wall	
N - Regional lymph nodes[3]		
NX	Regional lymph nodes cannot be assessed	
N0	No regional lymph node metastasis	
N1	Regional lymph node metastasis	
M - Distant metastasis[4]		
MX	Distant metastasis cannot be assessed	
M0	No distant metastasis	
M1	Distant metastasis	
	M1a	Non-regional lymph node(s)
	M1b	Bone(s)

	M1c	Other site(s)

1 *Tumour found in one or both lobes by needle biopsy, but not palpable or visible by imaging, is classified asT1c.*

2 *Invasion into the prostatic apex, or into (but not beyond) the prostate capsule, is not classified as pT3, but as pT2.*

3 *Metastasis no larger than 0.2 cm can be designated pN1 mi.*

4 *When more than one site of metastasis is present, the most advanced category should be used.*

Prognostic grouping

Group I	T1a-c	N0	M0 PSA < 10	Gleason ≤ 6
	T2a	N0	M0 PSA < 10	Gleason ≤ 6
Group IIA	T1a-c	N0	M0 PSA < 20	Gleason 7
	T1a-c	N0	M0 PSA ≥ 10 < 20	Gleason ≤ 6
	T2a, b	N0	M0 PSA < 20	Gleason ≤ 7
Group IIb	T2c	N0	M0 Any PSA	Any Gleason
	T1-2	N0	M0 PSA ≥ 20	Any Gleason
	T1-2	N0	M0 Any PSA	Gleason ≥ 8
Group III	T3a, b	N0	M0 Any PSA	Any Gleason
Group IV	T4	N0	M0 Any PSA	Any Gleason
	Any T	N1	M0 Any PSA	Any Gleason
	Any T	Any N	M1 Any PSA	Any Gleason

Note: When either PSA or Gleason is not available, grouping should be determined by cT category and whichever of either PSA of Gleason is available. When neither is available prognostic grouping is notpossible, use stage grouping

3.1 Gleason score

The ISUP 2005 Gleason score is the current standard for grading adenocarcinoma of the prostate on core biopsy and operative specimens (2). The Gleason score is the sum of the two most common patterns (grades 1-5) of tumour growth found. The Gleason score ranges between 2 and 10, with 2 being the least aggressive and 10 the most aggressive. In needle biopsies, the worst grade should always be incorporated in the Gleason score, even if comprising < 5% of the cancer (2).

4. RISK FACTORS

The factors that determine the risk of developing clinical PCa are not well known, although a few have been identified. There are three well-established risk factors for PCa:

- increasing age;
- ethnic origin;
- heredity.

If one first-line relative has PCa, the risk is at least doubled. If two or more first-line relatives are affected, the risk increases by 5-11-fold (1,2). A small subpopulation of individuals with PCa (about 9%) has true hereditary PCa. This is defined as three or more affected relatives, or at least two relatives who have developed early-onset disease, i.e. before age 55 (3). Patients with hereditary PCa usually have an onset 6-7 years prior to spontaneous cases, but do not differ in other ways (4).

The frequency of autopsy-detected cancers is roughly the same in different parts of the world (5). This finding is in sharp contrast to the incidence of clinical PCa, which differs widely between different geographical areas, being high in the USA and Northern Europe and low in Southeast Asia (6). However, if Japanese men move from Japan to Hawaii, their risk of PCa increases. If they move to California their risk increases even more, approaching that of American men (7) (LE: 2).

These findings indicate that exogenous factors affect the risk of progression from so-called latent PCa to clinical PCa. Factors such as food consumption, pattern of sexual behaviour, alcohol consumption, exposure to ultraviolet radiation, chronic inflammation (8) and occupational exposure have all been discussed as being aetiologically important (9). Prostate cancer is an ideal candidate for exogenous preventive measures, such as dietary and pharmacological prevention, due to some specific features: high prevalence, long latency, endocrine dependency, availability of serum markers (PSA), and histological precursor lesions (atypical small acinar proliferation [ASAP] or prostatic intraepithelial neoplasia [PIN]) (8). Dietary/nutritional factors that may influence disease development include total energy intake (as reflected by body mass index), dietary fat, cooked meat, micronutrients and vitamins (carotenoids, retinoids, vitamins C, D, and E), fruit and vegetable intake, minerals (calcium, selenium), and phyto-oestrogens (isoflavonoids, flavonoids, lignans), or statins and/or cholesterol intake. Since most studies reported to date are case-control analyses, there remain more questions than evidence-based data available to answer them. Several ongoing large randomised trials are trying to clarify the role of such risk factors and the potential for successful prostate cancer prevention (10).

In summary, hereditary factors are important in determining the risk of developing clinical PCa, while exogenous factors may have an important impact on this risk. The key question is whether there is enough evidence to recommend lifestyle changes (lowered intake of animal fat and increased intake of fruit, cereals, and vegetables) in order to decrease the risk (11). There is some evidence to support such a recommendation and this information can be given to male relatives of PCa patients who ask about the impact of diet (LE: 2-3).

5. SCREENING AND EARLY DETECTION

Population or mass screening is defined as the examination of asymptomatic men (at risk). It usually takes place as part of a trial or study and is initiated by the screener. In contrast, early detection or opportunistic screening comprises individual case findings, which are initiated by the person being screened (patient) and/or his physician. The primary endpoint of both types of screening has two aspects:

1. Reduction in mortality from PCa. The goal is not to detect more carcinomas, nor is survival the endpoint because survival is strongly influenced by lead-time from diagnosis.
2. The quality of life is important as expressed by quality-of-life adjusted gain in life years (QUALYs).

Prostate cancer mortality trends range widely from country to country in the industrialised world (1). Decreased mortality rates due to PCa have occurred in the USA, Austria, UK, and France, while in Sweden the 5-year survival rate has increased from 1960 to 1988, probably due to increased diagnostic activity and greater detection of non-lethal tumours (2). However, this trend has not been confirmed in a similar study from the Netherlands (3). The reduced mortality seen recently in the USA is often attributed to the widely adopted aggressive screening policy, but there is still no absolute proof that prostate-specific antigen (PSA) screening reduces mortality due to PCa (4) (LE: 2).

A non-randomised screening project in Tyrol (Austria) may support the hypothesis that screening can be effective in reducing mortality from PCa. An early detection programme and free treatment have been used to explain the 33% decrease in the PCa mortality rate seen in Tyrol compared to the rest of Austria (5) (LE: 2b). In addition, a Canadian study has claimed lower mortality rates in men randomised to active PCa screening (6), though these results have been challenged (7). Positive findings attributed to screening have also been contradicted by a comparative study between the US city of Seattle area (highly screened population) and the US state of Connecticut (seldom screened population) (8). The study found no difference in the reduction in the rate of PCa mortality (LE: 2b), even allowing for the very great diversity in PSA testing and treatment.

In 2009, the long awaited results of two prospective, randomised trials were published. The Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial randomly assigned 76,693 men at 10 US centres to receive either annual screening with PSA and DRE, or standard care as the control. After 7 years' follow-up, the incidence of PCa per 10,000 person-years was 116 (2,820 cancers) in the screening group and 95 (2,322 cancers) in the control group (rate ratio, 1.22) (9). The incidence of death per 10,000 person-years was 2.0 (50 deaths) in the screened group and 1.7 (44 deaths) in the control group (rate ratio, 1.13). The data at 10 years were 67% complete and consistent with these overall findings. The PLCO project team concluded that PCa-related mortality was very low and not significantly different between the two study groups (LE: 1b).

The European Randomized Study of Screening for Prostate Cancer (ERSPC) included a total of 162,243 men from seven countries aged between 55 and 69 years. The men were randomly assigned to a group offered PSA screening at an average of once every 4 years or to an unscreened control group. During a median follow-up of 9 years, the cumulative incidence of PCa was 8.2% in the screened group and 4.8% in the control group (10). The rate ratio for death from PCa was 0.80 in the screened group compared with the control group. The absolute risk difference was 0.71 deaths per 1,000 men. This means that 1,410 men would need to be screened and 48 additional cases of PCa would need to be treated to prevent one death from PCa. The ERSPC investigators concluded that PSA-based screening reduced the rate of death from PCa by 20%, but was associated with a high risk of over-diagnosis (LE: 1b).

Both trials have received considerable attention and comments. In the PLCO trial, the rate of compliance in the screening arm was 85% for PSA testing and 86% for DRE. However, the rate of contamination in the control arm was as high as 40% in the first year and increased to 52% in the sixth year for PSA testing and ranged from 41% to 46% for DRE. Furthermore, biopsy compliance was only 40-52% versus 86% in the ERSPC. Thus, the PLCO trial will probably never be able to answer whether or not screening can

influence PCa mortality.

In an update of the Gothenburg section of the ERSPC trial, which includes 20,000 men, the authors reported a reduction in PCa mortality of 50% after a median follow-up of 14 years. However, this finding was accompanied by a substantial risk of over-diagnosis (11).

In the complete ERSCP trial, the real benefit will only be evident after 10-15 years of follow-up, especially once the 41% reduction of metastasis in the screening arm has had an impact. A longer follow-up may reduce the number needed to screen and to treat (12).

Based on the results of these two large, randomised trials, most if not all of the major urological societies conclude that at present widespread mass screening for PCa is not appropriate. Rather, early detection (opportunistic screening) should be offered to the well-informed man (*see also* Section 6, Diagnosis). Two key questions remain open:

- At what age should early detection start?
- What is the screening interval for PSA and DRE?

A baseline PSA determination at age 40 years has been suggested, upon which the subsequent screening interval may then be based (13) (GR: B). A screening interval of 8 years might be enough in men with initial PSA levels ≤ 1 ng/mL (14). Further, PSA testing in men older than 75 years is not recommended because its early detection would not have any clinical impact (15).

6. DIAGNOSIS*

The main diagnostic tools to obtain evidence of PCa include DRE, serum concentration of PSA and transrectal ultrasonography (TRUS). Its definite diagnosis depends on the histopathologic verification of adenocarcinoma in prostate biopsy cores or operative specimens.

6.1 Digital rectal examination (DRE)

Most prostate cancers are located in the peripheral zone of the prostate and may be detected by DRE when the volume is about 0.2 mL or larger. In about 18% of all patients, PCa is detected by a suspect DRE alone, irrespective of the PSA level (1) (LE: 2a). A suspect DRE in patients with a PSA level of up to 2 ng/mL has a positive predictive value of 5-30% (2) (LE: 2a). A suspect DRE is a strong indication for prostate biopsy as it is predictive for more aggressive (Gleason score ≥ 7) prostate cancer (3,4).

6.2 Prostate-specific antigen (PSA)

The measurement of PSA level has revolutionised the diagnosis of PCa (5). PSA is a kallikrein-like serine protease produced almost exclusively by the epithelial cells of the prostate. For practical purposes, it is organ-specific but not cancer-specific. Thus, serum levels may be elevated in the presence of benign prostatic hypertrophy (BPH), prostatitis and other non-malignant conditions. The level of PSA as an independent variable is a better predictor of cancer than suspicious findings on DRE or TRUS (6).

There are many different commercial test kits for measuring PSA, but no commonly agreed international standard exists (7). The level of PSA is a continuous parameter: the higher the value, the more likely is the existence of PCa. The finding that many men may harbour PCa, despite low levels of serum PSA, has been underscored by recent results from a US prevention study (8) (LE: 2a). Table 4 gives the rate of PCa in relation to serum PSA for 2,950 men in the placebo-arm and with PSA values ≤ 4 ng / mL.

Table 4: Risk of PCa in relation to low PSA values

PSA level (ng/mL)	Risk of PCa	Risk of Gleason ≥ 7 PCa
0-0.5	6.6%	0.8%
0.6-1	10.1%	1.0%
1.1-2	17.0%	2.0%
2.1-3	23.9%	4.6%
3.1-4	26.9%	6.7%

The findings in Table 4 clearly demonstrate the occurrence of aggressive PCa even at very low PSA levels, precluding an optimal PSA threshold value for detecting non-palpable, but clinically significant, PCa (LE: 3). Use of nomograms may help reducing the number of unnecessary prostate biopsies (9).

Several modifications of serum PSA value have been described, which may improve the specificity of PSA in the early detection of PCa. They include: PSA density, PSA density of the transition zone, age-specific reference ranges, and PSA molecular forms. However, these derivatives and PSA isoforms (cPSA [complex

** Acknowledgment: Section 6.4 is partly based on the Guidelines of the AUO Study Group Urologic Oncology of the AustrianSociety of Urologists and Andrologists (W. Höltl, W. Loidl, M. Rauchenwald, M. Müller, M. Klimpfinger, A. Schratter-Sehn,C. Brössner).*

PSA], proPSA [precursor isoforms of PSA], BPSA [benign PSA], iPSA [intact PSA]) have limited usefulness in the routine clinical setting and have therefore not been considered for inclusion in these guidelines.

*6.2.1 **Free/total PSA ratio (f/t PSA)***

The free/total PSA ratio (f/t PSA) is the concept most extensively investigated and most widely used in clinical practice to discriminate BPH from PCa. The ratio is used to stratify the risk of PCa for men who have total PSA levels between 4 and 10 ng/mL and a negative DRE. In a prospective multicentre trial, PCa was found on biopsy in 56% of men with f/t PSA < 0.10, but in only 8% of men with f/t PSA > 0.25 (10) (LE: 2a). Nevertheless, the concept must be used with caution as several pre-analytical and clinical factors may influence the f/t PSA, e.g. instability of free PSA, variable assay characteristics and very large prostate size (11). For example, free PSA is unstable at both 4°C and at room temperature. In addition, assay characteristics may vary, and concomitant BPH in large prostates may result in a dilution effect (11). Furthermore, f/t PSA is of no clinical use in total serum PSA values > 10 ng/mL or during follow-up of patients with known PCa.

*6.2.2 **PSA velocity (PSAV), PSA doubling time (PSADT)***

There are two methods of measuring PSA over time: (1) PSAV, which is defined as an absolute annual increase in serum PSA (ng/mL/year) (12) (LE: 1b); and (2) PSADT, which measures the exponential increase of serum PSA over time, reflecting a relative change (13). These two concepts may have a prognostic role in patients with treated PCa (14), but they have limited use in the diagnosis of PCa because of background noise (total volume of prostate, BPH), the variations in interval between PSA determinations, and acceleration/deceleration of PSAV and PSADT over time. Prospective studies have shown that these measurements do not provide additional information compared to PSA alone (15-18).

*6.2.3 **PCA3 marker***

An increasingly studied new biomarker is PCA3, detectable in urine sediments obtained after three strokes of prostatic massage during digital rectal examination. The costly Progensa urine test for PCA3 is now commercially available. The amount of the prostate-specific non-coding mRNA marker, PCA3 normalized against PSA mRNA (urine sediment) gives a PCA3 score. The PCA3 score is superior to PSA total, and percent free PSA in detection of PCa in men with elevated PSA as it shows slight but significant increases in the AUC for positive biopsies (19-22). The PCA3 score may be used together with PSA and other clinical risk factors in a nomogram or other risk stratification tools to make a decision with regard to first or repeat biopsy (23). The PCA3 score increases with prostate cancer volume, but there is conflicting data about whether the PCA3 score independently predicts the Gleason score and its use as a monitoring tool in active surveillance has not been confirmed (23). The main current indication of the PCA3 urine test may be to determine whether a man needs a repeat biopsy after an initially negative biopsy outcome, but its cost-effectiveness remains to be shown.

6.3 Transrectal ultrasonography (TRUS)

The classic picture of a hypoechoic area in the peripheral zone of the prostate will not always be seen. Gray-scale TRUS does not detect areas of PCa with adequate reliability (24). It is therefore not useful to replace systematic with targeted biopsies of suspect areas. However, additional biopsies of suspect areas may be useful.

6.4 Prostate biopsy

*6.4.1 **Baseline biopsy***

The need for prostate biopsies should be determined on the basis of the PSA level and/or a suspicious DRE. The patient's biological age, potential co-morbidities (ASA Index and Charlson Comorbidity Index), and the therapeutic consequences should also be considered (25). Risk stratification is becoming an important tool to reduce unnecessary prostate biopsies (25)

The first elevated PSA level should not prompt an immediate biopsy. The PSA level should be verified after a few weeks by the same assay under standardised conditions (i.e. no ejaculation and no manipulations, such as catheterisation, cystoscopy or TUR, and no urinary tract infections) in the same diagnostic laboratory, using the same methods (26,27) (LE: 2a).

It is now considered the standard of care to perform prostate biopsies guided by ultrasound. Although a transrectal approach is used for most prostate biopsies, some urologists prefer to use a perineal approach. The cancer detection rates of perineal prostate biopsies are comparable to those obtained for transrectal biopsies (28,29) (LE: 1b).

The ultrasound-guided perineal approach is a useful alternative in special situations, e.g. after rectal amputation.

6.4.2 ***Repeat biopsy***

The indications for a repeat biopsy are: (1) rising and/or persistently elevated PSA; (2) suspicious DRE (30); (3) atypical small acinar proliferation (ASAP); and (4) extensive (multiple biopsy sites) prostatic intraepithelial neoplasia (PIN) (31).

High-grade PIN as an isolated finding is no longer considered an indication for repeat biopsy (32) (LE: 2a). A repeat biopsy should therefore be prompted by other clinical features, such as DRE findings and PSA level. If PIN is extensive (i.e. in multiple biopsy sites), this could be a reason for early repeat biopsy, because the risk of subsequent PCa is slightly increased. If clinical suspicion for PCa persists in spite of negative prostate biopsies, MRI may be used to investigate the possibility of an anterior located PCa, followed by TRUS or MRI-guided biopsies of the suspicious area (33).

6.4.3 ***Saturation biopsy***

The incidence of PCa detected by saturation repeat biopsy (> 20 cores) is between 30% and 43% and depends on the number of cores sampled during earlier biopsies (34) (LE: 2a). In special situations, saturation biopsy may be performed with the transperineal technique. This will detect an additional 38% of PCa. The high rate of urinary retention (10%) is a drawback (35) (LE: 2b).

6.4.4 ***Sampling sites and number of cores***

On baseline biopsies, the sample sites should be as far posterior and lateral as possible in the peripheral gland. Additional cores should be obtained from suspect areas by DRE/TRUS. These should be chosen on an individual basis.

Sextant biopsy is no longer considered adequate. At a glandular volume of 30-40 mL, at least eight cores should be sampled. The British Prostate Testing for Cancer and Treatment Study has recommended 10 core biopsies (36) (LE: 2a) More than 12 cores are not significantly more conclusive (37) (LE: 1a).

6.4.5 ***Diagnostic transurethral resection of the prostate (TURP)***

The use of diagnostic TURP instead of repeat biopsies is a poor tool for cancer detection (38) (LE: 2a).

6.4.6 ***Seminal vesicle biopsy***

Indications for seminal vesicle (staging) biopsies are poorly defined. At PSA levels > 15-20 ng/mL, the odds of tumour involvement are 20-25% (39) (LE: 2a), but a biopsy is only useful if the outcome will have a decisive impact on treatment, i.e. if the biopsy result rules out radical removal for tumour involvement or radiotherapy with intent to cure.

6.4.7 ***Transition zone biopsy***

Transition zone (TZ) sampling during baseline biopsies provides a very low detection rate and TZ sampling should therefore be confined to repeat biopsies (40) (LE: 1b).

6.4.8 ***Antibiotics prior to biopsy***

Oral or intravenous antibiotics are state-of-the-art treatment. Optimal dosing and treatment time vary. Quinolones are the drugs of choice, with ciprofloxacin superior to ofloxacin (41) (LE: 1b), but in the last few years increased resistance to quinolones has been reported (42) associated with a rise in severe infectious complications after biopsy (43).

6.4.9 ***Local anaesthesia prior to biopsy***

Ultrasound-guided peri-prostatic block is state-of-the-art (44) (LE: 1b). It does not make any difference whether the depot is apical or basal. Intrarectal instillation of a local anaesthetic is clearly inferior to peri-prostatic infiltration (45) (LE: 1b).

6.4.10 ***Fine-needle aspiration biopsy***

Fine-needle aspiration biopsy is no longer state of the art.

6.4.11 ***Complications***

Complications include macrohaematuria and haematospermia (Table 5) (46). Severe post-procedural infections were initially reported in < 1% of cases, but this rate has increased in the last few years as a consequence of the evolution of antibiotic resistance strains with more post-biopsy hospitalizations for infectious complications while the rate of non-infectious complications has remained stable (43) .

Low-dose aspirin is no longer an absolute contraindication (47) (LE: 1b).

Table 5: Percentage given per biopsy session, irrespective of the number of cores*

Complications	% of biopsies
Haematospermia	37.4
Haematuria > 1 day	14.5
Rectal bleeding < 2 days	2.2
Prostatitis	1.0
Fever > 38.5°C (101.3°F)	0.8
Epididymitis	0.7
Rectal bleeding > 2 days ± requiring surgical intervention	0.7
Urinary retention	0.2
Other complications requiring hospitalization	0.3

** Adapted from NCCN Guidelines Prostate Cancer Early Detection. V.s.2010 (42).*

6.5 Pathology of prostate needle biopsies

*6.5.1 **Grossing and processing***

Prostate core biopsies taken from different sites are usually sent to the pathology laboratory in separate vials and should be processed in separate cassettes. Before processing, number of cores per vial and length of each core should be recorded. There is a significant correlation between the length of prostate biopsy tissue on the histological slide and the detection rate of PCa (48). To achieve optimal flattening and alignment of individual cores, one should embed a maximum of three cores per cassette and use sponges or paper to keep the cores stretched and flat (49,50). To optimise the detection of small lesions, blocks should be cut at three levels (40). It is helpful routinely to mount intervening tissue sections in case additional immunostaining is needed.

*6.5.2 **Microscopy and reporting***

Diagnosis of prostate cancer is based on histological examination. Ancillary staining techniques (e.g. basal cell staining) and additional (deeper) sections should be considered if a suspect lesion is identified (51-53). Diagnostic uncertainty in biopsies may often be resolved by intradepartmental consultation or a second opinion from an external institution (51). Table 6 lists recommended concise terminology to report prostate biopsies (50).

Table 6: Recommended diagnostic terms to report prostate biopsy findings*

Benign/negative for malignancy. If appropriate, include a description (e.g. atrophy).
Active inflammation, negative for malignancy
Atypical adenomatous hyperplasia/adenosis, no evidence of malignancy
Granulomatous inflammation, negative for malignancy
High-grade PIN, negative for adenocarcinoma
High-grade PIN with atypical glands suspicious for adenocarcinoma
Focus of atypical glands/lesion suspicious for adenocarcinoma/atypical small acinar proliferation suspicious for cancer
Adenocarcinoma

**From Van der Kwast, 2003 (49).*
PIN = prostatic intra-epithelial neoplasia.

For each biopsy site, the proportion of biopsies positive for carcinoma and the ISUP 2005 Gleason score should be reported (54). A recent study has demonstrated the improved concordance of pattern and change of prognostic groups for the modified Gleason grading (55). According to current international convention, the (modified) Gleason score of cancers detected in prostate biopsy consists of the Gleason grade of the dominant (most extensive) carcinoma component plus the highest grade, irrespective of its extent (no 5% rule). When the carcinoma largely consists of grade 4/5 carcinoma, identification of a small portion (< 5% of the carcinoma) of Gleason grade 2 or 3 glands should be ignored. A diagnosis of Gleason score 4, or lower, should not be given on prostate biopsies (54). The presence of intraductal carcinoma and extraprostatic extension should be reported. In addition to a report of the carcinoma features for each biopsy site, an overall Gleason score based

on findings in the individual biopsies is commonly provided.

The proportion (%) or length (mm) of tumour involvement per biopsy core correlates with tumour volume, extraprostatic extension, and prognosis after prostatectomy (56-58), and an extent of > 5 mm or > 50% of adenocarcinoma in a single core is used as a cut-off triggering immediate treatment versus active surveillance in patients with Gleason score 6 carcinoma. For these reasons a measure of the extent of cancer involvement (mm or %) should be provided for each core. Length of carcinoma and percentage of carcinoma involvement of the biopsy have equal prognostic impact (59).

The extent of a single, small focus of adenocarcinoma, which is located in only one of the biopsies, should be clearly stated (e.g. < 1 mm or < 1%), as this might be an indication for further diagnostic work-up before selecting therapy as this finding is associated with an increased risk of vanishing cancer (60-62). A prostate biopsy that does not contain glandular prostate tissue should be reported as inadequate for diagnostics, except for staging biopsies.

6.6 Pathohistology of radical prostatectomy (RP) specimens

*6.6.1 **Processing of the RP specimen***

The histopathological examination of RP specimens aims to provide information about the actual pathological stage, grade, and surgical margin status of the prostate cancer. The weight and dimensions of the specimen are recorded before embedding it for histological processing. It is generally recommended that RP specimens are totally embedded to enable the best assessment of location, multifocality, and heterogeneity of the cancer.

However, for cost-effectiveness, partial embedding using a standard method may also be considered, particularly for large prostates (> 60 g). The most acceptable method includes the complete embedding of the posterior (dorsal) part of the prostate in addition to a single mid-anterior left and right section. Compared to total embedding, this method of partial embedding permitted detection of 98% of prostate cancers with a Gleason score ≥ 7 and accurate staging in 96% of cases (63).

Upon receipt in the histopathology laboratory, the entire RP specimen is inked in order to appreciate the surgical margin status. The specimen is fixed by immersion in buffered formalin for a few days, preferably prior to incision of the sample, as incision causes distortion of the tissue. Fixation can be enhanced by injecting formalin using 21-gauge syringes, which provides a more homogeneous fixation and sectioning after 24 hours (64). After fixation, the apex is removed and cut with (para)sagittal or radial sections; the shave method is not recommended (65). Separate removal and sagittal sectioning of the bladder neck is optional. The remainder of the RP specimen is generally cut in transverse sections at 3-4 mm steps, perpendicularly to the posterior surface. The resultant tissue slices can be embedded and processed either as whole-mounts or after quadrant sectioning. Whole-mount processing provides better topographic visualisation of the carcinoma and faster histopathological examination. However, it is a more time-consuming and more expensive technique that requires specialised equipment and personnel. Although whole-mount sectioning may be necessary for research, its advantages do not outweigh its disadvantages for routine sectioning.

6.6.1.1 Recommendations for processing a prostatectomy specimen

Total embedding of a prostatectomy specimen is preferred, either by conventional (quadrant sectioning) or by whole-mount sectioning.
The entire surface of RP specimens should be inked before cutting to evaluate the surgical margin status.
The apex should be separately examined using the cone method with sagittal or radial sectioning.

*6.6.2 **RP specimen report***

The pathology report provides essential information on the prognostic characteristics relevant for making clinical decisions (Table 7). As a result of the complex information provided on each RP specimen, the use of synoptic-(like) or checklist reporting is recommended (Table 8). Synoptic reporting of surgical specimens results in more transparent and complete pathology reporting (66).

Table 7: Information provided by the pathology report

Typing (> 95% of PCa represents conventional (acinar) adenocarcinoma)
Grading according to the Gleason score
(Sub)staging and surgical margin status of the tumour
If appropriate, location and extent of extraprostatic extension, presence of bladder neck invasion, laterality of extraprostatic extension or seminal vesicle invasion, location and extent of positive surgical margins
Additional information may be provided on multifocality, diameter of the dominant tumour and zonal location (transition zone, peripheral zone, anterior horn) of the dominant tumour

Table 8: Example checklist - reporting of prostatectomy specimens

Histological type
Type of carcinoma, e.g. conventional acinar, ductal, etc.
Histological grade
Primary (predominant) grade
Secondary grade
Tertiary grade (if applicable)
Total/global Gleason score
Approximate percentage of Gleason grade 4 or 5 (optional)
Tumour quantitation (optional)
Percentage of prostatic gland involved
Tumour size of dominant nodule (if identified), greatest dimension in mm
Pathological staging (pTNM)
Presence of extraprostatic extension (indicate focal or extensive) • If present, specify site(s) • Presence of seminal vesicle invasion
If applicable, regional lymph nodes • Location • Number of lymph nodes retrieved
• Number of lymph nodes involved
Surgical margins
Presence of carcinoma at margin • If present, specify sites and extra- or intraprostatic involvement
Other
If identified, presence of angioinvasion
Location (site, zone) of dominant tumour (optional)
Perineural invasion (optional) • If present, specify extra- or intraprostatic location

6.6.2.1 Gleason score

Grading of conventional prostatic adenocarcinoma using the (modified) Gleason score system (54) is the single strongest prognostic factor for clinical behaviour and treatment response. The Gleason score is therefore one of the parameters incorporated in nomograms that predict the risk of recurrence after prostatectomy (67).

6.6.2.2 Interpreting the Gleason score

The Gleason score is the sum of the most dominant and second most dominant (in terms of volume) Gleason grade. If only one grade is present, the primary grade is doubled. If a grade comprises ≤ 5% of the cancer volume, this grade is not incorporated in the Gleason score (5% rule). Both the primary and the secondary grade are reported in addition to the Gleason score (e.g. Gleason score 7 [4 + 3]). A global Gleason score is given when there are multiple tumours, but a separate tumour focus with a higher Gleason score should also

be mentioned. A tertiary Gleason grade 4 or 5, particularly if exceeding 5% of the prostate cancer volume, is an unfavourable prognostic indicator for biochemical recurrence. The presence of the tertiary grade and its approximate proportion of the cancer volume should also be reported (68), in addition to the Gleason score.

6.6.2.3 Definition of extraprostatic extension

The TNM staging system of the International Union Against Cancer (UICC) is recommended for pathological staging of prostate carcinoma (65,69). Pathologic substaging of pT2 prostate cancer is optional, since 1) it does not correlate with clinical T2 substage and 2) it lacks prognostic significance (70).

Extraprostatic extension is the recommended term for the presence of tumour beyond the confines of the prostate. Extraprostatic extension is defined as carcinoma mixed with periprostatic adipose tissue, or bulging out beyond the contours of the prostate gland, e.g. at the neurovascular bundle or the anterior prostate. Bladder neck invasion is also considered to be an extraprostatic extension.

It is useful to report not only the location, but also the extent of extraprostatic extension because extension is related to the risk of recurrence. There are no well-established and internationally accepted definitions of the terms 'focal' and 'non-focal' or 'extensive extraprostatic extension'. Some authors describe focal as 'a few glands' (71) or extension < 1 high-power field (72), whereas others measure the depth of extent in mm (73). Currently, it is considered clinically useful to report the extent of extraprostatic extension (e.g. less or more than 1 high-power field or 1 mm) (74).

At the apex of the prostate gland, tumour mixed with skeletal muscle does not constitute extraprostatic extension. In the bladder neck, microscopic invasion of small fibres of smooth muscle is not equated to (gross) bladder wall invasion, because it does not carry independent prognostic significance for PSA recurrence (75,76) and should be recorded as extraprostatic extension (pT3a). A positive margin at the bladder neck should be reported as an extraprostatic extension (pT3a) with positive margin and not as pT4 disease. Stage pT4 can only be assigned when tumour invades the muscle wall of the bladder as determined by the urologist (77).

6.6.3 ***Prostate cancer volume***

The independent prognostic value of the volume of PCa in RP specimens has not been established (72,78-81). Nevertheless, a PCa volume cut-off of 0.5 mL continues to be an important parameter to distinguish insignificant from clinically relevant cancer (78). Continued improvement in radioimaging of the prostate gland has allowed more accurate measurement of cancer volume before surgery. Therefore, it may be recommended to assess the greatest dimension of the dominant tumour nodule, if identified, or to provide a rough estimate of the percentage of cancer tissue in the prostate .

6.6.4 ***Surgical margin status***

Surgical margin status is an independent risk factor for biochemical recurrence. Margin status is positive if tumour cells are in touch with the ink on the surface of the specimen. Margin status is negative if tumour cells are very close to the inked surface of the margin (79) or when they are at the surface of the tissue lacking any ink.

If the tissue has severe crush artifacts (usually at the apex), it may not be possible to assign a surgical margin status (82). Surgical margin status is independent of the pathological stage and a positive margin is not evidence of extraprostatic extension (83). There is insufficient evidence to prove a relationship between the extent of positive margin and the risk of recurrence (72). However, some indication must be given of the multifocality and extent of margin positivity, such as the linear extent in millimetres, or number of blocks with positive margin involvement.

6.6.5 ***Other factors***

According to the College of American Pathologists consensus statement (84), additional potential biomarkers have not been sufficiently studied to demonstrate their additional prognostic value and clinical usefulness outside the standard patient care setting (category III), including perineural invasion, neuroendocrine differentiation, microvessel density, nuclear roundness, chromatin texture, other karyometric factors, proliferation markers, prostate-specific antigen derivatives, and other factors (e.g. oncogenes, tumour suppressor genes, or apoptosis genes).

7. CLINICAL STAGING

The primary extension assessment of prostate cancer (PCa) is usually made by digital rectal examination (DRE), prostate-specific antigen (PSA) measurement, and bone scan, supplemented with computed tomography (CT) or magnetic resonance imaging (MRI) and chest X-ray in specific situations.

7.1 T-staging

The first level is the assessment of local tumour stage, where the distinction between intracapsular (T1-T2) and extraprostatic (T3-T4) disease has the most profound impact on treatment decisions. DRE often underestimates the tumour extension; a positive correlation between DRE and pathological tumour stage was found in fewer than 50% of cases (1). However, more extensive examinations for adequate T-staging are only recommended in selected cases when more precise staging directly affects the treatment decision, i.e. when curative treatment is an option.

Serum PSA levels increase with advancing stage. Nevertheless, when PSA level is measured in an individual patient, it appears to have a limited ability to predict the final pathological stage accurately. Due to the production of PSA by benign and malignant prostatic tissue, there is no direct relationship between serum PSA concentration and the clinical and pathological tumour stage (2). A combination of serum PSA level, Gleason score on prostate biopsy and clinical T-stage, however, has been proven to be more useful in predicting the final pathological stage than the individual parameters per se (3).

The ability of the molecular forms of PSA to predict T-stage is controversial and their routine measurement is not indicated (4,5). The most commonly used method for viewing the prostate is transrectal ultrasound (TRUS). However, only 60% of tumours are visible with TRUS, and the remainder are not recognised due to their isoechogenicity. In a large multi-institutional study, TRUS was no more accurate at predicting organ-confined disease than was DRE (6). These findings were supported by another large study, which showed that there was no meaningful superiority of TRUS over DRE (7). A combination of DRE and TRUS can detect T3a PCa more accurately than either method alone (8) (LE: 3).

Three-dimensional TRUS (3D-TRUS) claimed to have better staging accuracy than 2-D techniques (9).

Several adjuncts to 3D greyscale TRUS have been investigated. A greater sensitivity for cancer detection has been achieved with the addition of power colour Doppler and contrast agents (10-12). Unfortunately, all TRUS techniques remain largely operator-dependent and are not able to differentiate between T2 and T3 tumours with sufficient accuracy to be recommended for routine use in staging.

Seminal vesicle invasion is predictive of local relapse and distant failure. Seminal vesicle biopsies may be used to increase the accuracy of pre-operative staging (13). This is not recommended as a first-line examination, but should be reserved for patients with a substantial risk of seminal vesicle invasion in whom a positive seminal vesicle biopsy would modify treatment decisions. Patients with a clinical stage greater than T2a and a serum PSA level of more than 10 ng/mL could be candidates for seminal vesicle biopsies (14,15). Patients with any of the basal biopsies positive for cancer are more likely to have positive seminal vesicle biopsies (16).

Of the prostate needle biopsy parameters examined, the percentage of tissue with cancer was the strongest predictor for positive surgical margins, seminal vesicle invasion and non-organ-confined disease (17). An increased number of biopsies involved with tumour independently predicts extraprostatic extension, margin involvement and lymph node invasion (18).

In a multivariate analysis, the best risk predictors of extracapsular extension on one side were the overall average of positive biopsy cores being 15% or greater, and the average from three ipsilateral biopsies being 15% or greater. When used in combination, these two factors yielded a model with a positive predictive value of 37%, and a negative predictive value of 95%. The high negative predictive value of the side-specific model identifies patients who are good candidates for nerve-sparing surgery (19). Furthermore, it may be useful to correlate the bioptic Gleason score with the final pathological stage: about 70% of patients have localized disease when the biopsy Gleason score is ≤ 6 (20).

It has been shown that transperineal three-dimensional prostate mapping biopsy (3D-PMB) provides more accurate determination of the extent and location of tumor compared to ultrasound guided 10-12 core biopsy, with Gleason score upgrading in 27.2% and up-staging in 45.6% of cases (21). The technique improves the differentiation between clinically significant cancers and low risk disease. Unlike transrectal saturation biopsy 3D-PMB has acceptable morbidity.

Both CT and MRI are now of a high technical standard, but neither modality is sufficiently reliable to make their use mandatory in the assessment of local tumour invasion (22,23). Endorectal MRI (e-MRI) may allow for more accurate local staging by complementing the existing clinical variables by improvements in spatial characterisation of the prostatic zonal anatomy and molecular changes (24). Image quality and localisation

improves significantly with e-MRI compared with external coil MRI (25). When compared with DRE and TRUS prostate biopsy findings, e-MRI contributes significant incremental value for local PCa staging (26), particularly in the pre-operative identification of extraprostatic extension (EPE) and seminal vesicle invasion (SVI) when interpreted by dedicated genitourinary radiologists (27,28).

E-MRI could impact on the decision to preserve or resect the neurovascular bundle (NVB) at the time of radical surgery (27,29,30).

When assessed for the ability to predict organ-confined PCa, the contribution of e-MRI to staging nomograms was significant in all risk categories, but the greatest benefit was seen in the intermediate and high risk groups (31). The combination of dynamic contrast-enhanced MRI and T2-weighted MR imaging yields improved assessment of EPE and better results for PCa staging compared with either technique independently (32) (LE: 3).

MR spectroscopic imaging (MRSI) allows for the assessment of tumour metabolism by displaying the relative concentrations of citrate, choline, creatinine and polyamines. Differences in the concentrations of these chemical metabolites between normal and malignant prostate tissues allow for better tumour localization within the peripheral zone, increasing the accuracy of EPE detection among less-experienced readers, and decreasing interobserver variability (33). Furthermore, correlations have been demonstrated between the metabolic signal pattern and a pathological Gleason score, suggesting the potential for a non-invasive assessment of PCa aggressiveness (34).

Despite the proposed accuracy and benefit of e-MRI and MRSI in PCa characterisation and localisation, e-MRI has several limitations that hamper its widespread application in PCa staging, e.g. difficulties in interpreting signal changes related to post-biopsy haemorrhage and inflammatory changes of the prostate, and the unquantifiable but significant inter- and intra-observer variability seen between both non-dedicated and dedicated radiologists that may lead to under- or overestimation of tumour presence and the local extent of disease (LE: 3). The overall accuracy of ^{11}C-choline positron emission tomography (PET) in defining local tumour stage (pT2 and pT3a-4) has been reported to be around 70%. PET tends to understage PCa, and has a limited value for making treatment decisions in patients with clinically localised PCa, especially if a nerve-sparing procedure is being considered (35) (LE: 2b).

7.2 N-staging

N-staging should be performed only when the findings will directly influence a treatment decision. This is usually the case in patients for whom potentially curative treatments are planned. High PSA values, stagesT2b-T3 disease, poor tumour differentiation and peri-neural tumour invasion have been associated with a higher risk of the presence of nodal metastases (3,36,37). The measurement of PSA level alone is unhelpful in predicting the presence of lymph node metastases for an individual patient.

The nomograms could be used to define a group of patients with a low risk of nodal metastasis (< 10%, *see reference number 38*). In such cases, patients with a serum PSA level of less than 20 ng/mL, stage T2a or less, and a Gleason score of 6 or less may be spared N-staging procedures before potentially curative treatment (3).

The extent of the Gleason 4 pattern in sextant biopsies has also been used to define the risk of N1 disease. If any core had a predominant Gleason 4 pattern, or > three cores any Gleason 4 pattern, the risk of nodal metastases was found to be 20-45%. For the remaining patients, the risk was 2.5%, supporting the idea that nodal staging is unnecessary in selected patients (39).

In the current published literature, the results indicate that CT and MRI perform similarly in the detection of pelvic lymph node metastases, although CT seems to be slightly superior (40) (LE: 2a). In either case, the decision about whether nodal involvement is present rests solely on whether there is enlargement of the investigated lymph nodes A threshold of 1 cm in the short axis for the oval nodes, and 0.8 cm for the round nodes, has been recommended as the criteria for the diagnosis of lymph node metastases (41).

A fine-needle aspiration biopsy (FNAB) might provide a decisive answer in cases of positive imaging results. However, the lymph node can be difficult to reach because of the anatomical position. In addition, FNAB is not a highly sensitive staging procedure, and a false-negative rate of 40% has been reported (41).

High-resolution MRI with lymphotrophic ultra-small super-paramagnetic iron oxide particles (USPIO) was more recently suggested in the detection of small and otherwise occult lymph node metastases in patients with PCa (42,43).

In asymptomatic patients with newly diagnosed PCa and a serum PSA level of less than 20 ng/mL, the likelihood of positive findings on CT or MRI is approximately 1% (32).

CT scanning may therefore be warranted in patients with a very high risk of harbouring lymph node metastases, as the specificity of a positive scan is high (93-96%). Radio-immunoscintigraphy and PET have been investigated in order to improve the diagnosis of metastatic disease to the lymph nodes. Both methods are still under investigation, and further evaluation is needed before they can be recommended for routine use in clinical practice, especially as negative results should be interpreted with caution (44). The results obtained

using ^{18}F-choline PET/CT scans for initial N-staging were discouraging, especially in terms of inability to detect small metastases/micrometastases (< 5 mm) (45). Furthermore, ^{11}C-choline PET/CT has quite a low sensitivity for the detection of lymph node metastases, but performed better than clinical nomograms, with equal sensitivity and better specificity (46).

The gold standard for N-staging is operative lymphadenectomy, either by open or laparoscopic techniques. It is worth pointing out that recent studies with more extensive lymphadenectomy have shown that the obturator fossa is not always the primary site for metastatic deposits in the lymph nodes, and pelvic lymph node dissection that is limited to the obturator fossa will therefore miss about 50% of lymph node metastases (47,48). When deciding on pelvic lymph node dissection, extended lymphadenectomy should be considered, despite its disadvantages: it requires surgical experience; it is time-consuming; and it often leads to more complications than the limited procedures. Furthermore, it may fail to identify lymph node metastases, however present, even outside the region of extended dissection (49).

The primary removal of the so-called sentinel lymph node (SLN), defined as the first lymph node that receives lymphatic drainage from PCa, has the main aim of reducing the eventual morbidity associated with an extended pelvic node dissection, while preserving maximal sensitivity for diagnosis of metastatic disease (50) (LE: 3) (*see section 9.7 'Treatment: radical prostatectomy, indication and extent of eLND'*).

7.3 M-staging

The axial skeleton is involved in 85% of patients who die from PCa (51). The presence and extent of bone metastases accurately reflect the prognosis for an individual patient. Elevated skeletal alkaline phosphatase levels may indicate the presence of bony metastasis in 70% of affected patients (52). Furthermore, the measurement of skeletal alkaline phosphatase and PSA at the same time increases clinical effectiveness to approximately 98% (53). In a prospective study, multiple regression analysis showed the extent of bone disease to be the only variable influencing the serum levels of skeletal alkaline phosphatase and PSA. However, in contrast to serum PSA, skeletal alkaline phosphatase demonstrated a statistical correlation with the extent of bone disease (54).

Early detection of bone metastases will alert the clinician to the possible complications inherent in skeletal destruction. Bone scintigraphy remains the most sensitive method of assessing bone metastases, being superior to clinical evaluation, bone radiographs, serum alkaline phosphatase measurement and prostatic acid phosphatase (PAP) determination (55,56). Technetium diphosphonates are the optimum radiopharmaceuticals currently available because of their extremely high bone-to-soft tissue ratio (57).

Increased ^{18}F-fluoride uptake in malignant bone lesions reflects the increase in regional blood flow and bone turnover that characterise these lesions.

Studies have shown that ^{18}F-fluoride PET/CT is a highly sensitive and specific imaging modality for detection of bone metastases (58,59). However, no definitive results have been obtained and therefore no final recommendations can be made (60).

Besides bone, PCa may metastasise to any organ, but most commonly it affects distant lymph nodes, lung, liver, brain and skin. Clinical examination, chest X-ray, ultrasound, CT and MRI scans are appropriate methods of investigation, but only if symptoms suggest the possibility of soft-tissue metastasis.

The need for reliable serum markers to improve the pre-treatment staging of patients with PCa has long been recognised. At present, PSA is the marker of choice. A pre-treatment serum PSA level greater than 100 ng/mL has been found to be the single most important indicator of metastatic disease, with a positive predictive value of 100% (61). Furthermore, it has helped to reduce the number of patients with newly diagnosed PCa who require a bone scan. Patients with a low serum PSA concentration have only rarely been found to harbour detectable skeletal metastases. The correlation between serum PSA and bone scintigraphy in patients with newly diagnosed untreated PCa has been further investigated (62). Results suggest that a staging bone scan may be superfluous if the serum PSA concentration is less than 20 ng/mL in asymptomatic patients with well or moderately (up to 7: 3+4) differentiated tumours. In contrast, in patients with poorly differentiated tumours and locally advanced disease, a staging bone scan should be obtained irrespective of the serum PSA value (63).

7.4 Guidelines for the diagnosis and staging of PCa

Diagnosis of PCa - Conclusions
An abnormal digital rectal examination (DRE) result or elevated serum PSA measurement could indicate PCa. The exact cut-off level of what is considered to be a normal PSA value has yet to be determined, but values of approximately < 2-3 ng/mL are often used for younger men.
The diagnosis of PCa depends on histopathological (or cytological) confirmation.
Staging of PCa - Conclusions
Despite its high specificity in the evaluation of extraprostatic extension (EPE) and seminal vesicle invasion (SVI), TRUS has low sensitivity and a tendency to understage PCa. Even with the advent of colour power Doppler and contrast enhancement the accuracy of TRUS in local staging remains inadequate and largely operator-dependent. In comparison with DRE, TRUS and computed tomography (CT), MRI demonstrates higher accuracy for the assessment of uni- or bi-lobar disease (T2), EPE and SVI (T3), as well as the invasion of adjacent structures (T4).
Currently only sentinel lymph node dissection or extended PLND allow for histological detection of lymph node metastases with high sensitivity.

Diagnosis of PCa - Recommendations		**GR**
Biopsy and further staging investigations are only indicated if they affect the management of the patient.		C
	Transrectal ultrasound (TRUS)-guided systemic biopsy is the recommended method in most cases of suspected PCa. A minimum of 8 systemic, laterally directed, cores are recommended, with perhaps more cores in larger volume prostates.	B
	Transition zone biopsies are not recommended in the first set of biopsies due to low detection rates.	C
	One set of repeat biopsies is warranted in cases with persistent indication for PCa (abnormal DRE, elevated PSA or histopathological findings suggestive of malignancy at the initial biopsy).	B
	Overall recommendations for further (three or more) sets of biopsies cannot be made; the decision must be made based on an individual patient.	C
Transrectal peri-prostatic injection with a local anaesthetic can be offered to patients as effective analgesia when undergoing prostate biopsies.		A
Staging of PCa - Recommendations		
Local staging (T-staging) of PCa should be based on magnetic resonance (MR) imaging. Further information is provided by the number and sites of positive prostate biopsies, the tumour grade and the level of serum PSA.		C
For local staging TRUS should not be used since it has low sensitivity and a tendency to understage PCa.		
	Lymph node status (N-staging) need only be assessed when potentially curative treatment is planned. Patients with stage T2 or less, PSA < 20 ng/mL and a Gleason score ≤ 6 have a lower than 10% likelihood of having node metastases and can be spared nodal evaluation.	B
	In clinically localized PCa, staging must be done by pelvic lymph node dissection since it presents the only reliable staging method, given the significant limitations of pre-operative imaging in the detection of small metastases (< 5 mm),	
Skeletal metastasis (M-staging) is best assessed by bone scan. This may not be indicated in asymptomatic patients if the serum PSA level is < 20 ng/mL in the presence of well or moderately differentiated tumours.		B
In equivocal cases, ^{11}C-choline-, ^{18}F-flouride-PET/CT or whole body MRI are an option.		C

CT = computed tomography; DCE-MRI = dynamic contrast-enhanced MRI; DRE = digital rectal examination; EPE = extraprostatic extension; MRI = magnetic resonance imaging; MRSI = magnetic resonance spectroscopic imaging; PCa = prostate cancer; PET = positron emission tomography; PLND = pelvic lymph-node dissection; PSA = prostate-specific antigen; SVI = seminal vesicle invasion; TRUS = transrectal ultrasound.

8. TREATMENT: DEFERRED TREATMENT (WATCHFUL WAITING/ACTIVE MONITORING)

8.1 Introduction

There is a great difference between the incidence of PCa and deaths from PCa. In 2007, in the USA, there were 240,890 new cases with only 33,720 deaths (1). Several autopsy studies of people dying from different causes have shown that while 60-70% of older men have histological PCa (2), a large proportion of these tumours will not progress. Prostate cancer is diagnosed in only 15-20% of men during their lifetime, with a 3% lifetime risk of death (3).

The incidence of small, localised, well-differentiated PCa is increasing, mainly as a result of prostate-specific antigen (PSA) screening and 'multicore' schemes of prostate biopsy. These data suggest that many men with localised PCa would not actually benefit from definitive treatment. With the aim of reducing the risk of overtreatment in this subgroup of patients, two conservative management strategies of 'watchful waiting' and 'active surveillance' have been proposed.

8.1.1 *Definition*

8.1.1.1 *Watchful waiting (WW)*

Watchful waiting is also known as 'deferred treatment' or 'symptom-guided treatment'. This term was coined in the pre-PSA screening era (before 1990) and referred to the conservative management of PCa until the development of local or systemic progression. At this point, the patient would then be treated palliatively with transurethral resection of the prostate (TURP) or other procedures for urinary tract obstruction, and hormonal therapy or radiotherapy for the palliation of metastatic lesions.

8.1.1.2 *Active surveillance (AS)*

Active surveillance is also known as 'active monitoring'. It is the new term for the conservative management of PCa. Introduced in the past decade, it includes an active decision not to treat the patient immediately. Instead, the patient is followed up under close surveillance and treated at pre-defined thresholds that classify progression (i.e. short PSA doubling time and deteriorating histopathological factors on repeat biopsy). The treatment options are intended to be curative.

8.2 Deferred treatment of localised PCa (stage T1-T2, Nx-N0, M0)

8.2.1 *Watchful waiting (WW)*

The rationale behind WW is the observation that PCa often progresses slowly, and is diagnosed in older men, in whom there is a high incidence of co-morbidity and related high competitive mortality (4). Watchful waiting can be considered as an option for treating patients with localised PCa and a limited life expectancy or for older patients with less aggressive cancers.

There have been several attempts to summarise the key papers dealing with deferred treatment in patients with presumed localised PCa (5-7). Most have presented the same results, as they analyse roughly the same series, but using somewhat different methodologies. The outcome studies in WW usually included patients, whose PSA readings were not always available and who had predominantly palpable lesions that would currently be defined as intermediate-risk tumours (8). The most recent study used data from the PSA era of the Surveillance, Epidemiology and End Results (SEER) database of the National Cancer Institute in the USA (9). These studies included patients with a follow-up of up to 25 years, for whom the endpoints are overall survival (OS) and disease-specific survival (DSS).

Several WW series show a very consistent DSS ratio at 10 years, ranging from 82-87% (5,10-14), and up to 80-95% if T1-T2 Gleason $\leq$ 7 (9). In three studies with data beyond 15 years, the DSS was 80%, 79% and 58%, respectively (11,13,14). Two of them reported a 20-year DSS of 57% and 32%, respectively (11,13).

Chodak et al. reported a pooled analysis of the original data from 828 patients treated by WW (5). The paper was based on patients from six non-randomised studies and described cancer-specific survival and metastasis-free survival after 5 and 10 years of follow-up (5) (LE: 2b).

Tumour grade is clearly significant, with very low survival rates for grade 3 tumours. Although the 10-year cancer-specific rate is equally good (87%) for grade 1 and 2 tumours, the latter have a significantly higher progression rate, with 42% of these patients developing metastases (Table 9).

Table 9: Outcome of deferred treatment in localised PCa in relation to tumour grade (6): percentage of patients (95% confidence interval) surviving at 5 and 10 years

Grade	5 years (%)	10 years (%)
Disease-specific survival		
Grade 1	98 (96-99)	87 (81-91)
Grade 2	97 (93-98)	87 (80-92)
Grade 3	67 (51-79)	34 (19-50)
Metastasis-free survival		
Grade 1	93 (90-95)	81 (75-86)
Grade 2	84 (79-89)	58 (49-66)
Grade 3	51 (36-64)	26 (13-41)

The importance of tumour grade on survival after conservative management of PCa was also underlined in a large register study using the SEER database (9) (LE: 3). Patients with grade 1, 2 and 3 tumours had 10-year cancer-specific survival rates of 91%, 90% and 74%, respectively, correlating with data from the pooled analysis.

The paper by Chodak et al. also specifically described the outcome for stage T1a patients (5), with cancer-specific 10-year survival rates of 96% and 94%, respectively, for grade 1 and 2 tumours. The

metastasis-free survival rate was 92% for patients with grade 1 tumours, but 78% for those with grade 2 tumours, indicating a higher risk of progression in individuals with moderately differentiated tumours. This difference in progression rate correlates with other studies on stage T1a disease (15,16).

The impact of grade on the risk of tumour progression and ultimately death from PCa was also described in a paper by Albertsen et al. in the pre-PSA era (17). The study re-evaluated all biopsy specimens using the more widely accepted Gleason score, and showed that the risk of PCa death was very high in Gleason 7-10 tumours, intermediate in Gleason 6 tumours, but low in Gleason 2-5 cancers (Table 10) (18,19) (LE: 3).

This paper also showed that Gleason 6-10 tumours carry a continuously increasing risk of ending the patient's life for up to 15 years of follow-up after conservative management. The cancer-specific survival curves for this group of patients have been published in a recent discussion article on different methods of assessing outcome in treatment for localised PCa (18).

Table 10: The 15-year risk of dying from PCa in relation to Gleason score at diagnosis in patients with localised disease aged 55-74 years (17,18)

Gleason score	Risk of cancer death* (%)	Cancer-specific mortality† (%)
2-4	4-7	8
5	6-11	14
6	18-30	44
7	42-70	76
8-10	60-87	93

** The figures on the risk of cancer death differ for different age groups and represent the true risk in the studied population (taking actual competing mortality from other causes into consideration).*

† The cancer-specific mortality compensates for differences in competing mortality and indicates the outcome if the patient actually lived for 15 years.

Three randomised clinical trials have reported long-term follow-up of patients randomised to WW or radical prostatectomy: the first was in the pre-PSA screening era (19); the second was at the beginning of PSA screening (20); and the third was a recent study, the results of which have not yet been published (21).

Between 1967 and 1975, the Veterans Administration Cooperative Urological Research Group randomised 142 patients affected by clinical localised PCa. The study was underpowered to detect treatment differences (22).

Between 1989 and 1999, the Scandinavian Prostate Cancer Group Study Number 4 (SPCG-4) randomised 695 patients with clinical stage T1-T2 to WW (348) or radical prostatectomy (347) (Table 11) (30). This study began after PSA screening was introduced into clinical practice, but only 5% of men were diagnosed by screening. After a median follow-up of 12.8 years, this study showed a significant decrease in cancer-specific mortality, overall mortality, metastatic risk progression and local progression in patients treated with radical prostatectomy versus WW (LE: 1b).

Table 11: Outcome of Scandinavian Prostate Cancer Group Study Number 4 (SPCG-4) at 15 years of follow-up (median of 12.8 years) (20)

	RP (N = 347) % (n)	WW (N = 348) % (n)	Relative risk (95% CI)	p value
Disease-specific mortality	14.6	20.7	0.62	0.01
Overall mortality	46.1	57.2	0.75 (0.61-0.92)	0.007
Metastatic progression	21.7	33.4	0.59 (0.45-0.79)	< 0.001
Local progression	21.5	49.3	0.34 (0.26-0.45)	

RP = radical prostatectomy; WW = watchful waiting.

Subgroup analysis showed that the overall difference was not modified by PSA level (below or above 10 ng/mL) or by the Gleason score (below 7 or above) at the time of diagnosis. However, age at that the time of randomisation had a profound impact, the benefit on overall survival and metastases free survival being only seen for those below 65 years of age. The Prostate Cancer Intervention Versus Observation Trial: VA/NCI/AHRQ Cooperative Studies Program #407 (PIVOT) is an ongoing, controlled, multicentre, randomised clinical

trial comparing radical prostatectomy with WW in patients with clinical stage T1-T2 disease. Between 1994 and 2002, 731 patients with a median age of 67 years were enrolled. The median PSA was 7.8 ng/mL (mean 10.2 ng/mL). Three-quarters of the men had clinical stage T1c disease. Using previously developed tumour risk categorizations based on PSA levels, Gleason histological grade and tumour stage, approximately 43% of men had low-risk PCa, 36% had medium-risk PCa, and 20% had high-risk PCa. Follow-up is planned for 15 years, and the primary endpoint is the overall mortality. Men enrolled in PIVOT are more representative of men diagnosed and treated in everyday clinical practice than those enrolled in SPCG-4. Preliminary unpublished results have been presented at the latest AUA meeting (21). The results suggested that overall there was a lack of survival benefit. However, there appeared to be an overall survival benefit in men with an intermediate- and high-risk PCa, as well as a cancer specific survival benefit in men with high-risk PCa or with a PSA above 10 ng/mL. Full results are urgently awaited.

No data are available comparing WW and radiotherapy. Some data are available for hormonal treatment. For patients who choose deferred treatment, there appears to be a modest risk of disease progression, although shorter cancer-specific survival times have been reported after deferred therapy compared with immediate hormone therapy, in presumed localised PCa (not using PSA for staging) after 15 years of follow-up (22). In contrast to Lundgren et al. (22), the report of the Casodex Early Prostate Cancer Trialists' Group programme showed a higher mortality in a group of men with localised PCa treated with bicalutamide, 150 mg/day, than in those who received placebo (23).

Conclusions on deferred treatment	**LE**
Clinical stage T1c currently represents 40-50% of new cases of PCa (24). The incidence of small, localised, well-differentiated PCa is increasing, mainly as a result of PSA screening and 'multicore' schemes of prostate biopsy.	
The SPCG-4 study demonstrated significant advantages for RP over WW, but only 5% of those studied were PSA-screened patients.	1b
During the past 20 years, there appears to have been a shift towards higher Gleason scoring levels (25), even in cases evaluating microscopic foci of PCa. Some tumours previously given a Gleason score of 6 (3 + 3) might be scored today as 7 (3 + 4) or higher.	3
The lead time in PSA screening is about 10 years (26,27). It is therefore possible that cancer-related mortality from untreated, non-screen-detected PCa in patients with contemporary Gleason scores of 6 might be as low as 10% at 20-year follow-up (28).	2a
The comparison of immediate hormonal treatment to WW in localised PCa remain controversial and may be associated with an increased mortality with bicalutamide.	2a

It appears that many small localised well-differentiated PCas will not progress, and radical therapy may lead to substantial overtreatment with resulting effects on the patients' quality of life and treatments costs. This has been further confirmed by a recent analysis at 5 and 10 years of 19,639 patients > 65 years from the SEER database not given curative treatment. Based on comorbidities (Charlson score), most men with a Charlson score ≥ 2 died from competing causes at 10 years, whatever their initial age (below or above 65 years). However, men with no or just one comorbidity had a low risk of death at 10 years, especially for well or moderately differentiated lesions (29). In men with a Charlson score ≥ 2, tumour aggressiveness had little impact on overall survival, suggesting that perhaps these patients could have been spared the biopsies and diagnosis of cancer. This strengthens the major role of initial comorbidity evaluation, leading to an individual survival probability, before embarking an individual on any form of medical intervention such as biopsies or treatment (30).

*8.2.2 **Active surveillance***

Active surveillance was conceived with the aim of reducing the ratio of overtreatment in patients with clinically confined very low-risk PCa, without giving up radical treatment, as happens with WW. Currently, the only data available is data from non-mature randomised clinical trials of active surveillance, with a follow-up of less than 10 years. Active surveillance can therefore only be proposed for highly selected low-risk patients, particularly as the data indicate there is a significant risk of tumour progression after conservative treatment for some patients with apparently localised PCa. This conclusion is also supported by other studies, which have shown that patients with a life expectancy > 10 years have a higher mortality rate from PCa in the absence of curative treatment. These studies include the Johansson series, which showed that there is a higher risk of dying from PCa in patients surviving more than 15 years with well- and moderately differentiated tumours at diagnosis (31) (LE: 3). In the light of these findings, it is essential that a more precise selection of candidates for active

surveillance is carried out.

A multicentre clinical trial of active surveillance versus immediate treatment was opened in the USA in 2006. Its results are expected in 2025. Choo, Klotz and co-workers were the first to report on a prospective active surveillance protocol (32,33). The most advanced cohort to date was reported last year by Klotz (43). A total of 450 patients with clinical stage T1c or T2a, PSA ≤ 10 ng/mL were enrolled with an overall Gleason score ≤ 6 (PSA ≤ 15), with patients > 70 years having a Gleason score ≤ 7 [3 + 4]. Initially, six biopsies were performed, followed by the usual extended 12-core protocol during the study. At a median follow-up of 6.8 years, the 10-year overall survival was 68%. At 10 years, the disease-specific survival was 97.2%, with 62% of men still alive on active surveillance. Subsequently, 30% of patients underwent a radical treatment for the following reasons: 48% for a PSA doubling time < 3 years; 27% for Gleason score progression on repeat biopsies; and 10% because of patient preference.

A variety of additional studies on active surveillance in clinically organ confined disease (Tables 12 and 13) have now been published. All have confirmed that, in well-selected patients with very low-risk disease, there was a very low rate of progression and cancer-specific death, with only a few patients required delayed radical intervention. However, an extended follow-up is necessary to obtain definitive results. Thus, active surveillance might mean no treatment at all for patients older than 70 years, while in younger patients, it might mean a possible treatment delayed for years. The repeated biopsies that are part of active surveillance might then become important for their potential side effect on nerve preservation if surgery is subsequently considered.

Table 12: Clinical trials of AS for organ-confined PCa: inclusion criteria

	N	Median age	Criteria
Dall'Era (35)	376	62	Gleason ≤ 3+3, PSAd ≤ 0,15 ng/dL, T ≤ T2, ≤ 33% biopsies+, ≤ 50% cores
Van den Berg (36)	616	66	Gleason ≤ 3+3, PSA ≤ 10 ng/mL, PSAd ≤ 0,2 ng/dL, T≤T2, ≤ 2 biopsies +
Van As (37)	326	67	Gleason ≤ 3+4, PSA ≤ 15 ng/mL, T ≤ T2a, ≤ 50% biopsies +
Soloway (38)	230	64	Gleason ≤ 6, PSA ≤ 10 ng/dL, T ≤ T2, ≤ 2 biopsies+, ≤ 20% cores +
Klotz (34)	453	70	Gleason ≤ 6, PSA ≤ 10 ng/dL, (up to 1999: Gleason ≤ 3+4, PSA ≤ 15 ng/mL) < 3 biopsies +, < 50% each core
Tosoain (39)	633	66	Gleason ≤ 3+3, PSAd ≤ 0,15 ng/dL, T1, ≤ 2 biopsies+, ≤ 50% cores
Adamy (40)	238	64	Gleason ≤ 3+3, PSA ≤ 10 ng/mL, T ≤ T2a, ≤ 3 biopsies+, ≤ 50% length

Table 13: Clinical trials of AS for organ-confined PCa: main results

		Progression			Survival (%)		
	Median follow-up (months)	Biopsy (%)	PSA / PSA DT	Patient's request	OS	CSS	PFS
Dall'Era	47	35	5	8	97	100	54
Van den Berg	52	-	13	18	91	100	68
Van As	22	13	18	2	98	100	73
Soloway	32	10	-	-	100	100	86
Klotz	82	9	14	3	68	97	70
Tosoain	32	14	-	9	98	100	54
Adamy	22	13	14	11	-	-	-

OS = overall survival: CSS = cancer-specific survival; PFS =progression-free survival.

Different series have identified several eligibility criteria for enrolment (41):

- clinically confined PCa (T1-T2);
- Gleason score < 7 for most studies;
- PSA < 10-15 ng/mL.

Limited tumour volume is defined by a low number of involved cores and a low tumour length on each involved core. The role of other tools. e.g. MRI, to better define acceptable lesions remains controversial, except probably for anterior lesions (42). The PCA3 level may become a practical tool in the future (43).

Active surveillance is based on repeated DRE, PSA and most importantly repeated biopsies, usually every year. The place of early repeated biopsy has become an important part of the selection process, based on the risk of under-detection of grade 4 (35,40,44,45).

The criteria for active treatment are less well defined (5), but most groups have used:

- PSA doubling time with a cut-off value ranging between ≤ 2 and ≤ 4 years. This criterion is becoming questionable because of a weak link between PSA doubling time and grade progression on repeated biopsy (46).
- Gleason score progression to ≥ 7 during follow-up systematic biopsies, at intervals ranging from 1-4 years.
- Patient's request mainly based on anxiety. This is a significant factor (36) and might affect up to 10% of treated patients. No data is available regarding active surveillance. However, data from the SPCG-4 trial has suggested that, based on self-administered questionnaires 87% of the included patients), the treatment group always reported inferior well-being, depression and psychological status, but this difference was never significant (47).

8.3 Deferred treatment for locally advanced PCa (stage T3-T4, Nx-N0, M0)

The literature reporting on deferred treatment for locally advanced PCa is sparse. There are no randomised studies that compare more aggressive treatments, such as radiotherapy or surgery, with or without hormones.

Most patients whose disease progresses after deferred treatment of locally advanced PCa will be candidates for hormone therapy. There are reports from non-randomised studies showing that hormone treatment may safely be delayed until metastatic progression occurs, as no survival advantage was noted between patients treated with immediate orchiectomy compared with delayed treatment (48,49).

In a recent prospective randomised clinical phase III trial (EORTC 30981), 985 patients with T0-4 N0-2 M0 PCa were randomly assigned to immediate androgen-deprivation therapy (ADT) or received ADT only on symptomatic disease progression or occurrence of serious complications (50,51). After a median follow-up of 7.8 years, the overall survival hazard ratio was 1.25 (95% confidence interval [CI]: 1.05-1.48; non-inferiority $p > 0.1$) favouring immediate treatment, seemingly due to fewer deaths of non-prostatic cancer causes ($p = 0.06$). The time from randomisation to progression of hormone-refractory disease did not differ significantly nor did prostate cancer-specific survival. The median time to the start of deferred treatment after study entry was 7 years. In this group, 126 patients (25.6%) died without ever needing treatment (44% of deaths in this arm). The conclusion drawn from this study is that immediate ADT resulted in a modest but statistically significant increase in overall survival, but no significant difference in PCa mortality or symptom-free survival. This raises the question of the usefulness of such a small statistical benefit.

Furthermore, the authors identified significant risk factors associated with a significantly worse outcome: in both arms. Patients with a baseline PSA > 50 ng/mL were at a > 3.5-fold higher risk of dying of PCa than patients with a baseline PSA ≤ to 8 ng/mL. If the baseline PSA was between 8 ng/mL and 50 ng/ mL, the risk of PCa death was approximately 7.5-fold higher in patients with a PSA doubling time < 12 months than in patients with a PSA doubling time > 12 months. The time to PSA relapse following a response to immediate ADT correlated significantly with baseline PSA, suggesting that baseline PSA may also reflect disease aggressiveness.

However, when early and delayed treatments were compared in a large randomised trial carried out by the Medical Research Council (MRC), a survival benefit for immediate hormone therapy was demonstrated (62), comparable with the results of the Lundgren et al. study mentioned above (22) (LE: 1b). In addition, a comparison of bicalutamide, 150 mg/day, with placebo showed that progression-free survival (PFS) was better with early treatment in patients with locally advanced PCa (23) (LE: 1b).

Fifty selected asymptomatic patients (mean age 71 years) with highly or moderately differentiated stage T3 M0 PCa were followed up for 169 months (53). The 5- and 10-year cancer-specific survival rates were 90% and 74%, respectively, and the likelihood of being without treatment at 5 and 10 years was 40% and 30%, respectively. The authors concluded that WW might be a treatment option for selected patients with non-poorly differentiated T3 tumours and a life expectancy of less than 10 years (LE: 3).

8.4 Deferred treatment for metastatic PCa (stage M1)

There are only very sparse data on this subject. The only candidates for such treatment should be asymptomatic patients with a strong wish to avoid treatment-related side-effects (LE: 4). As the median survival time is about 2 years, the time without any treatment (before symptoms occur) is very short in most cases. The MRC trial highlighted the risk of developing symptoms (pathological fractures, spinal cord compression), and even death from PCa, without receiving the possible benefit from hormone treatment (52,54) (LE:1b). If a deferred treatment policy is chosen for a patient with advanced PCa, close follow-up must be possible.

8.5 Summary of deferred treatment for prostate cancer

8.5.1 ***Indications***	**LE**
In presumed localised PCa (Nx-N0, M0):	
Stage T1a: well and moderately differentiated tumours. In younger patients with a life expectancy of more than 10 years, re-evaluation with PSA, TRUS and biopsies of the prostatic remnant is recommended.	2a
Stage T1b-T2b: well and moderately differentiated tumours. In asymptomatic patients with a life expectancy of < 10 years.	2a
Active surveillance	2a
In patients with the lowest risk of cancer progression: cT1-2a, PSA ≤ 10 ng/mL, biopsy Gleason score ≤ 6 (at least 10 cores), ≤ 2 positive biopsies, minimal biopsy core involvement (≤ 50% cancer per biopsy).	
Active surveillance selection is based on confirmatory biopsies.	
Follow-up is based on DRE, PSA and repeated biopsies. The optimal timing for follow-up is still unclear (yearly or every 2 years).	
The trigger for patients being moved off active treatment is based mainly on grade progression on repeated biopsies or at the patient's request.	
PSA progression is controversial.	
8.5.2 ***Options***	
In presumed localised PCa (Nx-N0, M0):	
Stage T1b-T2b patients who are well informed and have well-differentiated PCa and a life expectancy of 10-15 years.	
All patients not willing to accept side-effects of active treatment.	
Well-informed, asymptomatic patients with high PSA levels for whom cure is unlikely.	3
In locally advanced disease (stage T3-T4):	
Asymptomatic patients with well or moderately differentiated cancer, PCa and a short life expectancy.	3
PSA < 50 ng/mL and PSA doubling time > 12 months.	1
In metastatic disease (M1):	
A very rare patient without any symptoms and the possibility of close follow-up.	4

9. TREATMENT: RADICAL PROSTATECTOMY

9.1 Introduction

The surgical treatment of prostate cancer (PCa) consists of radical prostatectomy (RP), which involves removal of the entire prostate gland between the urethra and bladder, and resection of both seminal vesicles, along with sufficient surrounding tissue to obtain a negative margin. Often, this procedure is accompanied by bilateral

pelvic lymph node dissection. In men with localised PCa and a life expectancy ≥ 10 years, the goal of RP by any approach must be eradication of disease, while preserving continence and whenever possible potency (1). There is no age threshold for RP and a patient should not be denied this procedure on the grounds of age alone (2). Increasing comorbidity greatly increases the risk of dying from non-PCa-related causes (3). An estimation of life expectancy is paramount in counselling a patient about surgery (4).

RP was first applied at the beginning of the 20th century by Young (5) using a perineal approach, while Memmelaar and Millin were the first to perform retropubic RP (6). In 1982, Walsh and Donker described the anatomy of the dorsal venous complex and the neurovascular bundles (NVBs). This resulted in a significant reduction in blood loss and improved continence and potency rates (7). Currently, RP is the only treatment for localised PCa to show a benefit for cancer-specific survival (CSS), compared with conservative management, as shown in a prospective randomised trial (8). Surgical expertise has decreased the complication rates of RP and improved cancer cure (9-12).

Total surgical removal is an excellent treatment option in well-selected patients with localised PCa. If performed by an experienced surgeon, the patient's subsequent quality of life should be satisfactory. Lower rates of positive surgical margins for high-volume surgeons suggest that experience and careful attention to surgical details, adjusted for the characteristics of the cancer being treated, can decrease positive surgical margin rates and improve cancer control with RP (13,14).

Radical retropubic prostactectomy (RRP) and perineal prostatectomy are performed through open incisions, and more recently, minimally invasive laparoscopic radical prostatectomy (LRP) and robot-assisted laparoscopic prostatectomy (RALP) have been developed. RALP is displacing RRP as the gold standard surgical approach for clinically localised prostate cancer in the United States and is also being increasingly used in Europe and other parts of the world. This trend has occurred despite the paucity of high-quality evidence to support its relative superiority to more-established treatment modalities. Recent in-depth systematic reviews of the literature have compared the results of RRP versus LRP/RALP. It has been concluded that LRP and RALP are followed by significantly lower blood loss and transfusion rate, but the available data are not sufficient and of insufficient quality to prove the superiority of any surgical approach in terms of functional and oncological outcomes (15-17).

9.2 Low-risk, localised prostate cancer: cT1-T2a and Gleason score 2-6 and prostate-specific antigen < 10 ng/mL

Patients with low-risk, localised PCa should be informed about the results of the randomised trial comparing retropubic RP versus watchful waiting (WW) in localised PCa (8). In this study, the survival benefit was similar before and after 9 years of follow-up, was observed also among men with low-risk PCa, and was confined to men < 65 years of age. The number needed to treat to avert one death was 15 overall and seven for men < 65 years of age.

*9.2.1 **Stage T1a-T1b prostate cancer***

Stage T1a PCa is defined as an incidental histological finding of cancer in ≤ 5% of resected prostatic tissue [transurethral resection of the prostate (TURP) or open adenomectomy]. Stage T1b PCa is defined as > 5% cancer. Published series have shown a pT0 stage in 4-21% and an organ-confined stage in 47-85% of patients at subsequent RP (18).

A Swedish register-based study of 23,288 men with incidental PCa detected at TURP or open adenoma enucleation, mostly before the prostate-specific antigen (PSA) era, showed a 10-year PCa mortality of 26.6%. There were no details of the PSA level or Gleason score nor the numbers of cases with cT1a or cT1b PCa (19). Other older studies have shown that, even though the risk of disease progression of untreated T1a PCa after 5 years is only 5%, these cancers can progress in about 50% of cases after 10-13 years (20). Thus, it was believed that, in younger patients with a life-expectancy of ≥ 15 years, the chance of disease progression was real. In contrast, most patients with T1b tumours were expected to show disease progression after 5 years, and aggressive treatment was often warranted (20). Patients with T1b lesions were offered RP when they had a life expectancy of ≥ 10 years.

Nevertheless, it remains unclear whether these findings would still be valid in the PSA era. In a recent analysis of T1a/b PCa:

- The only significant predictors of the presence of residual cancer at RRP were PSA measured before and after surgery for BPH and Gleason score at surgery for BPH.
- The only independent predictors of biochemical recurrence after RRP were PSA measured after surgery for BPH and Gleason score at surgery for BPH.
- The stage (cT1a or cT1b) lost its significance in predicting the above-mentioned outcomes.

A predictive model has been proposed, which incorporates the PSA level before and after surgery and the Gleason score at surgery for BPH. The model has a predictive accuracy of 83.2% for estimating residual tumour and 87.5% for estimating biochemical progression, but needs external validation before it can be used in daily practice (18).

Systematic prostate biopsies of the remnant prostate may be useful in detecting residual cancer or concomitant peripheral zone cancer, or to ascertain a more correct tumour grade. RP may be difficult after thorough TURP, when almost no residual prostate is left behind (21).

9.2.2 ***Stage T1c and T2a prostate cancer***

Clinically unapparent tumour identified by needle biopsy because of an elevated PSA (cT1c) has become the most prevalent type of PCa. In an individual patient, it is difficult to differentiate between clinically insignificant and life-threatening PCa. Most reports, however, stress that cT1c tumours are mostly significant and should not be left untreated because up to 30% of cT1c tumours are locally advanced at final histopathological analysis (22). The proportion of insignificant tumours varies between 11% and 16% (23,24). Increasing the number of biopsies may carry the risk of detecting a higher number of insignificant cancers. However, a recent study has shown that increasing the number of biopsies to 12 did not increase the number of insignificant tumours (25). The major problem is how to recognise those tumours that do not need RP. The biopsy findings and the free PSA ratio are helpful in predicting insignificant disease (26). Partin tables may help better selection of patients who require surgical treatment, because of their ability to provide an estimation of the final pathological stage (27). Other authors have suggested the incorporation of biopsy information, such as the number of cores or the percentage of cores invaded (28). When only one or a few cores are invaded and the percentage of invasion in one core is limited, the chance of finding an insignificant PCa is more likely, certainly when the lesion is of low Gleason grade (29). It might be reasonable to follow up some patients whose tumours are most likely to be insignificant.

In general, however, RP should be advocated for patients with T1c tumours, bearing in mind that significant tumours will be found in most of these individuals. Stage T2a patients with a 10-year life expectancy should be offered RP because 35-55% of them will have disease progression after 5 years if not treated. If active monitoring is proposed for low-grade T2 cancer, it should be remembered that preoperative assessment of tumour grade by needle biopsy is often unreliable (30).

Extended pelvic lymph node dissection (eLND) is not necessary in low-risk, localised PCa, because the risk for positive lymph nodes does not exceed 5% (31).

9.3 Intermediate-risk, localised prostate cancer: cT2b-T2c or Gleason score = 7 or prostate-specific antigen 10-20 ng/mL

Patients with intermediate-risk, localised PCa should be informed about the results of the randomised trial comparing RRP versus WW in localised PCa (8). In this study, the survival benefit was similar before and after 9 years of follow-up and was confined to men < 65 years of age. The number needed to treat to avert one death was 15 overall and seven for men < 65 years of age.

RP is one of the recommended standard treatments for patients with intermediate-risk PCa and a life expectancy of > 10 years (32). The prognosis is excellent when the tumour is confined to the prostate, based on pathological examination (33,34). A policy of WW has been proposed for some patients with intermediate-risk localised tumours (35). However, when the tumour is palpable or visible on imaging and clinically confined to the prostate, disease progression can be expected in most long-term survivors.

The median time to progression of untreated T2 disease has been reported as 6-10 years. Stage T2b cancer confined to the prostate, but involving more than half a lobe or both lobes, will progress in > 70% of patients within 5 years (36). These data have been confirmed by a large randomised trial comparing RP and WW that included mostly T2 PCa patients, with a significant reduction in disease-specific mortality in favour of RP (8).

eLND should be performed in intermediate-risk, localised PCa if the estimated risk for positive lymph nodes exceeds 5% (31). In all other cases, eLND can be omitted, which means accepting a low risk of missing positive nodes. Limited LND should no longer be performed, because this misses at least half of the nodes involved.

9.3.1 ***Oncological results of radical prostatectomy in low- and intermediate-risk prostate cancer***

The results achieved in a number of studies involving RP are shown in Table 14.

Table 14: Oncological results of RP in organ-confined disease

Reference	No. of patients	Year of RP	Median follow-up (mo)	10-year PSA-free survival (%)	10-year cancer-specific survival (%)	15-year cancer-specific survival (%)	25-year cancer-specific survival (%)

Stephenson et al. (42)	6398	1987-2005	48			88	

The first externally validated nomogram predicting PCa-specific mortality after RP for patients treated in the PSA era was published recently. The nomogram predicts that few patients die from PCa within 15 years of RP, despite the presence of adverse clinical features. This nomogram can be used in patient counselling and clinical trial design (42).

9.4 High-risk, localised prostate cancer: cT3a or Gleason score 8-10 or prostate-specific antigen > 20 ng/mL

The widespread use of PSA testing has led to a significant migration in stage and grade of PCa, with > 90% of men in the current era diagnosed with clinically localised disease (27). Despite the trends towards lower-risk PCa, 20-35% of patients with newly diagnosed PCa are still classified as high risk, based on either PSA > 20 ng/mL, Gleason score > 8, or an advanced clinical stage (43). Patients classified with high-risk PCa are at an increased risk of PSA failure, the need for secondary therapy, metastatic progression and death from PCa. Nevertheless, not all high-risk patients have a uniformly poor prognosis after RP (44).

There is no consensus regarding the optimal treatment of men with high-risk PCa. Decisions on whether to elect surgery as local therapy should be based on the best available clinical evidence. Provided that the tumour is not fixed to the pelvic wall, or that there is no invasion of the urethral sphincter, RP is a reasonable first step in selected patients with a low tumour volume. Management decisions should be made after all treatments have been discussed by a multidisciplinary team (including urologists, radiation oncologists, medical oncologists and radiologists), and after the balance of benefits and side effects of each therapy modality has been considered by the patients with regard to their own individual circumstances.

*9.4.1 **Locally advanced prostate cancer: cT3a***

Stage T3a cancer is defined as cancer that has perforated the prostate capsule. In the past, locally advanced PCa was seen in about 40% of all clinically diagnosed tumours. This figure is lower today, although its management remains controversial. Surgical treatment of clinical stage T3 PCa has traditionally been discouraged (45), mainly because patients have an increased risk of positive surgical margins and lymph node metastases and/or distant relapse (46,47). Several randomised studies of radiotherapy combined with androgen-deprivation therapy (ADT) versus radiotherapy alone have shown a clear advantage for combination treatment, but no trial has ever proven combined treatment to be superior to RP (48). Another problem is "contamination" by the additional use of either adjuvant radiotherapy or immediate or delayed hormonal therapy (HT) in most series reporting the treatment of clinical T3 PCa. In recent years, there has been renewed interest in surgery for locally advanced PCa, and several retrospective case series have been published. Although still controversial, it is increasingly evident that surgery has a place in treating locally advanced disease (49-54).

Over-staging of cT3 PCa is relatively frequent and occurs in 13-27% of cases. Patients with pT2 disease and those with specimen-confined pT3 disease have similarly good biochemical and clinical

progression-free survival (PFS) (53,54). In 33.5-66% of patients, positive section margins are present, and 7.9-49% have positive lymph nodes (55). Thus, 56-78% of patients primarily treated by surgery eventually require adjuvant or salvage radiotherapy or HT (53,54). Nevertheless, excellent 5-, 10- and 15-year overall survival (OS) and cancer-specific survival (CSS) rates have been published (Table 15). These rates surpass radiotherapy-alone and are no different from radiotherapy combined with adjuvant HT (48).

The problem remains the selection of patients before surgery. Nomograms, including PSA level, stage and Gleason score, can be useful in predicting the pathological stage of disease (27,55). In addition, nodal imaging with computed tomography (CT), and seminal vesicle imaging with magnetic resonance imaging (MRI), or directed specific puncture biopsies of the nodes or seminal vesicles can help to identify those patients unlikely to benefit from a surgical approach (56). RP for clinical T3 cancer requires sufficient surgical expertise to keep the level of morbidity acceptable. Increased overall surgical experience must contribute to decreased operative morbidity and to better functional results after RP for clinical T3 cancer (53,57). It has been shown that continence can be preserved in most cases, and in selected cases, potency can also be preserved (58).

Table 15: OS and CSS rates for PCa.

Reference	no. of patients	Median and/or mean follow-up	BPFS (%)			CSS (%)		
			5 years	10 years	15 years	5 years	10 years	15 years
Yamada *et al*. (1994) (49)	57	Median, 5.4 years	45.5 (PSA > 0.4)	-	-	-	-	-
Gerber *et al*. (1997) (50)	242	Mean, 39 months Median, 26 months	-	-	-	85	57	-

Hsu *et al*. (2007) (54)	200	Mean, 70.6 months (cT3a only)	59.5 (PSA > 0.2)	51.1	-	99	92	-

BPFS = biochemical progression-free survival

*9.4.2 **High-grade prostate cancer: Gleason score 8-10***

Although most poorly differentiated tumours extend outside the prostate, the incidence of organ-confined disease is 26-31%. Patients with high-grade tumours confined to the prostate at histopathological examination still have a good prognosis after RP. Furthermore, one-third of patients with a biopsy Gleason score ≥ 8 may in fact have a specimen Gleason score ≤ 7 with better prognostic characteristics. The PSA value and percentage of positive prostate biopsies may help to select men with high-grade PCa who are most likely to benefit from RP (59).

*9.4.3 **Prostate cancer with prostate-specific antigen > 20 ng/mL***

Yossepowitch et al. have reported the results of RP as monotherapy in men with PSA > 20 ng/mL, in a cohort with mostly clinically organ-confined tumours, and found a PSA failure rate of 44% and 53% at 5 and 10 years, respectively (44). D'Amico et al. found that men with PSA levels > 20 ng/mL had a 50% risk of PSA failure at 5 years after RP (60). Spahn et al. published the largest multicentre clinical series of its kind, comprising 712 patients with PSA > 20 ng/mL, and reported a CSS of 90% and 85% at 10 and 15 years follow-up, respectively (61). In the same analysis, they demonstrated that the combination of PSA > 20 ng/mL with cT3 stage and/or biopsy Gleason score 8-10 significantly lowered CSS. More recently, Gontero and co-workers described a subanalysis of the same patient cohort. Ten-year CSS was 80%, 85% and 91% in patients with PSA > 100 ng/mL, 50.1-100 ng/mL and 20.1-50 ng/mL, respectively. These results argue for aggressive management with RP as the initial step (62).

eLND should be performed in all high-risk cases, because the estimated risk for positive lymph nodes is 15-40% (31). Limited LND should no longer be performed, because it misses at least half the nodes involved.

9.5 Very-high-risk, localised prostate cancer: cT3b-T4 N0 or any T, N1

9.5.1 ***cT3b-T4 N0***

Men with very-high-risk PCa generally have a significant risk of disease progression and cancer-related death if left untreated. Very-high-risk PCa presents two specific challenges. There is a need for local control as well as treatment of any microscopic metastases that are likely to be present but undetectable until disease progression.

The optimal treatment approach therefore often necessitates multiple modalities. The exact combinations, timing and intensity of treatment continue to be strongly debated. A recent US study has shown that 72 patients who underwent RP for cT4 disease had better survival than those who received HT or radiotherapy alone, and comparable survival to men who received radiotherapy plus HT (63). Another study has compared the outcomes of RP in very-high-risk PCa (T3-T4 N0-N1, N1, M1a) with those in localised PCa. The two groups did not differ significantly in surgical morbidity except for blood transfusion, operative time, and lymphoceles, which showed a higher rate in patients with advanced disease. OS and CSS at 7 years were 76.69% and 90.2% in the advanced disease group and 88.4% and 99.3% in the organ-confined disease group, respectively (64).

Provided that the tumour is not fixed to the pelvic wall, or there is no invasion of the urethral sphincter, RP is a reasonable first step in selected patients with very-high-risk PCa and low tumour volume. Management decisions should be made after all treatments have been discussed by a multidisciplinary team (including urologists, radiation oncologists, medical oncologists and radiologists), and after the balance of benefits and side effects of each therapy modality has been considered by the patients with regard to their own individual circumstances.

9.5.2 ***Any T, N1***

The indication for RP in all previously described stages assumes the absence of clinically detectable nodal involvement. Lymph-node-positive (N+) disease will mostly be followed by systemic disease progression, and all patients with significant N+ disease ultimately fail treatment.

Nevertheless, the combination of RP and early adjuvant HT in N+ PCa has been shown to achieve a 10-year CSS rate of 80% (65,66). Most urologists are reluctant to perform RP for clinical N+ disease, or cancel surgery if a frozen section shows lymph node invasion. However, a recent study has shown a dramatic improvement in CSS and OS in favour of completed RP versus abandoned RP in patients who were found to be N+ at the time of surgery. These results suggest that RP may have a survival benefit and the abandonment of RP in N+ cases may not be justified (67). These findings have been corroborated in a contemporary series (68). RP resulted in superior survival of patients with N+ PCa after controlling for lymph node tumour burden. The findings from these studies support the role of RP as an important component of multimodal strategies of N+ PCa.

It should also be noted that definitive pathological examination after RP could show microscopic lymph node invasion. The incidence of tumour progression is lower in patients with fewer positive lymph nodes and in those with microscopic invasion only (69,70). In patients who prove to be pN+ after RP, early adjuvant HT has been shown to improve CSS and OS significantly in a prospective randomised trial. However, this trial included mostly patients with high-volume nodal disease and multiple adverse tumour characteristics. It is unclear whether early adjuvant HT should still be used in the present era of increased detection of microscopic involvement as a result of more eLND. The benefits should be judged against the side effects of long-term HT. Follow-up of PSA and HT in patients with increased PSA level is therefore an acceptable option in selected cases. Interestingly, maximal local control with radiotherapy of the prostatic fossa appears to be beneficial in PCa patients with pN+ after RP, treated adjuvantly with continuous ADT (71).

9.6 Indication and extent of extended pelvic lymph node dissection

Although it is generally accepted that eLND provides important information for prognosis (number of nodes involved, tumour volume within the lymph node, and capsular perforation of the node) that cannot be matched by any other current procedure, consensus has not been reached about when eLND is indicated and to what extent it should be performed. When making such decisions, many physicians rely on nomograms based on preoperative biochemical markers and biopsies (27).

According to these nomograms, patients with PSA < 10 ng/mL and biopsy Gleason score < 7 have a low risk of lymph node metastasis, and therefore, eLND might not be beneficial. However, the fact that most nomograms are based on a limited eLND (obturator fossa and external iliac vein) probably results in underestimation of the incidence of patients with positive nodes (31). Lymphography studies have shown that the prostate drains not only to the obturator and external iliac lymph nodes but also to the internal iliac and

presacral nodes. Performing eLND results in removal of all lymph nodes in these particular anatomical regions, producing a higher yield of excised lymph nodes (mean: 20 nodes) compared with limited LND (mean: 8-10 nodes).

In patients with PSA < 10 ng/mL and Gleason score ≥ 7, the incidence of nodal involvement has been reported as 25% (72). Different reports mention that 19-35% of positive lymph nodes are found exclusively outside the area of the traditionally limited LND (73,74). Clearly, the removal of a greater number of nodes results in improved staging. In the largest study of its kind, a cut-off ≤ 2 versus > 2 affected nodes was shown to be an independent predictor of CSS (69).

9.6.1 ***Conclusions***

Extended LND is not necessary in low-risk, localised PCa, because the risk for positive lymph nodes does not exceed 5% (31).

Extended LND should be performed in intermediate-risk, localised PCa if the estimated risk for positive lymph nodes exceeds 5%, as well as in high-risk cases. In these circumstances, the estimated risk for positive lymph nodes is 15-40% (31). Limited LND should no longer be performed, because it misses at least half the nodes involved.

9.6.2 ***Extent of extended lymph node dissection***

Extended LND includes removal of the nodes overlying the external iliac artery and vein, the nodes within the obturator fossa located cranially and caudally to the obturator nerve, and the nodes medial and lateral to the internal ileac artery. Some lymph node mapping studies have advocated extending the template to include the common iliac lymph nodes up to the ureteric crossing. With this template, 75% of all anatomical landing sites are cleared (75). For eLND to be representative, a mean of 20 lymph nodes should be removed (76). It is recommended that the nodes should be sent in separate containers for each region for histopathological analysis, because this will usually be associated with a higher diagnostic gain by the uropathologist.

9.6.3 ***Therapeutic role of extended lymph node dissection***

Besides being a staging procedure, pelvic LND/eLND can be curative, or at least beneficial, in a subset of patients with limited lymph node metastases (77-79). In some series, the number of nodes removed during lymphadenectomy has correlated significantly with time to progression (80). In one population-based study with a 10-year follow-up, patients undergoing excision of at least four lymph nodes (node-positive and node-negative patients) or > 10 nodes (only node-negative patients) had a lower risk of PCa-specific death at 10 years than those who did not undergo lymphadenectomy (81). Further studies should confirm these results.

9.6.4 ***Morbidity***

Pelvic eLND remains a surgical procedure that increases morbidity in the treatment of PCa. When comparing extended versus limited LND, threefold higher complication rates have been reported by some authors (82). Complications consist of lymphocoeles, lymphoedema, deep venous thrombosis, and pulmonary embolism. Other authors, however, have reported more acceptable complication rates (83,84).

9.6.5 ***Conclusions extended lymph node dissection***

Extended LND may play a role in the treatment of a subset of intermediate-risk cases with > 5% nomogram predicted risk of positive lymph nodes, and in all high-risk cases.
Extended LND may increase staging accuracy and influence decision making with respect to adjuvant therapy. The number of lymph nodes removed correlates with time to progression.
Surgical morbidity must be balanced against the therapeutic effects, and decisions need to be made based on individual cases.

9.7 Summary of radical prostatectomy in high-risk localised disease

RP is a reasonable treatment option in selected patients with cT3a PCa, Gleason score 8-10 or PSA > 20. Furthermore, RP is optional in highly selected patients with cT3b-4 N0 or any cT N1 PCa in the context of a multimodality approach.
Management decisions should be made after all treatments have been discussed by a multidisciplinary team (including urologists, radiation oncologists, medical oncologists and radiologists), and after the balance of benefits and side effects of each therapy modality has been considered by the patients with regard to their own individual circumstances.

If RP is performed, pelvic eLND must be performed, because lymph node involvement is common.
The patient must be informed about the likelihood of a multimodal approach. In case of adverse tumour characteristics (positive section margin, extraprostatic extension, or seminal vesicle invasion), adjuvant radiotherapy may reasonably be used after recuperation from surgery.
When nodal involvement is detected after surgery, adjuvant ADT may be selected.

9.8 Neoadjuvant hormonal therapy and radical prostatectomy

Neoadjuvant or up-front HT is defined as therapy given before definitive local curative treatment (e.g., surgery or radiotherapy). PCa is an androgen-dependent tumour, therefore, neoadjuvant hormonal therapy (NHT) is an appealing concept. Attempts to decrease the size of the prostate before RP were first reported by Vallett as early as 1944 (85). In a recent review and meta-analysis, the role of NHT and prostatectomy has been studied (86). NHT before prostatectomy did not improve OS or disease-free survival (DFS), but did significantly reduce positive margin rates [relative risk (RR): 0.49; 95% confidence interval (CI): 0.42-0.56, $P < 0.00001$), organ confinement (RR: 1.63; 95% CI: 1.37-1.95, $P < 0.0001$) and lymph node invasion (RR: 0.49; 95% CI: 0.42-0.56, $P < 0.02$). Thus, the absence of improvement in clinically important outcomes (OS, disease-specific survival or biochemical DFS) was demonstrated despite improvements in putative pathological surrogate outcomes, such as margin-free positive status. This calls into question the use of these pathological markers of treatment outcomes as valid surrogates for clinically relevant outcomes.

Further studies are needed to investigate the application of HT as both neoadjuvant treatment and with chemotherapy in early disease. More information is also needed to evaluate these agents in terms of side effects and quality of life, which was lacking in most studies presented in this review.

Further cost analyses should be undertaken to update the data. A recent Cochrane review and meta-analysis have studied the role of adjuvant HT following RP: the pooled data for 5-year OS showed an odds ratio (OR) of 1.50 and 95% CI: 0.79-2.84. This finding was not statistically significant, although there was a trend favouring adjuvant HT. Similarly, there was no survival advantage at 10 years. The pooled data for DFS gave an overall OR of 3.73 and 95% CI: 2.3-6.03. The overall effect estimate was highly significant ($P < 0.00001$) in favour of the HT arm.

It is noteworthy that the Early Prostate Cancer Trialists' Group (EPC) trial was not included in the Cochrane review. The third update from this large randomised trial of bicalutamide, 150 mg once daily, in addition to standard care in localised and locally advanced, non-metastatic PCa was published in November 2005 (87). Median follow-up was 7.2 years. There was a significant improvement in objective PFS in the RP group. This improvement was only significant in the locally advanced disease group [hazard ratio (HR): 0.75; 95% CI: 0.61-0.91]. There was no significant improvement in OS in the RP-treated groups (localised and locally advanced disease). In the WW group, there was an OS trend in favour of WW alone in the localised disease group (HR: 1.16; 95% CI: 0.99-1.37).

*9.8.1 **Summary of neoadjuvant and adjuvant hormonal treatment and radical prostatectomy***

NHT before RP does not provide a significant OS advantage over prostatectomy alone.
NHT before RP does not provide a significant advantage in DFS over prostatectomy alone.
NHT before RP does substantially improve local pathological variables such as organ-confined rates, pathological down-staging, positive surgical margins, and rate of lymph node involvement.
Adjuvant HT following RP shows no survival advantage at 10 years.
Adjuvant HT following RP: the overall effect estimate for DFS is highly significantly ($P < 0.00001$) in favour of the HT arm.

9.9 Complications and functional outcome

The postoperative complications of RP are listed in Table 16. The mortality rate is 0-1.5% (81); urinary fistulas are seen in 1.2-4% of patients (88); and urinary incontinence persists after 1 year in 7.7% (89). In men undergoing prostatectomy, the rates of postoperative and late urinary complications are significantly reduced if the procedure is performed in a high-volume hospital and by a surgeon who performs a large number of such procedures (90-92).

Erectile dysfunction used to occur in nearly all patients, but this can be avoided by using nerve-sparing techniques in early-stage disease (93). Patients who benefit from nerve-sparing RP may have a higher chance of local disease recurrence and should therefore be selected carefully.

Table 16: Complications of RP

Complication	Incidence (%)
Perioperative death	0.0-2.1
Major bleeding	1.0-11.5
Rectal injury	0.0-5.4
Deep venous thrombosis	0.0-8.3
Pulmonary embolism	0.8-7.7
Lymphocoele	1.0-3.0
Urine leak, fistula	0.3-15.4
Slight stress incontinence	4.0-50.0
Severe stress incontinence	0.0-15.4
Impotence	29.0-100.0
Bladder neck obstruction	0.5-14.6
Ureteral obstruction	0.0-0.7
Urethral stricture	2.0-9.0

9.10 Summary of indications for nerve-sparing surgery* (100-104)

Reference name	Sofer (94)	Walsh (95)	Alsikafi (96)	Graefen (97)	Bianco (98)
Preoperative selection criteria					
Stage > T2	+	+	+	+	+
PSA > 10	+				
Biopsy Gleason score 7			+		
Biopsy Gleason score 8-10	+			+	
Partin tables		+			+
Side with > 50% tumour in biopsy			+		
Side with perineural invasion		+/-	+		
Intra-operative selection criteria					
Side of palpable tumour			+		
Side of positive biopsy				+	
Induration of lateral pelvic fascia		+			+
Adherence to neurovascular bundles		+			+
Positive section margins	**24%**	**5%**	**11%**	**15.9%**	**5%**

**Clinical criteria used by different authors when NOT to perform a nerve-sparing RP*

Nerve-sparing RP can be performed safely in most men undergoing RP (99,100). In the past decade, a dramatic shift towards lower-stage tumours has become evident. More importantly, men are younger at the time of diagnosis and more interested in preserving sexual function. Nevertheless, clear contraindications are patients in whom there is a high risk of extracapsular disease, such as any cT3 PCa, cT2c, any Gleason score > 7 on biopsy, or more than one biopsy > 6 at the ipsilateral side. Partin tables help to guide decision making (27).

If any doubt remains regarding residual tumour, the surgeon should remove the neurovascular bundle (NVB). Alternatively, the use of intraoperative frozen-section analysis can help guide these decisions. This is especially helpful in patients with a lesion palpable close to the capsule during nerve-sparing RP. A wedge of the prostate can then be resected and inked differently. In case carcinoma is adherent to the capsule on frozen section analysis, the NVB is resected; otherwise, the NVB remains in situ. In patients with intraoperatively detected tumour lesions during nerve-sparing, planned RP, frozen-section analysis objectively supports the decision of secondary NVB resection, as well as preservation (101).

The patient must be informed before surgery about the risks of nerve-sparing surgery, the potency rates achieved, and the possibility that, to ensure adequate cancer control, the nerves may be sacrificed despite any preoperative optimism favouring the potential for their salvage.

The early administration of intracavernous injection therapy could improve the definitive potency rates (102,103). Finally, the early use of phosphodiesterase-5 inhibitors in penile rehabilitation remains controversial. A recent placebo-controlled prospective study has shown no benefit from daily early administration of vardenafil versus on-demand vardenafil in the postoperative period (104), whereas another placebo-controlled prospective study has shown that sildenafil has a significant impact on return of normal spontaneous erections (105).

9.11 Conclusions and recommendations for radical prostatectomy

Indications	**LE**
In patients with low and intermediate risk localised PCa (cT1a-T2b and Gleason score 2-7 and PSA ≤ 20 ng/mL) and life expectancy > 10 years.	1b
Optional	
Patients with stage T1a disease and a life expectancy >15 years or Gleason score 7.	3
Selected patients with low-volume, high-risk, localised PCa (cT3a or Gleason score 8-10 or PSA > 20 ng/mL).	3
Highly selected patients with very-high-risk, localised PCa (cT3b-T4 N0 or any T N1) in the context of multimodality treatment.	3
Recommendations	
Short-term (3 months) or long-term (9 months) neoadjuvant therapy with gonadotrophin-releasing hormone analogues is not recommended for the treatment of stage T1-T2 disease.	1a
Nerve-sparing surgery may be attempted in preoperatively potent patients with low risk for extracapsular disease (T1c, Gleason score < 7 and PSA < 10 ng/mL or see Partin tables/nomograms).	3
Unilateral nerve-sparing procedures are an option in stage T2a-T3a disease.	4

10. TREATMENT: DEFINITIVE RADIATION THERAPY

10.1 Introduction

There are no randomised studies comparing radical prostatectomy (RP) with either external beam radiation therapy (EBRT) or brachytherapy for localised PCa. However, the National Institutes of Health (NIH) consensus set up in 1988 (1) remains available: external irradiation offers the same long-term survival results as surgery; moreover, EBRT provides a QoL at least as good as that provided by surgery (2).

Intensity modulated radiotherapy (IMRT) +/- image guided (IGRT) is the gold standard and all centres unable to offer this should have a plan to introduce it as a routine for the definitive treatment of prostate cancer (PCa).

In addition to external irradiation, transperineal low-dose or high-dose rate brachytherapy are widely used. In localised and locally advanced PCa, several randomised phase III trials conducted by radiation therapy scientific societies, such as the Radiation Therapy Oncology Group (RTOG) and European Organisation for Research and Treatment of Cancer (EORTC), have established the indications for the combination of external irradiation and androgen deprivation treatment (ADT).

Whatever the technique used, the choice of treatment - after the appropriate assessment of tumour

extension - must be based on a multidisciplinary approach and should consider the following:

- 2009 TNM classification;
- Gleason score defined on a sufficient number of core biopsies (at least 12);
- baseline PSA;
- age of the patient;
- patient's co-morbidity, life expectancy and QoL;
  IPSS score and uroflowmetry recordings;
- National Comprehensive Cancer Network (NCCN) and prognostic class D'Amico's prognostic factor classification (2b).

It is essential to obtain a patient's informed consent after providing full information to him, regarding diagnosis, therapeutic modalities and morbidity. Additional information on the various aspects of radiotherapy in the treatment of PCa is available in a newly published extensive overview (3).

10.2 Technical aspects: three-dimensional conformal radiotherapy (3D-CRT) and intensity modulated external beam radiotherapy (IMRT)

Anatomical data, acquired by scanning the patient in a treatment position, are transferred to the 3D treatment planning system, which visualises the clinical target volume and then adds a (surrounding) safety margin. At the time of irradiation, a multi-leaf collimator automatically and, in the case of IMRT, continuously, adapts to the contours of the target volume seen by each beam. Real-time verification of the irradiation field by means of portal imaging allows for comparison of the treated and simulated fields, and correction of deviations where displacement is more than 5 mm. Three-dimensional CRT improves local control through dose escalation, without increasing the risk of morbidity.

The use of IMRT is possible with linear accelerators equipped with the latest multileaf collimators and specific software. Movement of the leaves during the course of the irradiation allows for a more complex distribution of the dose to be delivered within the treatment field, and provides concave isodose curves, which are particularly useful as a means of sparing the rectum.

Whatever the techniques and their sophistication, quality assurance plays a major role in the management of radiotherapy, requiring the involvement of physicians, physicists, dosimetrists, radiographers, radiologists and computer scientists.

10.3 Radiotherapy for non-metastatic prostate cancer

Several randomized and non-randomised studies have shown that dose escalation (range, 76-80 Gy) has a significant impact on 5-year survival without biochemical relapse (5-7,10-12,15).
Two randomised trials focused on clinical stages T1-3 N0 M0 have paved the way for dose escalation:

- The MD Anderson study compared 78 Gy with 70 Gy conventional radiotherapy: it included 305 stage T1-3 patients with a pre-treatment PSA level of more than 10 ng/mL and, with a median follow-up of 8.7 years, showed a significant increase in freedom from biochemical and/or clinical failure for low-risk patients ($p = 0.04$) (5).
- The PROG 95-09 study evaluated 393 T1b-T2b patients, of whom 75% had a Gleason score ≤ 6 and a PSA < 15 ng/mL. Patients were randomised to receive an initial boost to the prostate alone, using conformal protons of either 19.8 Gy or 28.8 Gy, and then 50.4 Gy to a larger volume. With a median follow-up of 5.5 years, there was a significant increase in 5-year freedom from biochemical failure ($p < 0.001$) in favour of low-risk patients given a higher dose (79.2 Gy) versus those given a conventional dose (70.2 Gy) (6).

In daily practice, a minimum dose of ≥ 74 Gy is recommended for EBRT + hormone therapy (expert opinion) (7).

The following phase III trials argue for the combination of ADT and RT, or for dose-escalated RT:

- A Dutch randomised phase III trial comparing 68 Gy with 78 Gy showed a significant increase in 5-year freedom from clinical or biochemical failure for patients in an intermediate-risk group (10).
- The phase III trial of the French Federation of Cancer Centres compared 70 Gy with 80 Gy in 306 patients with a pelvic lymph node involvement risk of < 10% (Partin) or pN0, with no hormonal therapy allowed before, during, or after radiotherapy. With a median follow-up of 59 months, a high dose should provide a better 5-year biological outcome in intermediate-risk patients, especially if the initial PSA > 15 ng/mL (11).
- The RTOG 94-08 trial in 1979 patients with T1b-T2b, PSA < 20 ng/mL has shown that the addition of complete androgen blockade for 2 months before, and 2 months during conventional, lower-dose RT (66 Gy) significantly improved 10-year overall survival (62% vs 57%, $p = 0,03$) (12).
- Patients who are reluctant to accept short-term hormonal treatment (13) can receive definitive

radiotherapy alone, provided that a dose escalation up to 78-80 Gy is proposed.

- The MRC RT01 study, comparing a dose of 64 Gy with 74 Gy, both with neoadjuvant hormonal therapy, showed an 11% difference in 5-year BDFS (14).
- The PROG 95-09 study showed a significant increase in 5-year freedom from biochemical failure ($p < 0.02$) in favour of high-risk patients given a higher dose (79.2 Gy) versus those given a conventional dose (70.2 Gy) (10).
- An MD Anderson study showed a significant improvement in mestatases-free survival for high-risk patients ($p = 0.004$) (5).
- The EORTC trial 22991, comparing 3D-CRT +/- IMRT with a choice of three levels of dose (70 Gy, 74 Gy or 78 Gy), with or without 6 months of neoadjuvant and concomitant hormonal therapy, was closed in April 2008 after recruiting 800 patients; its results are awaited (15).

A combination of external irradiation with short-term ADT improves overall survival, based on the results of a phase III randomised trial which included 206 patients with a PSA level of at least 10 ng/mL (maximum 40 ng/mL), a Gleason score of at least 7 (range 5-10), or radiographic evidence of extra-prostatic disease, compared 3D-CRT alone or in combination with 6 months of ADT. After a median follow-up of 7.6 years, intermediate- or high-risk patients without moderate or severe co-morbidity, who had been randomised to receive 3D-CRT + ADT, showed a 13% improvement in overall survival rate ($p < 0.001$) (13). In contrast, data from the EORTC-22961 randomised phase III trial, comparing 36 months of hormonal treatment + radiotherapy with 6 months of hormonal treatment + radiotherapy, showed that increased hormonal treatment improved overall survival in patients with high-risk PCa at 5 years (14).

*10.3.1 **Prophylactic irradiation of pelvic lymph nodes in high-risk localised PCa***

Invasion of the pelvic lymph nodes is a poor prognostic factor and mandates systemic medical treatment because radiotherapy alone is insufficient (15). Prophylactic whole-pelvis irradiation has been abandoned since randomised trials failed to show that patients benefited from prophylactic irradiation (46-50 Gy) of the pelvic lymph nodes in high-risk cases. Such studies include the RTOG 77 06 study with 484 T1b-T2 patients (16), the Standford study with only 91 patients (17), and the GETUG-01 trial, which included 444 T1b-T3 N0 pNx M0 patients (18). Pelvic lymphadenectomy may be needed to improve the selection of patients who might benefit from pelvic lymph node irradiation and to supplement the use of Partin's tables (19) and/or the Roach formula (20). The results of pelvic lymphadenectomy, particularly for young patients, will enable radiation oncologists to tailor both the planning target volume and the duration of ADT: specifically, no pelvic irradiation for pN0 patients, but pelvic irradiation for pN1 patients with long-term ADT. The benefits of pelvic nodal irradiation merit further investigation in a clinical trail (one trial using high-dose IMRT is currently being designed).

10.4 Innovative techniques

*10.4.1 **Intensity modulated radiotherapy***

Intensity modulated radiotherapy enables radiation oncologists to increase radiation doses homogeneously, up to as much as 86 Gy within the target volume, while respecting the tolerance doses in organs at risk. Certainly, IMRT is the only safe means of treatment delivery for dose escalation beyond 75 Gy, using conventional 2 Gy fraction sizes, or for dose escalation using hypofractionated radiotherapy, in which there has been renewed interest. However, both treatment scenarios should be performed only within the confines of a properly designed clinical trial.

To date, no randomised trials have been published comparing dose escalation using IMRT and 3D-CRT.

With dose escalation using IMRT, organ movement becomes a critical issue, in terms of both tumour control and treatment toxicity. Evolving techniques will therefore combine IMRT with some form of image-guided radiotherapy (IGRT), in which organ movement can be visualised and corrected for in real time, although the optimum means of achieving this is still unclear (21).

Another evolving technique for the delivery of IMRT is tomotherapy, which uses a linear accelerator mounted on a ring gantry that rotates as the patient is delivered through the centre of the ring, analogous to spiral computed tomography (CT) scanning. Preliminary data suggest that this technique is feasible in PCa treatment (22).

*10.4.2 **Proton beam and carbon ion beam therapy***

In theory, proton beams are an attractive alternative to photon beam radiotherapy for PCa because they deposit almost all their radiation dose at the end of the particle's path in tissue (the Bragg peak), in contrast to photons, which deposit radiation along their path. Additionally, there is a very sharp fall-off for proton beams beyond their deposition depth, meaning that critical normal tissues beyond this depth could be effectively

spared. In contrast, photon beams continue to deposit energy until they leave the body, including an exit dose.

In practice, however, this has the disadvantage that dose distributions from protons are highly sensitive to changes in internal anatomy, such as might occur with bladder or rectal filling, and prostate proton therapy is usually delivered with lateral beams. It is also possible that high linear energy transfer (LET) radiation therapy using protons or carbon ions offers inherent biological advantages over photons, having more capacity for DNA damage dose-for-dose.

Only one randomised trial has incorporated proton therapy in one arm: the Loma Linda/Massachusetts General Hospital trial mentioned above compared standard-dose conformal radiotherapy with dose-escalated radiotherapy using protons for the boost dose (6). This trial cannot, however, be used as evidence for the superiority of proton therapy per se, as its use here could be viewed simply as a sophisticated method for dose escalation. A randomised trial comparing equivalent doses of proton beam therapy with IMRT is needed to compare the efficacy of protons versus photons; such a study is under consideration by the RTOG.

Two recent planning studies comparing conformal proton therapy with IMRT have yielded conflicting results; one study suggested that the two are equivalent in terms of rectal dose sparing, but that IMRT is actually superior in terms of bladder sparing (23); the other study suggested a clearer advantage to protons (24). Further studies are clearly needed. Meanwhile, proton therapy must be regarded as a promising, but experimental, alternative to photon beam therapy. Theoretically, proton therapy may be associated with a lower risk of secondary cancers compared with IMRT, because of the lower integral dose of radiation, but there are no data in patients treated for PCa to support this.

Carbon ions offer similar theoretical advantages as protons, as an alternative to photon beam therapy. In a phase II study, 175 patients with T1-3, N0-1, M0 PCa were treated with carbon ions in a dose equivalent to 66 Gy in 20 fractions over 5 weeks (25). Treatment appeared to be well tolerated, with no RTOG grade 3 or 4 bowel or genitourinary toxicity, and an overall four-year BDFR of 88% (24). As with protons, a randomised trial comparing carbon ions with IMRT and using equivalent doses is required.

10.5 Transperineal brachytherapy

Transperineal brachytherapy is a safe and effective technique. There is consensus on the following eligibility criteria:

- stage cT1b- T2a N0, M0;
- a Gleason score ≤ 6 assessed on a sufficient number of random biopsies;
- an initial PSA level of ≤ 10 ng/mL;
- $\leq 50\%$ of biopsy cores involved with cancer;
- a prostate volume of < 50 cm^3;
- an International Prostatic Symptom Score ≤ 12 (IPSS) (26).

Patients with low-risk PCa are the most suitable candidates for low-dose rate (LDR) brachytherapy. Further guidelines on the technical aspects of brachytherapy have been published recently and are strongly recommended (27).

In 1983, Holm et al. described the transperineal method with endorectal sonography in which the patient is positioned in a dorsal decubitus gynaecological position (28). Implantation is undertaken under general anaesthesia or spinal block, and involves a learning curve for the whole team: the surgeon for delineation of the prostate and needle placement, the physicist for real-time dosimetry, and the radiation oncologist for source loading. The sonography probe introduced into the rectum is fixed in a stable position.

There are no randomised trials comparing brachytherapy with other curative treatment modalities, and outcomes are based on non-randomised case series. Results of permanent implants have been reported from different institutions, with a median follow-up ranging between 36 and 120 months (29). Recurrence-free survival after 5 and 10 years was reported to range from 71% to 93% and from 65% to 85%, respectively (30-37).

A significant correlation has been shown between the implanted dose and recurrence rates (38). Patients receiving a D90 of > 140 Gy demonstrated a significantly higher biochemical control rate (PSA < 1.0 ng/mL) at 4 years than patients receiving less than 140 Gy (92% vs 68%). There is no benefit from adding neoadjuvant or adjuvant ADT to LDR brachytherapy (29).

Some patients experience significant urinary complications following implantation, such as urinary retention (1.5-22%), post-implant transurethral resection of the prostate (TURP) (up to 8.7%), and incontinence (0-19%) (39b). A small randomised trial has suggested that prophylactic tamsulosin does not reduce the rates of acute urinary retention, but may improve urinary morbidity (39). This observation requires further study in a larger number of patients. Chronic urinary morbidity can occur in up to 20% of patients, depending on the severity of symptoms prior to brachytherapy. Previous TURP for benign prostatic hyperplasia increases the risk of post-implant incontinence and urinary morbidity.

The incidence of grade III toxicity is less than 5%. Erectile dysfunction develops in about 40%

of patients after 3-5 years. In a recent retrospective analysis of 5,621 men who had undergone LDR brachytherapy (40), urinary, bowel and erectile morbidity rates were 33.8%, 21% and 16.7%, respectively, with invasive procedure rates of 10.3%, 0.8% and 4%, respectively.

In cases of permanent implants, iodine-125 in granular form is the radio-element of reference, while palladium-103 may be used for less differentiated tumours with a high doubling time. The dose delivered to the planning target volume is 144 Gy for iodine-125, and 125 Gy for palladium-103. A Gleason score of 7 remains a 'grey area', but patients with a Gleason score of 4 + 3 showed no difference in outcome (41).

A small randomised trial has suggested that the use of stranded rather than loose seeds is associated with better seed retention and less seed migration, and this should be the standard choice (42).

In cases of intermediate- or high-risk localised PCa, brachytherapy in combination with supplemental external irradiation (43) or neoadjuvant hormonal treatment (44) may be considered.

The optimum dose of supplemental EBRT is unclear. A randomised trial comparing 44 Gy with 20 Gy of EBRT + palladium-103 brachytherapy closed early, showing no difference in biochemical outcomes (45).

Non-permanent transperineal interstitial prostate brachytherapy using a high-dose rate iridium-192 stepping source and a remote afterloading technique can be applied with a total dose of 12-20 Gy in two to four fractions combined with fractionated external radiotherapy of 45 Gy (46). Higher doses of supplemental EBRT than this may best be delivered with IMRT; a report from Memorial Sloan-Kettering indicates that this approach is safe and feasible (47).

Recent data suggest an equivalent outcome in terms of BDFS compared with high-dose EBRT (HD EBRT) (48). In a retrospective analysis of modern series (49,50), BDFS rates of 85.8%, 80.3% and 67.8% in men with low-, intermediate- and high-risk PCa, respectively, are reported after a mean follow-up of 9.43 years. Quality-of-life changes are similar between high-dose EBRT and high-dose rate (HDR) brachytherapy in terms of diarrhoea and insomnia (51). However, the frequency of erectile dysfunction was significantly increased with HDR brachytherapy (86% vs 34%). A single randomised trial of EBRT versus EBRT + HDR brachytherapy has been reported (52). A total of 220 patients with organ-confined PCa were randomised to EBRT alone with a dose of 55 Gy in 20 fractions, or EBRT with a dose of 35.75 Gy in 13 fractions, followed by HDR brachytherapy with a dose of 17 Gy in two fractions over 24 hours. Compared to EBRT alone, the combination of EBRT and HDR brachytherapy showed a significant improvement in biochemical relapse-free survival ($p = 0.03$). There were no differences in the rates of late toxicity. Patients randomised to EBRT + brachytherapy had a significantly better QoL as measured by their Functional Assessment of Cancer Therapy-prostate (FACT-P) score at 12 weeks. However, a very high, uncommon rate of early recurrences was observed in the EBRT-arm alone, even after 2 years, possibly due to the uncommon fractionation used (52). There is still a need to compare dose-escalated EBRT + hormone therapy, with the same followed by a brachytherapy boost, in intermediate- and high-risk patients.

For T1-2 N0 M0 disease, the 5-year biochemical failure rates are similar for permanent seed implantation, high-dose (> 72 Gy) external radiation, combination seed/external irradiation, and RP, according to a study of 2991 patients diagnosed with T1-2 consecutive localised PCa treated between 1990 and 1998 at the Cleveland Clinic Foundation and Memorial Sloan-Kettering Cancer Center with a minimum of 1-year follow-up (48).

10.6 Late toxicity

Patients must be informed about the potential late genitourinary or gastrointestinal toxicity that may occur, as well as the impact of irradiation on erectile function. Late toxicity was analysed using a dose of 70 Gy in the prospective EORTC randomised trial 22863 (1987-1995) (53), in which 90% of patients were diagnosed as stage T3-4. A total of 377 patients (91%) out of 415 enrolled were evaluable for long-term toxicity, graded according to a modified RTOG scale. Eighty-six (22.8%) patients had grade ≥ 2 urinary or intestinal complications or leg oedema, of which 72 had grade 2 (moderate) toxicity, 10 had grade 3 (severe) toxicity, and four died due to grade 4 (fatal) toxicity. Although four (1%) late treatment-related deaths occurred, long-term toxicity was limited, with fewer than 5% grade 3 or 4 late complications being reported (Table 17). These data can be used as a baseline for comparison with irradiation techniques currently in use, such as 3D-CRT or IMRT.

Table 17: Incidence of late toxicity by RTOG grade (from EORTC trial 22863)

Toxicity	Grade 2		Grade 3		Grade 4		Any significant toxicity (≥ grade 2)	
	No.	%	No.	%	No.	%	No.	%
Cystitis	18	4.7	2	0.5	0	0	20	5.3
Haematuria	18	4.7	0	0	0	0	18	4.7
Urinary stricture	18	4.7	5	1.3	4	1	27	7.1
Urinary incontinence	18	4.7	2	0.5	0	0	20	5.3
Overall GU toxicity	**47**	**12.4**	**9**	**2.3**	**4†**	**1†**	**60**	**15.9**
Proctitis	31	8.2	0	0	0	0	31	8.2
Chronic diarrhoea	14	3.7	0	0	0	0	14	3.7
Small bowel obstruction	1	0.2	1	0.2	0	0	2	0.5
Overall GI toxicity	**36**	**9.5**	**1**	**0.2**	**0**	**0**	**37**	**9.8**
Leg oedema	**6**	**1.5**	**0**	**0**	**0**	**0**	**6**	**1.5**
Overall toxicity*	**72**	**19.0**	**10**	**2.7**	**4**	**1**	**86**	**22.8**

GU = genitourinary; GI = gastrointestinal.

** Overall toxicity included GU and GI toxicity and leg oedema. As most patients had more than one type of toxicity, the overall toxicity does not result from simple addition.*

† Two of the grade 4 patients were irradiated with cobalt-60.

Note: There was no other significant (≥ grade 2) toxicity among patients irradiated with cobalt-60 (n = 15) except for two patients with grade 4 GU (stated above) and only one patient with grade 2 GI toxicity.

Radiotherapy affects erectile function to a lesser degree than surgery according to retrospective surveys of patients (2). A recent meta-analysis has shown that the 1-year rate of probability for maintaining erectile function was 0.76 after brachytherapy, 0.60 after brachytherapy + external irradiation, 0.55 after external irradiation, 0.34 after nerve-sparing radical prostatectomy, and 0.25 after standard radical prostatectomy.

When studies with more than 2 years of follow-up were selected (i.e. excluding brachytherapy), the rates became 0.60, 0.52, 0.25, and 0.25, respectively, with a greater spread between the radiation techniques and surgical approaches (54).

Recent studies have demonstrated a significantly increased risk of developing secondary malignancies of the rectum and bladder following EBRT (55,56). In a retrospective evaluation of 30,552 and 55,263 men who had undergone either EBRT or RP, the risk of being diagnosed with rectal cancer increased 1.7-fold in comparison with the surgery group (55). Another analysis (56) showed that the relative risk of developing bladder cancer increased by 2.34-fold compared with a healthy control population. On the other hand, a re-analysis of SEER data with more than 100,000 patients demonstrated a risk of about 0.16% (i.e. 160 cases per 100,000 patients) of radiation-induced malignant tumours (57).

Corresponding data on late toxicity has also been reported by the Memorial Sloan-Kettering Cancer Center group, from its experience in 1,571 patients with T1-T3 disease treated with either 3D-CRT or IMRT in doses of between 66 Gy and 81 Gy, with a median follow-up of 10 years (57). Both acute GI and GU toxicity appeared to predict for corresponding late toxicity. The overall rates of NCIC-CTC grade 2 or more GI toxicity was 5% with IMRT, compared with 13% with 3D-CRT. The incidence of grade 2 or more late GU toxicity was 20% in patients treated with 81 Gy, compared with 12% in patients treated with lower doses. The overall incidence of grade 3 GI toxicity was 1%, and grade 3 GU toxicity was 3%. These data suggest that IMRT can successfully protect against late GI toxicity, but, interestingly, with dose escalation, GU toxicity may become the dominant morbidity (58).

10.7 Immediate and delayed post-operative external irradiation after radical prostatectomy

Extracapsular invasion (pT3) is associated with a risk of local recurrence, which can be as high as 30% (59). In a multifactorial analysis, the predictors of biochemical relapse are:

- PSA level ($p = 0.005$);
- Gleason score of the surgical specimen ($p = 0.002$);
- positive surgical margins ($p < 0.001$) (60).

Three prospective randomised trials have assessed the role of immediate post-operative radiotherapy (adjuvant radiotherapy, ART). The EORTC study 22911, with a target sample size of 1,005 patients, compared

immediate post-operative radiotherapy (60 Gy) with radiotherapy delayed until local recurrence (70 Gy) in patients classified as pT3 pN0 with risk factors R1 and pT2R1 after retropubic RP. Immediate post-operative radiotherapy proved to be well tolerated, with a risk of grade 3-4 urinary toxicity of less than 3.5%, without significantly worsening the rate of incontinence and/or stricture of the anastomosis. The study concludes that immediate post-operative radiotherapy after surgery significantly improved 5-year clinical or biological survival: 72.2% versus 51.8% ($p < 0.0001$) (61). After re-evaluation by central pathological review, the highest impact (30%) was seen in patients with positive margins (R1), but there was also a positive effect of 10% after 5 years for pT3 with negative margins and other risk factors (62,63).

The most suitable candidates for immediate radiation therapy might be those with multifocal positive surgical margins and a Gleason score > 7. The conclusions of the ARO trial 96-02 (n = 385) appear to support those of the EORTC study. After a median follow-up of 54 months, the radiotherapy group demonstrated a significant improvement in biochemical progression-free survival of 72% versus 54%, respectively ($p = 0.0015$). However, of major interest and in contrast to other studies, patients were randomised after achieving an undetectable PSA following RP (< 0.1 ng/mL) and only pT3-tumours were included. This finding indicates that adjuvant radiotherapy works even in the setting of an undetectable PSA after RP and additional risk factors (63). Conversely, the updated results, with a median follow-up of more than 12 years, of the SWOG 8794 trial, which randomised 425 pT3 patients, showed that adjuvant radiation significantly improved metastasis-free survival, with a 10-year metastasis-free survival of 71% versus 61% (median prolongation of 1.8 years, $p = 0.016$) and a 10-year overall survival of 74% versus 66% (median: 1.9 years prolongation, $p = 0.023$) (65).

Thus, for patients classified as pT3 pN0 with a high risk of local failure after RP due to positive margins (highest impact), capsule rupture, and/or invasion of the seminal vesicles, who present with a PSA level of < 0.1 ng/mL, two options can be offered within the framework of an informed consent:

- *either* immediate radiotherapy (ART) to the surgical bed (61,63,65,66) upon recovery of urinary function;
- *or* clinical and biological monitoring followed by salvage radiotherapy (SRT) before the PSA exceeds 0.5 ng/mL (67,68).

Early salvage radiotherapy provides the possibility of cure to patients with an increasing or persisting PSA after RP. More than 60% of patients who are treated before the PSA level rises to more than 0.5 ng/mL will achieve an undetectable PSA level again (67,68), so providing patients with the chance of about 80% being progression-free 5 years later (68). A retrospective analysis based on 635 patients undergoing RP from 1982-2004, followed up through to December 2007, who experienced biochemical and/or local recurrence and received no salvage treatment (397) or salvage radiotherapy alone (160) within 2 years of biochemical recurrence, has shown that SRT was associated with a threefold increase in PCa-specific survival relative to those who received no salvage treatment ($p < 0.001$). Salvage radiotherapy has also been effective in patients who have had a rapid PSA-doubling time (69). So far, the optimal SRT-dose has not been well defined. It should be at least 66 Gy. However, newer data suggest that higher total doses can achieve higher rates of biochemical control at 3 to 5 years (70,71).

The role of an additional ADT in combination with SRT remains controversial. The RTOG 9601 randomised, multi-centre phase III trial was designed to compare anti-androgen therapy (bicalutamide monotherapy 150 mg/dL) plus SRT (n = 387) to a placebo plus SRT alone (n = 383) in men with pT3 (n = 518)/ pT2 R1 (n = 252) N0 M0 prostate cancer with an elevated PSA after surgery. The median follow-up in surviving patients was 7.1 years. The addition of 24 months of peripheral and androgen blockade during and after RT significantly improved freedom from PSA progression (FFP) 57% versus 40% ($p < 0.0001$) and reduced the incidence of metastatic PCa (7.4% versus 12.6%, $p < 0.04$), without adding significantly to radiation toxicity. Longer follow-up is required to assess the significance of benefit in overall survival and to provide analysis of risk-stratified subsets (72).

These two approaches, together with the efficacy of neoadjuvant hormone therapy, are currently being compared in the UK MRC RADICALS randomised trial. The role of short-term hormone therapy in combination with radiotherapy is being investigated in the EORTC 22043 randomised trial.

10.8 Locally advanced PCa: T3-4 N0, M0

The incidence of locally advanced PCa has declined as a result of individual or mass screening. Pelvic lymph node irradiation is optional for N0 patients, but the results of radiotherapy alone are very poor (73). Because of the hormonal dependence of PCa (74), ADT has been combined with external irradiation with the aim of:

- reducing the risk of distant metastases by potentially sterilising micrometastases already present at the moment of diagnosis;
- decreasing the risk of non-sterilisation and/or local recurrence as a source of secondary metastases (73) through the effect of radiation-induced apoptosis (75,76). Numerous randomised trials have confirmed the value of long-term administration.

10.8.1 ***Neo-adjuvant and concomitant short-term androgen deprivation therapy***

The Trans-Tasman Radiation Oncology Group 96.01 trial included 818 men randomly assigned to RT alone (66 Gy/33 fractions) (77), 3 months of ADT with goserelin and flutamide starting 2 months before radiotherapy, or 6 months of ADT with the same regimen starting 5 months before RT. After a median follow-up of 10.6 years, those assigned to 3 months of ADT had a decreased cumulative incidence of PSA progression ($p = 0.003$), local progression ($p = 0.0005$), and event-free survival ($p = 0.0001$), compared with patients assigned to RT alone. Six months of ADT reduced PSA progression ($p < 0.0001$) and local progression ($p = 0.0001$) and led to a greater improvement in event-free survival ($p < 0.0001$). Furthermore, 6 months of ADT decreased distant progression ($p = 0.001$), cancer-specific mortality ($p = 0.0008$), and all-cause mortality ($p = 0.0008$) compared with RT alone (77).

10.8.2 ***Neo-adjuvant and concomitant hormonal therapy***

The RTOG study 86-10 included 471 patients with bulky (5 x 5 cm) tumours T2-4 N0-X M0. Androgen deprivation therapy was administered at 2 months before irradiation and during irradiation, or in the case of relapse in the control arm. Thirty-two per cent of patients were diagnosed as T2, 70% as T3-4, and 91% as N0. The hormone treatment consisted of oral eulexine, 250 mg three times daily, and goserelin acetate (Zoladex), 3.6 mg every 4 weeks by subcutaneous injection. The pelvic target volume received 45 Gy and the prostatic target volume received 20-25 Gy. The 10-year overall survival estimates were 43% for ADT + irradiation versus 34% for hormonal treatment, although the difference was not significant ($p = 0.12$). There was a significant improvement in the 10-year disease-specific mortality (23% vs 36%; $p = 0.01$), disease-free survival (11% vs 3%; $p < 0.0001$) and in biochemical failure (65% vs 80%; $p < 0.0001$), with the addition of ADT having no statistical impact on the risk of fatal cardiac events (78).

10.8.3 ***Concomitant and long-term adjuvant hormonal therapy***

The EORTC study 22863 recruited 415 patients diagnosed with T1-2 grade 3 WHO (World Health Organization) or T3-4 N0 M0 and any histological grade, and compared radiotherapy + adjuvant ADT with radiotherapy alone. The use of ADT was allowed in cases of relapse. A total of 82% of patients was diagnosed as T3, 10% as T4, and 89% as N0.

Hormonal treatment consisted of oral cyproterone acetate (CPA), 50 mg three times daily for 1 month, beginning 1 week before the start of radiotherapy, and goserelin acetate (Zoladex), 3.6 mg subcutaneously every 4 weeks for 3 years, starting on the first day of radiotherapy. The pelvic target volume received was 50 Gy, and the prostatic target volume was 20 Gy. With a median follow-up of 66 months, combination therapy compared with radiotherapy alone yielded significantly better survival (78% vs 62%, $p = 0.001$) (79). At a median follow-up of 9.1 years, the 10-year overall survival remained significantly higher at 58.1% vs 39.8% ($p < 0.0001$), as did clinical progression-free survival at 47.7% vs 22.7% ($p < 0.0001$). The 10-year cumulative incidence of PCa mortality was 11.1% versus 31% ($p < 0.0001$), and the 10-year cumulative incidence of cardiovascular mortality was 11.1% versus 8.2% ($p = 0.75$) (80).

10.8.4 ***Long-term adjuvant hormonal therapy***

The RTOG study 8531 recruited 977 patients diagnosed with T3-4 N0-1 M0, or pT3, after RP. Androgen deprivation therapy was begun in the last week of irradiation and continued up to relapse (Group I) or was started at recurrence (Group II). A total of 15% of patients in Group I and 29% in Group II had undergone RP, and 14% of patients in Group I and 26% in Group II were pN1. Goserelin acetate, 3.6 mg subcutaneously, was administered every 4 weeks. The pelvis was irradiated with 45 Gy, while the prostatic bed received 20-25 Gy. Patients diagnosed with stage pT3 received 60-65 Gy. With a median follow-up time of 7.6 years for all patients, the 10-year overall survival was significantly greater for the adjuvant arm, at 49% versus 39% ($p = 0.002$) (81).

The National Cancer Institute of Canada (NCIC)/UK Medical Research Council (MRC)/Southwest Oncology Group (SWOG) intergroup PR3/PR07 study included 1205 patients with T3-4 (n = 1057) or T2, PSA > 40 ng/mL (n = 119), or T2, PSA > 20 ng and Gleason > 8 (n = 25) and N0-X M0 PCa, who were randomised to lifelong ADT (bilateral orchidectomy or LHRH agonist), with or without RT (65-70 Gy to prostate +/- 45 Gy to pelvic lymph nodes). With a median follow-up of 6 years, the addition of RT to ADT reduced the risk of death from any cause by 23% ($p = 0.03$) and the risk of death due to PCa by 46% ($p = 0.0001$) (82,83).

The GETUG trial included 273 patients with locally advanced PCa T3-4 or pT3 N0 M0, who were randomly assigned to lifelong ADT using an LHRH agonist (leuproreline), with or without RT (70 Gy to the prostate plus 48+/- 2Gy to pelvic lymph nodes). With a median follow-up of 67 months, there was a significant improvement in 5-year disease free survival ($p < 0.001$), metastases disease-free survival ($p < 0.018$) and loco-regional progression-free survival ($p < 0.0002$), but the effect on overall survival was not reported (84).

The SPCG-7/SFUO-3 randomised study (85) compared hormonal treatment alone (i.e. 3 months of continuous androgen blockade followed by continuous flutamide treatment (n = 439) with the same treatment

combined with radiotherapy (n = 436). After a median follow-up of 7.6 years, the 10-year cumulative incidence for prostate cancer-specific mortality was, respectively, 23.9% and 11.9% (95% CI: 4.9-19.1), and the 10-year cumulative incidence for overall mortality was 39.4% in the hormonal treatment-only group, and 29.6% in the hormonal + RT group (95% CI: 0.8-18%).

10.8.5 ***Neo-adjuvant, concomitant and long-term adjuvant hormonal therapy***

The RTOG 9202 trial closed in 1995 after accruing 1554 patients. Statistically significant improvements were observed in actuarial biochemical freedom from disease control, distant metastatic failure, local control, and disease-free survival in patients receiving long-term ADT (before, during, and 2 years after radiotherapy), compared with short-term ADT (2 months before and during radiotherapy). With a median follow-up of 11.27 years of all survival patients, the long-term ADT arm showed significant improvement over the short-term ADT arm in all efficacy endpoints, except 10-year overall survival, which was 51.6% versus 53.9% (p = 0.36), respectively. In a subset of patients that was not part of the original study design, with Gleason score 8-10 tumours, the long-term ADT arm showed significantly better overall survival after 10 years than the short-term ADT arm, with 45% versus 32% (p = 0.006) (86).

10.8.6 ***Short-term or long-term adjuvant hormonal treatment***

Following the EORTC trial 22863, the EORTC equivalence trial 22961 was set up to test whether similar survival could be achieved in patients who underwent irradiation (to 70 Gy) and 6 months of combined ADT without further ADT, i.e. short-term ADT arm, compared with patients with 2.5 years of further treatment with luteinising hormone-releasing hormone analogue, i.e. long-term ADT arm. Eligible patients had T1c-2b N1-2 or pN1-2, or T2c-4 N0-2 (UICC 1992) M0 PCa with PSA < 150 ng/mL.

Non-inferior survival was defined as a mortality hazard ratio (HR) = 1.35 for short-term ADT versus long-term ADT. A total of 970 patients were randomised. With a 5.2-year median follow-up, the 5-year overall survival rate was 85.3% on long-term ADT, and 80.6% on short-term ADT (HR = 1.43; 96.4% CI; 1.04-1.98), and failed to prove non-inferiority (87).

10.8.7 ***Dose escalation with hormonal therapy***

Zelefsky et al. (88) reported a retrospective analysis of 2251 patients with T1-3 N0-X M0 PCa comprised of 571 low-risk patients (22.4%), 1074 intermediate-risk patients (42.1%) and 906 high-risk patients (35.5%), according to the National Comprehensive Cancer Network classification. Three-dimensional conformal radiotherapy (3D-CRT) or IMRT were given to the prostate and seminal vesicles only. The prostate dose ranged from 64.8 to 86.4 Gy; doses beyond 81 Gy were delivered within the last 10 years by employing image-guided IMRT. Androgen deprivation therapy by complete androgen blockade with a luteinizing hormone releasing hormone (LHRH) agonist plus oral anti-androgen was given at the discretion of the treating physician to 1,249 patients (49%), including 623 high-risk patients (69%), 456 intermediate-risk patients (42%) and 170 low-risk (30%) patients. The duration of ADT was 3 months for low-risk patients and 6 months for intermediate-risk and high-risk patients, starting at 3 months prior to RT and continued during RT. The end-points were 10-year biochemical disease-free survival and distant metastases-free survival. With an 8-year median follow-up, the 10-year biochemical disease-free survival of each risk group was significantly improved by dose escalation: 84% (> 75.6 Gy) versus 70% for low-risk patients (p = 0.04), 76% (> 81 Gy) vs 57% for intermediate- risk patients (p = 0.0001), and 55% (> 81 Gy) versus 41% for high-risk patients (p = 0.0001). The 6-month ADT also influenced the biochemical disease-free survival of intermediate-risk and high-risk patients, with 55% versus 36% for high-risk patients (p < 0.0001). In multivariate analysis, a dose greater than 81 Gy (p = 0.027) and ADT (p = 0.052) were significant predictors for distant metastases-free survival, but none of these parameters influenced PCa mortality or overall survival. There were very low rates of grade 3-4 acute or late toxicity (89).

10.9 Very high-risk PCa: c or pN1, M0

Patients with a pelvic lymph node involvement lower than the iliac regional nodes, younger than 80 years old, with a WHO performance status 0-1, and no severe co-morbidity may be candidates for EBRT plus immediate long-term hormonal manipulation. The RTOG 85-31 randomised phase III trial has shown, with a median follow-up of 6.5 years, that 95 patients out of the 173 pN1 patients who received pelvic radiotherapy with immediate hormonal therapy had better 5-year (54%) and 9-year (10%) progression-free survival (PSA < 1.5 ng/mL) versus 33% and 4%, respectively, with radiation alone and hormonal manipulation instituted at the time of relapse (p < 0.0001). Multivariate analysis showed that this combination had a statistically significant impact on overall survival, disease-specific failure, metastatic failure and biochemical control (90). The GETUG 12 trial has addressed the impact of neoadjuvant chemotherapy with docetaxel on progression-free survival in a cohort of 413 high-risk patients, defined as having one or more of the following criteria: T3-4, Gleason score ≥ 8, PSA ≥ 20 ng/mL, pN+. Patients were randomly assigned to either goserelin, 10.8 mg every 3 months for 3 years, plus 4 cycles of docetaxel, 70 mg/m^2 every 3 weeks plus estramustine 10 mg/kg/dL on days 1 to 5 (arm 1), or

goserelin alone (arm 2). Local therapy was administered at 3 months and consisted of RT in 358 patients (87%). Toxicity included grade 3-4 neutropenia (27%) with neutropenic fever in 2%, but no toxicity-related death and no secondary leukaemia. With a median follow-up of 4.6 years, the 4-year progression-free survival was 85% in arm 1 versus 81% in arm 2 (p = 0.26), but the data need to mature (91).

10.10 Guidelines summary for definitive radiation therapy

	LE
In localised prostate cancer T1c-T2c N0 M0, 3D-CRT with or without IMRT is recommended, even for young patients who refuse surgical intervention.	2
For high-risk patients, long-term ADT prior to and during radiotherapy is recommended because it results in increased overall survival.	2a
In patients with cT1-T2a, Gleason score < 7 (or 3 + 4), PSA ≤ 10 ng/mL, prostate volume ≤ 50 mL, without a previous TURP and with a good IPSS, transperineal interstitial brachytherapy with permanent implants can be an alternative.	2b
In patients with pathological tumour stage T3 N0 M0, immediate post-operative external irradiation after RP may improve overall survival and biochemical and clinical disease-free survival with the highest impact in cases of positive margins.	1
In patients with pathological tumour stage T2-3N0M0, salvage irradiation is indicated in case of persisting PSA or biochemical failure, but before the PSA level rises above 0.5 ng/mL.	3
In locally advanced prostate cancer T3-4 N0 M0, concomitant and adjuvant hormonal therapy for a total duration of 3 years, with external beam irradiation for patients with WHO 0-2 performance status, is recommended because it improves overall survival.	1
In a subset of patients with T2c-T3 N0-X and a Gleason score of 2-6, short-term ADT before and during radiotherapy can be recommended because it may favourably influence overall survival.	1b
In very high-risk prostate cancer, c-pN1 M0 with no severe co-morbidity, pelvic external irradiation and immediate long-term adjuvant hormonal treatment is recommended because it will improve overall survival, disease-specific failure, metastatic failure and biochemical control.	2b

11. EXPERIMENTAL LOCAL TREATMENT OF PROSTATE CANCER

11.1 Background

Besides radical prostatectomy (RP), external beam radiation and/or brachytherapy, cryosurgical ablation of the prostate (CSAP) and high-intensity focused ultrasound (HIFU) have emerged as alternative therapeutic options in patients with clinically localised PCa (1-4).

Although HIFU is still considered to be an experimental treatment, CSAP has been recognised as a true therapeutic alternative according to the guidelines of the American Urological Association. Both HIFU and CSAP have been developed as minimally invasive procedures, which have potentially the same therapeutic efficacy as established surgical and non-surgical options, with reduced therapy-associated morbidity.

11.2 Cryosurgery of the prostate (CSAP)

Cryosurgery uses freezing techniques to induce cell death by:

- dehydration resulting in protein denaturation;
- direct rupture of cellular membranes by ice crystals;
- vascular stasis and microthrombi, resulting in stagnation of the microcirculation with consecutive ischaemia;
- apoptosis (1-4).

Freezing of the prostate is ensured by placement of 12-15 17G-cryoneedles under transrectal ultrasound (TRUS) guidance, placement of thermosensors at the level of the external sphincter and bladder neck, and insertion of a urethral warmer. Two freeze-thaw cycles are used under TRUS guidance, resulting in a temperature of -40°C in the mid-gland and at the neurovascular bundle.

*11.2.1 **Indication for CSAP***

Patients who are ideal candidates for CSAP are those who have organ-confined PCa and those identified as having minimal tumour extension beyond the prostate (1-3). The prostate should be < 40 mL in size. Prostate glands > 40 mL should be hormonally downsized to avoid any technical difficulty in placing cryoprobes under the pubic arch. Prostate-specific antigen (PSA) serum levels should be < 20 ng/mL, and the biopsy Gleason score should be < 7. It is important that patients with a life expectancy > 10 years should be fully informed that there are no data, or only minimal data, on the long-term outcome for cancer control at 10 and 15 years.

*11.2.2 **Results of modern cryosurgery for PCa***

When comparing treatment modalities, it is important to bear in mind that, in modern RP patients with clinically organ-confined PCa, there is a very low risk (2.4%) of dying from PCa at 10 years after surgery (5). Therapeutic results have improved over time with enhanced techniques, such as gas-driven probes and transperineal probe placement, as used in third-generation cryosurgery (6-11).

An objective assessment of PSA outcome is not easily performed because some institutions use PSA values

< 0.1 ng/mL as an indicator of therapeutic success, whereas others use the American Society of Therapeutic Radiology and Oncology (ASTRO) criteria, which requires three consecutive increases in PSA level.

With regard to second-generation CSAP, if a PSA nadir < 0.5 ng/mL is used, biochemical disease-free survival (BDFS) at 5 years is 60% and 36% for low-risk and high-risk patients, respectively (6,7).

Long et al. (6) have performed a retrospective analysis of the multicentre, pooled, CSAP results of 975 patients stratified into three risk groups. Using PSA thresholds of 1.0 ng/mL and < 0.5 ng/mL at a mean follow-up of 24 months, the 5-year actuarial BDFS rate was:

- 76% and 60%, respectively, for the low-risk group;
- 71% and 45%, respectively, for the intermediate-risk group;
- 61% and 36%, respectively, for the high-risk group.

However, according to a recent meta-analysis of 566 cryosurgery-related publications, there were no controlled trials, survival data or validated biochemical surrogate end-points available for analysis (12).

Cryosurgery showed progression-free survival (PFS) of 36-92% (projected 1- to 7-year data), depending on risk groups and the definition of failure. Negative biopsies were seen in 72-87% of cases, but no biopsy data were available for the currently used third-generation cryotherapy machines.

With regard to third-generation cryosurgery, clinical follow-up is short, with a 12-month PSA follow-up carried out in only 110/176 (63%) patients (6-11). Eighty of these (73%) patients still had a PSA nadir < 0.4 ng/mL, whereas 42/65 (64.6%) low-risk patients remained free from biochemical progression using the 0.4 ng/mL cut-off.

Longer follow-up has been reported by Bahn et al. (9), who have analysed the therapeutic results of 590 patients undergoing CSAP for clinically localised and locally advanced PCa. At a PSA cut-off level of < 0.5 ng/mL, the 7-year BDFS for low-, medium- and high-risk groups was 61%, 68% and 61%, respectively.

Nerve-sparing cryosurgery, as reported recently (13), must still be considered an experimental therapeutic option. Nerve-sparing surgery was performed in nine patients with unilateral PCa confirmed on repeated biopsies; CSAP was carried out on the side of the positive biopsy, whereas the negative biopsy side was spared from freezing.

*11.2.3 **Complications of CSAP for primary treatment of PCa***

Erectile dysfunction occurs in about 80% of patients and remains a consistent complication of the CSAP procedure, independent of the generation of the system used. The complication rates described in third generation cryosurgery include tissue sloughing in about 3%, incontinence in 4.4%, pelvic pain in 1.4% and urinary retention in about 2% (6-11). The development of fistula is usually rare, being < 0.2% in modern series. About 5% of all patients require transurethral resection of the prostate (TURP) for subvesical obstruction.

Quality of life and sexuality following CSAP have been investigated in a clinical phase II trial recruiting 75 men (14). Quality-of-life analysis by the prostate-specific FACT-P questionnaire showed that most subscales return to pre-treatment levels by 12 months after CSAP. Furthermore, no significant changes are seen when comparing data at 36 months with those at 12 months. With regard to sexuality, 37% of men were able to have intercourse 3 years after CSAP.

In a recent, prospective, randomised clinical trial, 244 men with newly diagnosed organ-confined PCa were randomised to receive either external beam radiation therapy (EBRT) or to undergo CSAP (15). After a follow-up of 3 years, sexual function was significantly less impaired in the EBRT group.

*11.2.4 **Summary conclusions for CSAP***

Patients with low-risk PCa (PSA < 10 ng/mL, < T2a, Gleason score < 6) or intermediate-risk PCa (PSA > 10 ng/mL, or Gleason score > 7, or stage > 2b) represent potential candidates for CSAP.
Prostate size should be < 40 mL at the time of therapy.
Long-term results are lacking, whereas 5-year BDFS rates are inferior to those achieved by RP in low-risk patients. Patients must be informed accordingly.

11.3 HIFU of the prostate

HIFU consists of focused ultrasound waves emitted from a transducer, which cause tissue damage by

mechanical and thermal effects as well as by cavitation (16). The goal of HIFU is to heat malignant tissues above 65°C so that they are destroyed by coagulative necrosis.

HIFU is performed under general or spinal anaesthesia, with the patient lying in the lateral position. The procedure is time-consuming, with about 10 g prostate tissue treated per hour.

In a recent review, 150 papers related to HIFU were identified and evaluated with regard to various oncological and functional outcome parameters (12). No controlled trial was available for analysis, and no survival data were presented. No validated biochemical, surrogate end-point was available for HIFU therapy.

11.3.1 ***Results of HIFU in PCa***

As with CSAP, it appears to be difficult to interpret oncological outcome in patients undergoing HIFU because various PSA thresholds are defined, and no international consensus exists on objective response criteria. The results of HIFU are limited, with outcome data from < 1,000 PCa cases published in the literature.

According to the recent review mentioned above (12), HIFU showed PFS (based on PSA ± biopsy data) of 63-87% (projected 3- to 5-year data), but median follow-up in the studies ranged from 12-24 months only.

In one of the largest single-centre studies, 227 patients with clinically organ-confined PCa were treated with HIFU, and their outcome data were analysed after a mean follow-up of 27 months (range: 12-121 months) (17). The projected 5-year BDFS was 66%, or only 57% if patients had exhibited a pre-therapeutic PSA value of 4-10 ng/mL. Incontinence and bladder neck stricture decreased over time from 28% and 31% to 9% and 6%, respectively. In one of the studies (18), a significant decrease in pre-treatment PSA serum levels from 12 to 2.4 ng/mL was observed. However, 50% of the 14 patients demonstrated positive prostate biopsies during follow-up. In another study (19), a complete response rate (i.e., PSA < 4 ng/mL) and six negative biopsies were achieved in 56% of the patients.

Thüroff *et al*. (19) have summarised the efficacy results of a European multicentre study comprising the data of 559 patients with mainly low- and intermediate-risk PCa, and have reported a negative biopsy rate of 87.2% in 288 men with a follow-up of at least 6 months. A PSA nadir after 6 months' follow-up could be determined in 212 patients, and was 1.8 ng/mL. However, following the initial procedure, it could be demonstrated that the PSA nadir might be reached in 12-18 months.

Blana *et al*. have reported the results of 146 patients undergoing HIFU with a mean follow-up of 22.5 months (20). The mean PSA level at initiation of therapy was 7.6 ng/mL; the PSA nadir achieved after 3 months was 0.07 ng/mL. However, after 22 months, the median PSA level was 0.15 ng/mL. Of the 137 men available for analysis, 93.4% demonstrated a negative control biopsy. The PSA nadir appeared to be strongly associated with treatment failure (21) ($P < 0.001$). Patients with a PSA nadir of 0.0-0.2 ng/mL had a treatment failure rate of only 11% compared with 46% in patients with a PSA nadir of 0.21-1.00 ng/mL, and 48% with a PSA nadir of > 1.0 ng/mL. Recently, the group has updated its results, with a total of 163 men treated for clinically organ-confined PCa. Within the 4.8 ± 1.2 years of follow-up, the actuarial DFS rate at 5 years was 66%, with salvage treatment initiated in 12% of patients (22).

In another study, 517 men with organ-confined or locally advanced PCa were treated with HIFU (23). Biochemical failure was defined as the PSA nadir + 2 ng/mL, according to the Phoenix guidelines with regard to radiotherapy. After a median follow-up of 24 months, the BDFS was 72% for the entire cohort. The BDFS in patients with stage T1c, T2a, T2b, T2c and T3 groups at 5 years was 74%, 79%, 72%, 24% and 33%, respectively ($P < 0.0001$). The BDFS in patients in the low-, intermediate- and high-risk groups at 5 years was 84%, 64% and 45%, respectively ($P < 0.0001$). The BDFS in patients treated with or without neoadjuvant hormonal therapy at 7 years was 73% and 53% ($P < 0.0001$), respectively. Postoperative erectile dysfunction was noted in 33 out of 114 (28.9%) patients who were preoperatively potent.

In a recent retrospective study, 137 patients with PCa underwent HIFU (24). After a median follow-up of 36 months, 22% of the patients relapsed according to the Phoenix criteria. The 5-year DFS rate was 78% based on these criteria, and 91%, 81% and 62% in the low-, intermediate- and high-risk group, respectively. Urge incontinence (16 cases) and dysuria (33 cases) occurred after removal of the urethral catheter in 11.8% and 24.1%, respectively.

To evaluate whether the location (apex/midgland/base) of PCa influences the risk of incomplete transrectal HIFU ablation, Bouiter et al. (25) analysed 99 patients who underwent PCa HIFU ablation (Ablatherm; EDAP, Vaulx-en-Velin, France) with a 6-mm safety margin at the apex, and had systematic biopsies at 3-6 months after treatment. After treatment, residual cancer was found in 36 patients (36.4%) and 50 sextants (8.4%); 30

(60%) positive sextants were in the apex, 12 (24%) in the midgland, and eight (16%) in the base. Statistical analysis showed that the mean (95% CI) probability for a sextant to remain positive after HIFU ablation was 8.8% (3.5-20.3%) in the base, 12.7% (5.8-25.9%) in the midgland, and 41.7% (27.2-57.89%) in the apex. When a 6-mm apical safety margin was used, treatment-associated side effects, especially incontinence and erectile dysfunction, were fewer but residual cancer after HIFU ablation was significantly more frequent in the apex.

Komura et al. (26) have analysed the oncological outcome in 144 patients with T1/T2 PCa and a median follow-up of 47 (2-70) months. Thirty-nine percent patients relapsed and approximately 40% developed a clinical or subclinical urethral stricture postoperatively. Most interestingly, the 5-year DFS was significantly better in those with a stricture as compared to those without (78.2% vs. 47.8%, $P < 0.001$), indicating the need for more aggressive treatment especially at the apex of the prostate.

11.3.2 ***Complications of HIFU***

Urinary retention appears to be one of the most common side effects of HIFU, developing in almost all patients, with the mean interval of catheterisation via a suprapubic tube varying between 12 and 35 days (16-18). Grade I and II urinary stress incontinence occurs in about 12% of patients. Subsequent TURP or bladder neck incision to treat subvesical obstruction is common, and is sometimes even performed at the time of HIFU. Post-operative impotence occurs in 55-70% of patients.

Elterman et al. (27) have treated 95 patients with clinically organ-confined PCa using the Sonablate-500 device, and have evaluated the type and frequency of treatment-associated complications. With a minimum follow-up of 6 months, 17% (7/41) of the men had significant incontinence and 2% developed significant erectile dysfunction. Early and late subvesical obstruction necessitating surgical treatment occurred in 17 (17.9%) and 20 (21.1%) patients, respectively.

11.4 Focal therapy of PCa

During the past two decades, there has been a trend towards earlier diagnosis of PCa due to greater public and professional awareness, leading to the adoption of both formal and informal screening strategies. The effect of this has been to identify men with smaller tumours at an earlier stage, which occupy only 5-10% of the prostate volume, with a greater propensity for unifocal or unilateral disease (28-30).

Most focal therapies to date have been achieved with ablative technologies; cryotherapy, HIFU or photodynamic therapy. So far, three groups have proposed that non-diseased prostate tissue be left untreated in the hope and expectation that genitourinary function might be preserved and the tumour treated adequately (31-33). Although focal therapy is currently not the standard for men with organ-confined PCa, it is the therapeutic approach with the most important future potential.

11.4.1 ***Pre-therapeutic assessment of patients***

The high number of random and systematic errors associated with TRUS-guided biopsy regimens means that this procedure is not sufficiently accurate for selecting candidates for focal therapy. The current standard for characterising men considering focal therapy is transperineal prostate biopsy using a template-guided approach (34,35). When used with a 5-mm sampling frame, this approach can rule in and rule out PCa foci of 0.5 and 0.2 mL volume, with 90% certainty (36). Thus, the exact anatomical localisation of the index lesion - defined as the biologically most aggressive- can be accurately determined.

11.4.2 ***Patient selection for focal therapy***

The primary objective of treatment must be the eradication of measurable and biologically aggressive disease. However, although treatment is usually intended to be one-off, patients should know that further treatment might be necessary in the future.

Based on published data, the following criteria identify possible candidates for currently ongoing trials of focal treatment:

- Candidates for focal therapy should ideally undergo transperineal template mapping biopsies. However, a state-of-the-art multifunctional MRI with TRUS biopsy at expert centres may be acceptable.
- Focal therapy should be limited to patients with a low to moderate risk. The clinical stage of the tumour should be < cT2a and the radiological stage < cT2b.
- Patients with previous prostate surgery should be counselled with caution because no data on functional and oncological outcomes are available. Patients who have undergone radiation therapy of the prostate are not candidates for focal therapy.
- Patients must be informed that the therapy is still experimental and that there is a possibility of repeat-treatment.

11.5 Summary of experimental therapeutic options to treat clinically localised PCa

Conclusion	
All other minimally invasive treatment options - such as HIFU microwave and electrosurgery - are still experimental or investigational. For all of these procedures, a longer follow-up is mandatory to assess their true role in the management of PCa.	
Recommendation	**GR**
In patients who are unfit for surgery, or with a life expectancy < 10 years CSAP has evolved from an investigational therapy to a possible alternative treatment for PCa.	**C**
Focal therapy of PCa is still in its infancy and cannot be recommended as a therapeutic alternative outside clinical trials.	**C**

12. HORMONAL THERAPY

12.1 Introduction

In 1941, Huggins and Hodges assessed the effect of surgical castration and oestrogen administration on the progression of metastatic prostate cancer (PCa). They demonstrated for the first time the responsiveness of PCa to androgen deprivation (1,2). Since then, androgen-suppressing strategies have become the mainstay of advanced PCa management. More recently, there has been a move towards the increasing use of hormonal treatment in younger men with earlier disease (i.e. non-metastatic) or recurrent disease after definitive treatment, either as the primary single-agent therapy or as a part of a multimodality approach (3).

However, even if hormonal treatment effectively palliates the symptoms of advanced disease, there is currently no conclusive evidence to show that it extends life.

*12.1.1 **Basics of hormonal control of the prostate***

Prostate cells are physiologically dependent on androgens to stimulate growth, function and proliferation. Testosterone, although not tumorigenic, is essential for the growth and perpetuation of tumour cells (4). The testes are the source of most androgens, with adrenal biosynthesis providing only 5-10% of androgens (i.e. androstenedione, dihydroepiandrosterone and dihydroepiandrosterone sulphate).

Testosterone secretion is regulated by the hypothalamic-pituitary-gonadal axis. Hypothalamic luteinising hormone-releasing hormone (LHRH) stimulates the anterior pituitary gland to release luteinising hormone (LH) and follicle-stimulating hormone (FSH). Luteinising hormone stimulates the Leydig cells of the testes to secrete testosterone. Within the prostate cell, testosterone is converted to 5-α-dihydrotestosterone (DHT) by the enzyme 5-α-reductase; DHT is an androgenic stimulant about 10 times more powerful than testosterone. Meanwhile, circulating testosterone is peripherally aromatised and converted to oestrogens, which, together with circulating androgens, exert a negative feedback control on hypothalamic LH secretion.

If prostate cells are deprived of androgenic stimulation, they undergo apoptosis (programmed cell death). Any treatment that results ultimately in suppression of androgen activity is referred to as androgen deprivation therapy (ADT).

*12.1.2 **Different types of hormonal therapy***

Androgen deprivation can be achieved by either suppressing the secretion of testicular androgens by surgical or medical castration or inhibiting the action of circulating androgens at the level of their receptor in prostate cells using competing compounds known as anti-androgens. These two methods of androgen deprivation (surgical or medical castration and the use of anti-androgens) can be combined to achieve what is commonly known as complete (or maximal or total) androgen blockade (CAB).

12.2 Testosterone-lowering therapy (castration)

*12.2.1 **Castration level***

Surgical castration is still considered the ‘gold standard’ for ADT, against which all other treatments are rated. Removal of the testicular source of androgens leads to a considerable decline in testosterone levels and induces a hypogonadal status, although a very low level of testosterone (known as the ‘castration level’) persists.

The standard castrate level is < 50 ng/dL. It was defined more than 40 years ago, when testosterone level testing was limited. However, current testing methods using chemiluminescence have found that the mean value of testosterone after surgical castration is 15 ng/dL (5). This has led to a revisiting of the current definition of castration, with some authors suggesting < 20 ng/dL as a more appropriate level.

12.2.2 ***Bilateral orchiectomy***

Bilateral orchiectomy, either total or by means of a subcapsular technique (i.e. with preservation of tunica albuginea and epididymis), is a simple and virtually complication-free surgical procedure. It is easily performed under local anaesthesia (6) and is the quickest way to achieve a castration level, usually within less than 12 hours.

The main drawback of orchiectomy is that it may have a negative psychological effect: some men consider it to be an unacceptable assault on their manhood. In addition, it is irreversible and does not allow for intermittent treatment. The use of bilateral orchiectomy has declined in recent years, probably because of stage migration towards earlier disease and the introduction of equally effective pharmacological modalities of castration.

12.2.3 ***LHRH agonists***

Long-acting LHRH agonists (busereline, gosereline, leuproreline, triptoreline) have been used in advanced PCa for more than 15 years and are currently the main forms of ADT (3). They are synthetic analogues of LHRH, generally delivered as depot injections on a 1-, 2-, 3-, or 6-monthly basis. Initially, they stimulate pituitary LHRH receptors, inducing a transient rise in LH and FSH release. This then elevates testosterone production (known as the 'testosterone surge' or 'flare-up' phenomenon), which begins about 2-3 days after the first injection and lasts for about the first week of therapy.

12.2.3.1 Achievement of castration levels

Chronic exposure to LHRH agonists eventually results in down-regulation of LHRH-receptors. This then suppresses pituitary LH and FSH secretion and testosterone production, so that testosterone levels decrease to castration levels usually within 2-4 weeks (7). However, about 10% of patients treated with LHRH agonists fail to achieve castration levels (8). This proportion rises to 15% if the castration threshold is defined as 20 ng/dL.

A recent meta-analysis evaluating single-therapy ADT for advanced PCa showed that LHRH agonists have comparable efficacy to orchiectomy and DES (9) (LE: 1a). This finding raises a question about the clinical impact of changing the definition of the castrate testosterone level from 50 ng/dL to 20 ng/dL. In addition, although only based on indirect comparison, the LHRH agonists seemed equally effective whatever their formulation (9) (LE: 3).

12.2.3.2 Flare-up phenomenon

Today, LHRH agonists have become the 'standard of care' in hormonal therapy because they avoid the physical and psychological discomfort associated with orchiectomy and lack the potential cardiotoxicity associated with DES. However, the main concerns associated with the administration of LHRH agonists are the potentially detrimental effects associated with 'flare phenomenon' in advanced disease, namely increased bone pain, acute bladder outlet obstruction, obstructive renal failure, spinal cord compression, and fatal cardiovascular events due to hypercoagulation status.

A review (10) concluded that clinical flare needs to be distinguished from the more common biochemical flare (i.e. increasing levels of PSA), and even from asymptomatic radiographic evidence of progression. The review also identified that patients at risk of clinical flare are usually patients with high-volume, symptomatic, bony disease, which account for only 4-10% of M1 patients.

Anti-androgen treatment

Concomitant therapy with an anti-androgen decreases the incidence of clinical relapse (i.e. clinical flare), but does not completely remove the possibility of its occurrence. Anti-androgens should be started on the same day as the depot LHRH injection and should be continued for a 2-week period. However, other strategies for immediately ablating testosterone levels, such as bilateral orchiectomy or LHRH-antagonists, must be used in patients with impending spinal cord compression. Except in this patient group, the clinical impact of the flare-up observation is unknown.

Long-term use of LHRH agonists

Some "mini-flares" have also been observed with the long-term use of LHRH agonists. The clinical impact is unknown but it has been suggested that a mini-flare is associated with a negative impact on overall survival (*see* Section 17.4).

12.2.4 ***LHRH antagonists***

In contrast to LHRH agonists, LHRH antagonists bind immediately and competitively to LHRH receptors in the pituitary gland. The effect is a rapid decrease in LH, FSH and testosterone levels without any flare. This seemingly more desirable mechanism of action has made LHRH antagonists very attractive. However, practical

shortcomings have limited clinical studies, as many LHRH antagonists have been associated with serious and life-threatening histamine-mediated side-effects and, until recently, no depot formulation was available.

12.2.4.1 Abarelix

Two published phase III randomised multicentre trials compared the LHRH antagonist, abarelix, with the LHRH agonist, leuprorelin acetate (11), and with CAB (12), in patients with metastatic or recurrent PCa. Both trials showed no difference in achieving and maintaining castration levels of testosterone and in reducing serum PSA. The biochemical 'flare up' phenomenon was not reported in the abarelix arm and the overall incidence of severe adverse events (including allergic reactions) was similar across all treatment groups. Data on survival end-points and long-term safety are not yet available.

The US Food and Drug Administration has recently licensed the clinical use of abarelix, but only in metastatic and symptomatic PCa, for which no other treatment option is available. However, based on prolonged analysis, the FDA have issued a warning about allergic reactions with the long-term use of abarelix, which has resulted in suspension of its further development.

12.2.4.2 Degarelix

Degarelix is another LHRH antagonist that has shown promising preliminary results in a monthly subcutaneous formulation. Following phase II trials, a large, randomised, non-inferiority, dose-finding study (n = 610) compared two degarelix dosages with 7.5 mg monthly leuprorelin injections (13). The study showed that the standard dosage of degarelix should be 240 mg the first month, followed by 80 mg monthly injections. More than 95% of patients achieved a castrate level at day 3 with degarelix, which was associated with a quicker decline in PSA as quickly as day 14. No allergic reaction was observed. The main criterion (suppression of testosterone $\leq$ 0.5 ng/mL at all monthly measurements) was similar in the three treatment groups at 1 year. The main specific side-effect of degarelix was a painful injection (moderate or mild) reported in 40% of patients, mainly after the first injection. An extended follow-up has been recently published (median 27.5 months), suggesting that degarelix might result in better progression-free survival compared to monthly leuprorelin (14).

12.2.4.3 Conclusions

Overall, this new family of agents seems appealing, but their advantages over LHRH agonists are far from proven. Further trials are needed to confirm the preliminary observed increased efficacy compared to leuprorelin. The use of LHRH antagonists is limited by a monthly formulation, compared with 3-month and 6-month depot formulations for the available LHRH analogues. Suppression of the initial flare-up with monotherapy is only clinically relevant in a few symptomatic metastatic patients.

12.3 Oestrogens

Oestrogens have several mechanisms of action:

- down-regulation of LHRH secretion;
- androgen inactivation;
- direct suppression of Leydig cell function;
- direct cytotoxicity to the prostate epithelium (in-vitro evidence only) (15).

12.3.1 ***Diethylstilboesterol (DES)***

Diesthylstilboesterol (DES) is the most commonly used oestrogen in PCa. Early studies by the Veterans Administration Co-operative Urological Research Group (VACURG) tested oral DES at a dosage of 5 mg/day, as it was the dosage used in CAB. However, this dosage was associated with high cardiovascular morbidity and mortality, due to first-pass hepatic metabolism and formation of thrombogenic metabolites. Lower oral doses of 1 mg/day and 3 mg/day were therefore tested and were both found to provide a therapeutic efficacy similar to that of bilateral orchiectomy. However, 3 mg daily of DES was still associated with high cardiotoxicity. Although 1 mg daily of DES resulted in much fewer adverse cardiovascular events than 5 mg daily of DES, the side-effects were still significantly greater than with castration. Because of these concerns and the introduction of LHRH agonists and anti-androgens, the use of DES was greatly reduced. There has been renewed interest in using oestrogens (9).

12.3.2 ***Renewed interest in oestrogens***

There are three main reasons for a renewed interest in using oestrogens to treat PCa:

1. LHRH agonists have a number of deleterious side-effects and their long-term widespread use is costly, while oestrogens suppress testosterone levels and do not seem to lead to bone loss and cognitive decline (16) (LE: 3).
2. In phase II trials with patients diagnosed with hormone-refractory PCa (HRPC), oestrogenic compounds (DES, DES-diphosphate) have induced prostate-specific antigen (PSA) response rates as high as 86%.

3. Discovery of a new oestrogen receptor-® (ER-®), possibly involved in prostate tumorigenesis (15).

12.3.3 ***Strategies to counteract the cardiotoxicity of oestrogen therapy***

Two strategies have been used to try and neutralise the cardiotoxicity associated with oestrogen therapy, which is its main disadvantage:

- parenteral route of administration - so avoiding first-pass hepatic metabolism;
- concomitant use of cardiovascular-protective agents.

The Scandinavian Prostatic Cancer Group Study 5 set up a prospective randomised trial of more than 900 men with metastatic PCa, which compared a parenteral oestrogen (polyoestradiol phosphate) with CAB (orchiectomy, or an LHRH agonist + flutamide). The trial found no significant difference in disease-specific survival and OS between the treatment groups, and no significant increase in cardiovascular mortality in the oestrogen-treated group. However, in the oestrogen-treated group, there was a significantly higher incidence of non-fatal adverse cardiovascular events, particularly ischaemic and heart decompensation events (17).

In addition, thromboembolic complications have been observed in recent (though small) phase II trials of patients with advanced PCa or CRPC. The trials evaluated the combination of DES, 1 mg/day or 3 mg/ day, with either a low dose of warfarin sodium, 1 mg/day, or a low dose of aspirin, 75-100 mg/day, for the prevention of cardiovascular toxicity (18,19).

12.3.4 ***Conclusions***

Diethylstilboesterol is one of the classic forms of hormonal therapy. Its efficacy was demonstrated many years ago and was recently re-confirmed in a meta-analysis as comparable to that of bilateral orchiectomy (9) (LE:1a). However, there is still concern about the significant cardiovascular side-effects of DES, even at lower dosages. Further data are needed before oestrogens can be re-admitted into clinical practice as a standard first-line treatment option.

12.4 Anti-androgens

Anti-androgens compete with testosterone and DHT at the receptor level in the prostate cell nucleus, thus promoting apoptosis and inhibiting PCa growth (20).

These oral compounds are classified according to their chemical structure as:

- steroidal, e.g. cyproterone acetate (CPA), megestrol acetate and medroxyprogesterone acetate;
- non-steroidal or pure, e.g. nilutamide, flutamide and bicalutamide.

Both classes compete with androgens at the receptor level. This is the sole action of non-steroidal anti-androgens. In addition, steroidal anti-androgens have progestational properties due to central inhibition of the pituitary gland. As a consequence, non-steroidal antiandrogens do not lower testosterone levels, which remain normal or, conversely, slightly elevated.

12.4.1 ***Steroidal anti-androgens***

These compounds are synthetic derivatives of hydroxyprogesterone. In addition to peripherally blocking androgen receptors, they have progestational properties and inhibit the release of gonadotrophins (LH and FSH) and suppress adrenal activity. At high doses, megestrol acetate is cytotoxic. Since steroidal antiandrogens lower testosterone levels, the main pharmacological side-effects are loss of libido and erectile dysfunction, while gynaecomastia is quite rare. The non-pharmacological side-effects are cardiovascular toxicity (4-40% for CPA) and hepatotoxicity.

12.4.1.1 Cyproterone acetate (CPA)

Cyproterone acetate was the first anti-androgen to be licensed and is the most widely used. However, it is the least studied, with many questions about its use unanswered, e.g. the optimal dose, or unclear, e.g. comparison with standard forms of castration, surgical or with an agonist.

Comparison of CPA with medical castration

There has been only one randomised trial (21) comparing CPA with standard hormonal therapy, i.e. medical castration. Patients in arm A (no contraindications to DES) were randomly assigned to CPA, goserelin or DES, while patients in arm B (contraindications to DES) were assigned to CPA or goserelin. In arm A, treatment with CPA was associated with a significantly poorer median OS than goserelin only; adjusting for baseline characteristics did not account for this difference. Although there are other studies in CPA monotherapy, methodological limitations prevent firm conclusions being made from their results about the relative efficacy of CPA and castration.

Dosage regimen of CPA
Because there have been no dose-finding studies of CPA monotherapy, the most effective dose is still unknown. Although CPA has a relatively long half-life (31-41 hours), it is usually administered in two or three fractionated doses of 100 mg each (22).

Comparative study of CPA with flutamide
The only comparative study on anti-androgens as monotherapy was recently published by the European Organisation for Research and Treatment of Cancer (EORTC). The final analysis of Protocol 30892 (a randomised trial of 310 patients comparing CPA with flutamide in metastatic PCa) showed no difference in cancer-specific survival and OS at a median follow-up of 8.6 years, although the study was underpowered (23) (LE: 1b).

12.4.1.2 Megestrol acetate and medroxyprogesterone acetate
Very limited information is available on these two compounds. Early studies with megestrol acetate demonstrated a symptomatic and partially beneficial clinical response, both in previously untreated metastatic PCa (24,25) and less so in CRPC (26). No apparent dose-response correlation was found (27). The overall poor efficacy has prevented megestrol acetate and medroxyprogesterone acetate from being recommended for either primary- or second-line hormonal therapy.

The only prospective randomised trial evaluating medroxyprogesterone acetate as primary therapy in advanced (M0-1) PCa is the EORTC 30761 study (28), in which 236 patients were given CPA, DES or medroxyprogesterone acetate. There was no difference in cancer-specific survival and OS between CPA and DES. However, medroxyprogesterone acetate resulted in a less favourable course, with a shorter survival time and time to progression than CPA or DES.

12.4.2 ***Non-steroidal anti-androgens***
The use of non-steroidal anti-androgens as monotherapy has been promoted on the basis of improved quality of life (QoL) and compliance compared to castration. They do not suppress testosterone secretion and it is claimed that libido, overall physical performance and bone mineral density (BMD) are preserved (29). Although they have not been directly compared in a monotherapy setting, the severity of pharmacological side-effects, namely gynaecomastia, breast pain and hot flashes, appears similar for the three available non-steroidal anti-androgens. However, there are differences in non-pharmacological side-effects, with bicalutamide showing a more favourable safety and tolerability profile than nilutamide and flutamide (30). All three agents share a common liver toxicity and liver enzymes must be monitored regularly.

12.4.2.1 Nilutamide
There are no comparative trials of nilutamide monotherapy with castration or with other anti-androgens.

A large randomised controlled trial in 457 patients with M1 PCa showed a significant benefit for cancer-specific survival and OS with orchiectomy + nilutamide, 300 mg/day, versus orchiectomy + placebo (31). Nilutamide has recently shown encouraging results as a second-line hormonal therapy in HRPC (32,33).

Non-pharmacological side-effects are visual disturbances (i.e. delayed adaptation to darkness), alcohol intolerance, nausea, hepatotoxicity, and interstitial pneumonitis. Even if exceptional, interstitial pneumonitis is potentially life-threatening and is specific to nilutamide. Nilutamide is not licensed for monotherapy.

12.4.2.2 Flutamide
Flutamide was the first non-steroidal anti-androgen available for clinical use. Although it has been studied as monotherapy for more than 20 years, there are no dose-finding studies against a currently accepted end-point (e.g. PSA response). Flutamide is a pro-drug, and the half-life of the active metabolite is 5-6 hours, so it must be administered three times daily to maintain therapeutic serum levels. The recommended daily dosage is 750 mg (22).

Early phase II trials demonstrated the efficacy of flutamide in advanced PCa, even though the reported response rates cannot be correlated with currently recommended end-points. The main advantage shown in these small single-arm studies was the preservation of sexual function, which was maintained in up to 80% of patients with no pre-treatment erectile dysfunction. This rate has not been confirmed in the above-mentioned EORTC trial 30892 (23), in which as few as 20% of men treated with flutamide maintained sexual activity for up to 7 years.

Although several phase III studies have been conducted, the results are often difficult to evaluate because of several drawbacks, such as the use of non-standard combinations, short-term follow-up and underpowering. Of these studies, survival data for advanced PCa has been reported in only one published phase III randomised trial comparing flutamide monotherapy with CAB (34).

No significant difference in OS for flutamide or castration in patients with a PSA < 100 ng/mL (34). At a higher PSA, flutamide was inferior. However, both trials were underpowered. Results are eagerly awaited from an ongoing Swedish study, which randomised 700 patients with M1 PCa to flutamide, 250 mg three times daily, or CAB (29). The non-pharmacological side-effects of flutamide are diarrhoea and hepatotoxicity (occasionally fatal).

12.4.2.3 Bicalutamide

Dose-finding studies of bicalutamide

Early studies with bicalutamide monotherapy used the 50 mg/day dosage licensed for use in CAB. Although this dosage provided clinical benefits, it resulted in a poorer OS than with castration (median difference 97 days) (35). Subsequent dose-finding studies established that bicalutamide, 150 mg once daily, achieved a similar PSA response to castration, while maintaining a good tolerability profile (36). Accordingly, the 150 mg dosage was chosen for further evaluation as both primary and adjuvant monotherapy.

Primary monotherapy with bicalutamide

Bicalutamide, 150 mg/day, as first-line monotherapy has been compared to medical or surgical castration in two large prospective randomised trials with identical study designs, including a total of 1,435 patients with locally advanced M0 or M1 PCa (37). A pooled analysis showed:

- In M1 patients, an improvement in OS with castration, although the difference in median survival between the groups was only 6 weeks (37);
- In M0 patients (n = 480), no significant difference was noted in OS (38) based on the Kaplan-Meier test, with median survival being 63.5 months in the bicalutamide arm compared with 69.9 months in the castration one.

In two smaller randomised trials, high-dose bicalutamide was compared with CAB. In the first trial (251 patients with predominantly M1 stage), there was no apparent difference in OS (39). In the second trial (220 patients with M0 and M1 stage), there was no difference in OS for well-differentiated tumours or tumours that were only moderately well-differentiated (40) (LE: 1b). However, both studies were underpowered, and the first one has not yet been fully published.

Adjuvant therapy with bicalutamide

In the adjuvant setting, the ongoing Early Prostate Cancer Programme (EPCP) is a study comprising three different clinical trials (known as Trials 23, 24 and 25) of similar design. The programme included 8,113 patients worldwide and evaluated the efficacy and tolerability of high-dose (150 mg/day) bicalutamide versus placebo, given in addition to standard primary care (i.e. radical prostatectomy, radiotherapy or watchful waiting) in either localised PCa (T1-2, N0-X) or locally advanced PCa (T3-4, any N, or any T N+). The first combined analysis of the programme showed that, after a median follow-up of 3 years, adjuvant bicalutamide reduced the risk of objective disease progression by 42% compared with standard care alone (41).

After a median follow-up of 5.4 years, the positive effects of bicalutamide were obvious in patients with locally advanced disease (stage M0). Bicalutamide significantly improved PFS, irrespective of standard care. However, survival appeared to be reduced in patients with localised disease treated with bicalutamide versus those given placebo (42). After a median follow-up of 7.4 years, there appeared to be no benefit to PFS from the addition of bicalutamide to standard care in localised PCa, with a trend towards decreased survival in patients otherwise undergoing watchful waiting (WW) (hazard ratio [HR], 1.16; 95% CI: 0.99-1.37; p = 0.07).

The same overall results were observed in the most recent analysis of the bicalutamide treatment arm of the EPCP 24 trial (43). Bicalutamide significantly improved OS in patients receiving radiotherapy (HR, 0.65; 95% CI: 0.44-0.95; p = 0.03), mainly due to a lower risk of PCa-related deaths. Bicalutamide produced a trend towards improved OS in patients with locally advanced disease otherwise undergoing WW (HR, 0.81; 95% CI:0.66-1.01; p = 0.06). No survival difference was evident in the subgroup undergoing radical prostatectomy (42).

Even though the EPCP is a combination of three trials and among the largest conducted in PCa patients, it is difficult to draw clear conclusions because of the following problems with the protocols:

- The three trials grouped for analysis were different in terms of patients; 80% of patients underwent prostatectomy in Trial 23 versus 13% in Trial 25. In addition, treatment duration was 2 years in Trial 23, but treatment was prolonged until progression in Trials 24 and 25.
- The OS benefit claimed with radiotherapy is mainly driven by a respiratory or cardiovascular improvement, and not by a cancer-specific survival benefit, which is different to other trials with LHRH agonists.
- Furthermore, the EPCP trials are underpowered for locally advanced patients, compared with oriented trials such as the Bolla (44) or Pilepich (45) trials.

- Direct protocol analysis revealed quite different results, such as those from EPCP Trial 23 (80% prostatectomy, 19% radiotherapy) (46). At a median 7.7 years of follow-up, no PFS benefit was observed (HR, 1.00; 95% CI: 0.84-1.19; p = 0.991). Likewise, OS did not differ. Even after stratifying for disease stage, no PFS benefit was apparent.
- The OS benefit must be balanced by the very prolonged (mainly permanent) use of bicalutamide combined with radiotherapy in contrast to the more limited use of agonists (6 months to 3 years).
- Although a QoL benefit has been claimed, in fact a QoL benefit cannot be demonstrated because none of the EPCP trials used a systematic, validated QoL questionnaire. The only available data were derived from a specific questionnaire and a limited population. The observed benefit was only significant for physical capacity and sexual interest (not function!). For all other QoL items (emotional well-being, vitality, social function, pain, activity limitation and bed disability), there was no difference compared with castration (38). The breast problems related to bicalutamide are also important, as they can lead to a 16.4% treatment cessation (47).

The lack of data means that many questions are still debatable with bicalutamide, such as the practical management after progression under bicalutamide. Furthermore, the clear trend (even if not statistically significant) towards a decreased OS in localised disease otherwise treated with WW is a clear argument against the use of bicalutamide in such situations (42). The mechanisms involved remain unclear.

Conclusions for the use of bicalutamide in primary and adjuvant therapy

High-dose bicalutamide has emerged as an alternative to castration for patients with locally advanced (M0) if PFS is the target, and in highly selected, well-informed cases of M1 PCa with a low PSA.
Bicalutamide monotherapy should be avoided in patients with localised PCa.
The expected benefit of bicalutamide for QoL compared with castration is far from being proven.
The survival benefit observed with adjuvant use after radiotherapy in locally advanced PCa must be considered with caution, as the EPCP trials do not have the clear power of trials conducted with LHRH agonists. The lack of any direct comparison between both bicalutamide and LHRH agonists in combination with radiotherapy leads to a major limitation of any guidelines, which should therefore be based on unquestionable trials, which are mainly those with analogues

Side-effects of bicalutamide

Non-pharmacological side-effects are mainly gynaecomastia (70%) and breast pain (68%), which may be prevented by anti-oestrogens (49-51), prophylactic radiotherapy (52), or treatment with surgical mastectomy or radiotherapy (53). However, bicalutamide clearly offers bone protection compared with LHRH analogues and probably LHRH antagonists (54,55).

12.5 Combination therapies

*12.5.1 **Complete androgen blockade (CAB)***

Although castration reduces serum testosterone levels by up to 95%, an intraprostatic androgen stimulus is sustained by the conversion of circulating androgens of adrenal origin into DHT within the prostate cells. However, the action of these adrenal androgens can be blocked by the addition of an anti-androgen to either surgical or pharmacological castration, a concept known as complete (or maximal or total) androgen blockade (CAB).

The many studies comparing CAB with monotherapy (castration through LHRH analogues) have produced contrasting results (56). According to the most recent systematic reviews and meta-analyses, at a follow-up of 5 years, CAB appears to provide a small survival advantage (< 5%) versus monotherapy (57-60) (LE: 1a). However, some of the largest trials included were methodologically flawed (61). It remains debatable whether this small advantage, if any, is useful in everyday clinical practice, as the survival benefit seems limited to patients taking non-steroidal antiandrogens (62) and only appears after 5 years of follow-up.

Gastrointestinal, ophthalmological, and haematological side-effects are worse with CAB. Although LHRH analogues and non-steroidal anti-androgens have the highest estimated quality-adjusted survival, there is an incremental cost of more than US$1 million per quality-adjusted life-year for CAB over orchiectomy alone.

*12.5.2 **Minimal androgen blockade (or peripheral androgen blockade)***

Minimal androgen blockade is produced by combining finasteride with a non-steroidal anti-androgen. Finasteride reduces intraprostatic levels of DHT by inhibiting 5-α-reductase, while the anti-androgen competes with the binding of the residual DHT to its receptor. This enables testosterone levels to be maintained within normal ranges to ensure acceptable sexual function and a reasonable QoL.

Several phase II trials (63-67) have evaluated the association of finasteride and flutamide, either given together or sequentially, using the PSA response rate in patients with advanced or biochemically recurrent PCa. Notwithstanding the small sample and short follow-up, nearly all patients experienced a substantial decline in PSA (by up to 96% compared with the baseline level at entry). In a long-term follow-up of one study, stronger end-points were reported, including castration-free survival (median: 37 months), androgen independent PCa-free survival (median: 48.6 months) and OS (65% at 5 years). These results indicated that combination therapy was able to induce an overall period of hormone-responsive disease exceeding 4 years (68). In all these trials, sexual function was preserved in 55-86% of men studied.

The preliminary data make minimal androgen blockade a very attractive option in the management of patients for whom QoL is the main concern. However, while awaiting the results of follow-up and larger controlled trials, this treatment should be considered investigational.

12.5.3 ***Intermittent versus continuous ADT***

For reasons beginning to be clarified, long-term CAB, which stimulates prostate cell apoptosis, fails to eliminate the entire malignant cell population. Thus, after a variable period (averaging 24 months), the tumour inevitably relapses, characterised by an castrate-independent state of growth. Experimental data indicate that castrate-independent progression may begin early after the administration of hormonal therapy, coinciding with the cessation of androgen-induced differentiation of stem cells (69). It has therefore been suggested that stopping androgen deprivation prior to progression of androgen-independent cells would mean any subsequent tumour growth would be solely sustained by the proliferation of androgen-dependent stem cells. The stem cells should therefore be susceptible once again to androgen withdrawal. Thus, intermittent androgen blockade (IAD) would delay the emergence of the androgen-independent clone. It should be noted that this rationale has been developed mainly through models (e.g. the Shionoggi model), which may be significantly different from the behaviour of total tumour in men.

Other possible benefits of IAD include the preservation of QoL in off-treatment periods and a reduction in the cost of treatment.

Phase II results

A detailed systematic review was recently published (70), with no other trials published since this review. According to the review, several phase II trials demonstrated the feasibility of IAB in metastatic or biochemically recurrent disease (70). Both PSA response rates and symptom improvement were similar to those seen with CAB. However, these trials included very heterogeneous patients and used different PSA thresholds for decisions regarding castration. This should be borne in mind when considering the main findings.

- Most patients were treated with an LHRH agonist, with or without an anti-androgen.
- The cycle lengths were quite stable regarding the off-treatment periods.
- Testosterone recovery, when tested, was frequent during the first cycle, but tended to decrease during subsequent cycles.
- Early occurrence of early refractory status was quite uncommon.
- Overall tolerability was acceptable, and sometimes there was a QoL benefit, especially for sexual function.

These findings suggest a potential benefit for IAD. However, randomised trials are required to clarify the potential survival benefit suggested by animal models.

Randomised controlled trials

Overall, eight randomised trials are underway, only some of which have published findings. Most of the trials included a mixed patient population of both locally advanced and metastatic disease. Only three trials included only metastatic patients, and two trials only relapsing patients. The two largest trials each contained more than 1,300 patients, with one trial focused only on metastatic patients (SWOG 9346) and the other on relapsing patients after radiotherapy (SWOG PR7). Few fully published trials are available, some are pending. But, all available results are similar so far, allowing the inclusion of abstract-only references. A short summary of the most important published findings from these trials follows.

- The South West Oncology Group (SWOG) trial 9346 randomised 1,134 men with stage D2 PCa to intermittent and continuous ADT after 7 months' induction ADT with PSA reduction < 4 ng/mL. A very preliminary analysis has identified no significant differences with regard to survival between treatment groups (71). A PSA reduction to < 0.2 ng/mL, < 4 ng/mL and > 4 ng/mL was identified as a significant prognostic factor with regard to survival, achieving 13 months, 44 months and 75 months, respectively. In a similar patient population and using a quite similar protocol, no difference was observed in OS or in PFS between IAD and CAB in 173 randomised patients (72), with a mean follow-up of 47 months. No QoL benefit was observed in any treatment arm. The same lack of difference in OS was seen with CPA in another randomized study of 366 patients (73), after a mean follow-up of 66 months.

- The largest trial available so far (still unpublished) has been presented at several meetings (74). A total of 1,386 patients relapsing after radiotherapy, given as either primary treatment or for relapsing patients after surgery, were randomized to continuous ADT or intermittent ADT. Continuous treatment was for a fixed 8-month period. Intermittent ADT was stopped when PSA < 4 ng/mL and resumed when above 10 ng/mL. After a median 7 years of follow-up, the median OS was 9.1 years in the continuous arm and 8.8 years in the intermittent arm (HR: 1.02:; 95% CI= 0.86-1.21).
- In other studies (75,76) of mixed populations of locally advanced and metastatic PCa, there has also been no evidence found of decreased survival using IAD. The larger study (76) included 478 patients with either M1 disease (40%) or N+ (N1-3) disease. In this study, 335 patients were randomised to IAD after 6 months of CAB if the PSA decreased to < 4 ng/mL or a decrease of > 90% was observed. The mean initial level of PSA was 158 ng/mL in the IAD-treated group and 139 ng/mL in the CAB-treated group. In the IAD group, treatment was resumed if the PSA rose > 10 ng/mL and stopped when it decreased < 4 ng/mL. However, after a median follow-up of 50.5 months, no significant difference was observed in the median PFS (16.6 months in the IAD group vs 11.5 months in the CAB group, p = 0.17) in either the total study population or in the N+ or M1 subgroup populations. In the IAD arm, 88% of patients were off-treatment for more than 50% of the time and normalised their testosterone in a mean of 70 days after stopping treatment.
- To date, the largest fully published trial (n = 766) has been carried out by the South European Uro-Oncological Group (SEUG) (77). Patients followed an induction regimen of 3 months, in which CPA was given for 2 weeks followed by monthly LHRH + CPA. Patients with a PSA < 4 ng/mL or a PSA decrease > 80% were randomised to IAD or CAB. In the IAD-treated group, treatment was resumed, if the PSA level rose to ≥ 10 ng/mL for symptomatic patients. For patients whose PSA level dropped to < 80% of the initial value, therapy was restarted when the PSA level rose to ≥ 20% above the nadir. The primary end-point was time to progression. After a median follow-up of 51 months, there was no difference in either time to progression (HR: 0.81; p = 0.11) or OS (HR: 0.99). Metastatic status and PSA at randomisation were associated with specific death rates. No overall QoL benefit was seen, except for more frequent side-effects in the CAB-treated group. However, there was a clear benefit for improved sexual function in the IAD group versus the CAB group (28% sexually active vs 10% at 15 months after randomisation, respectively). After follow-up for a median of 7 years, it should be highlighted that both the IAD treatment arm and the continuous treatment arm showed similar non-significant specific death increases. This finding suggests that, even if continuous treatment provides a specific survival difference compared to IAD, the survival difference is completely counterbalanced by the increased specific toxicity of continuous ADT, which therefore results in a lack of difference in OS survival, the increasing of which remains the main objective.

Alternative IAD regimen

Recently, a published randomised trial (n = 129) suggested an alternative IAD regimen, which alternated fixed 6-month periods of CAB treatment and surveillance (78). The PSA response was not used to guide treatment in the heterogeneous study population. After a mean follow-up of 44.8 months, no difference was observed in OS, cancer-specific survival or PFS. The QoL also showed no difference between the two groups, except that painkillers were required more often in the IAD arm, and the ability to get and maintain an erection was better in the IAD arm.

Other benefits of IAD

Intermittent androgen deprivation has not been shown to be associated with prolonged hormone-sensitive status or OS increase. This modality is well accepted by patients, urologists and oncologists. Although the QoL benefit is less than expected or absent, except in two studies (73,74), IAD is better tolerated and sometimes benefits sexual functioning (76,77). Other possible long-term benefits, which are not clearly proven, include bone protection (79,80) and/or a protective effect against metabolic syndrome. Testosterone recovery is seen in most studies (70), leading to an intermittent castration (not just an intermittent treatment delivery).

Optimal threshold for stopping or resuming ADT

The optimal thresholds at which ADT must be stopped or resumed are empirical (70). The best candidates for IAD have still not been completely defined (70,80), but are probably patients with locally advanced or relapsing disease, provided a perfect response is obtained (*see below*). Nevertheless, several points are clear (70,81):

- Because IAD is based on intermittent castration, only drugs leading to castration are suitable for use in IAD.
- It is unclear if an LHRH agonist may be used alone, as published experiences are based on CAB. An LHRH antagonist might be a valid alternative, provided clear results are obtained from randomised trials.

- The initial (induction) cycle must last between 6 and 9 months, otherwise testosterone recovery is unlikely.
- The treatment is stopped only if patients have fulfilled all the following criteria:
  - well-informed and compliant patient
  - no clinical progression, i.e. a clear PSA response, empirically defined as a PSA < 4 ng/mL in metastatic disease, or 0.5 ng/mL in relapsing disease.
- Strict follow-up must be applied once treatment has stopped, with clinical examination every 3-6 months. The more advanced the disease, the closer is the follow-up). The PSA level should be measured by the same laboratory to ensure standardization of testing.
- Treatment is resumed when the patient reaches either a clinical progression, or a PSA value above a predetermined, empirically fixed threshold. This is usually 4-10 ng/mL in non-metastatic situations or 10-15 ng/mL in metastatic patients (80).
- The same treatment is used for at least 3-6 months.
- Subsequent cycles of treatment are based on the same rules until the first sign is seen of hormone-refractory status.

In conclusion, IAD is currently widely offered to patients with PCa in various clinical settings, and its status should no longer be regarded as investigational (LE: 2).

Increased duration of off-treatment periods in IAD

There have recent attempts to increase the duration of off-treatment periods in IAD. Although hormonal manipulation using finasteride (82) has been suggested, finasteride has never been tested in randomised trials and its use in PCa has been recently questioned (83). However, there have been trials of non-hormonal compounds, including a COX-2 inhibitor (84) and anti-angiogenic drugs (85). In a study of the anti-angiogenic drug, thalidomide, 159 patients, who had relapsed after local treatment, were randomized to an LHRH antagonist for 6 months, followed by placebo or thalidomide, 200 mg daily. When PSA progression occurred, a crossover was done using the same regimen. A non-significant difference was observed in the time-to-PSA progression during the first treatment round (15 vs 9.6 months). However, after crossover, the time-to-PSA progression showed a highly significant difference (17.1 vs 6.6 months, p = 0.0002) in favour of the thalidomide treatment arm. This finding was not linked to any hormonal effect. This observation provides proof of principle and warrants further larger studies, particularly because thalidomide required dose reduction in 47% of patients due to intolerability.

12.5.4 ***Immediate versus deferred ADT***

There is still controversy over the most appropriate time to introduce hormonal therapy in patients with advanced PCa. Should ADT be given immediately upon diagnosis in locally advanced and asymptomatic metastatic disease or deferred until there are signs and symptoms of clinical progression? (This has already been partly discussed in Section 8.3.)

The controversy over whether only immediate treatment with ADT has a positive effect on survival and QoL has arisen because of the lack of properly conducted randomised controlled trials. Many trials are methodologically flawed because of small size and underpowering, heterogeneity of patient enrolment with advanced PCa (i.e. locally advanced, nodal and metastatic stages of disease), and variation in the hormonal treatments given and in the follow-up schedules and modalities used.

Bearing these limitations in mind, the evidence for immediate versus deferred ADT is provided by four systematic reviews of the literature (including a meta-analysis). A report by the Agency for Health Care Policy and Research (AHCPR) indicated a possible survival advantage for early ADT in single studies where hormonal treatment was the primary therapy (86). Furthermore, androgen suppression was shown to be the most cost-effective therapy if initiated after patients had experienced symptoms from metastatic disease (87).

The Cochrane Library review extracted four, good-quality, randomised, controlled trials, i.e. namely VACURG I and II studies, the MRC trial and the Eastern Cooperative Oncology Group (ECOG) 7887 study, which were all conducted in the pre-PSA era. The studies included patients with advanced PCa, who received early versus deferred ADT, either as primary therapy or adjuvant to radical prostatectomy (but not to radiotherapy). Early androgen suppression significantly reduced disease progression and complication rates due to progression itself. However, it did not improve cancer-specific survival and provided a relatively small benefit in OS, with an absolute risk reduction of 5.5% after 10 years (88). Finally, a systematic review was published last year, highlighting again the benefit of immediate versus deferred ADT in term of overall survival (+ 10%) and specific survival (+ 20%) (89). In the PSA era, the EORTC 30891 study (90) has produced the same results, namely a small benefit in OS, but no cancer-specific survival benefit. Furthermore, only young patients with a high PSA are likely to clearly benefit.

Based on a systematic review of the literature, recently published ASCO guidelines on initial hormonal

treatment for androgen-sensitive, metastatic, recurrent or progressive PCa concluded that no recommendation can be made on when to start hormonal therapy in advanced asymptomatic PCa, until data becomes available from studies using modern diagnostic and biochemical tests and standardised follow-up schedules (48).

Based on meta-analyses published, treatment appears to be most cost-effective when started after the onset of symptoms. Based on exploratory analysis, treatment with anti-androgen monotherapy does not lead to a survival benefit in men with localised PCa managed with non-definitive therapy, and the impact is still questionable after external beam therapy. This was explored in detail above with regard to the EPCP trials (*see Section* 12.4.2.3).

For asymptomatic patients with locally or regionally advanced PCa who undergo radiotherapy, several randomised controlled trials have produced good evidence to show that concomitant and/or adjuvant hormonal therapy provides longer time-to-disease progression and/or longer OS than radiotherapy alone followed by androgen suppression at progression (*see Section* 12.8) (LE: 1b).

The detailed discussion on immediate or deferred ADT combined with surgery or radiation therapy is discussed in Section 8.3.

12.6 Indications for hormonal therapy

Table 18 lists the indications for hormonal therapy.

Table 18: Indications for hormonal therapy

Hormonal therapy Indications for castration	**Benefits**	**LE**
M1 symptomatic	To palliate symptoms and to reduce the risk for potentially catastrophic sequelae of advanced disease (spinal cord compression, pathological fractures, ureteral obstruction, extraskeletal metastasis).	1b
	Even without a controlled randomised trial, this is the standard of care and must be applied and considered as level 1 evidence.	1
M1 asymptomatic	Immediate castration to defer progression to a symptomatic stage and prevent serious disease progression-related complications.	1b
	An active clinical surveillance protocol may be an acceptable option in clearly informed patients if survival is the main objective.	3
N+	Immediate castration to prolong PFS and even OS.	1b
	Might be questioned in single micrometastasis after extended lymph node dissection and radical prostatectomy.	3
Locally advanced M0	Immediate castration to improve cancer-free survival.	1b
- Locally advanced disease treated with radiotherapy	High-risk d'Amico: combined and prolonged ADT.	1a
	Intermediate-risk d'Amico: - If low dose (< 75 Gy) radiotherapy: 6 months of ADT; - If high dose (> 75 Gy) radiotherapy: ADT questionable.	1b 2a
- Locally advanced disease treated with radical prostatectomy	No benefit in term of survival either as neoadjuvant or adjuvant treatment.	3
- Locally advanced asymptomatic unfit for local definitive treatment	Limited OS improvement not related to a CSS benefit (90).	1a
	CAB compared compared to castration monotherapy: survival benefit (<5% after 5 years of follow-up).	1a
Anti-androgens		
Short-term administration	To reduce the risk of the 'flare-up' phenomenon in patients with advanced metastatic disease who are to receive an LHRH agonist (91,92).	1b

Non-steroidal anti-androgen monotherapy	Primary monotherapy as an alternative to castration in patients with locally advanced PCa (T3-4, any N, or any T).	2a
	No place in localised disease as a single-treatment modality.	
	Combined with radiotherapy: no clear recommendation is possible at the present time.	
	Combined with radical prostatectomy: no place so far in an adjuvant setting.	

12.7 Contraindications for various therapies

Table 19 lists the contraindications for various therapies.

Table 19: Contraindications for various therapies.

Therapy	Contraindications
Bilateral orchiectomy	Psychological reluctance to undergo surgical castration.
Oestrogens	Known cardiovascular disease.
LHRH agonists alone	Patients with metastatic disease at high risk for clinical 'flare up' phenomenon.
Anti-androgens	Localised PCa as primary therapy.

12.8 Outcome

Outcome depends on the stage and grade of disease at diagnosis.

In M1 cases, the median OS ranges between 28 and 53 months (9). Only 7% of patients with metastatic cancer treated with hormonal therapy have been reported alive at 10 years or longer (93). Survival is likely to depend on the PSA level at diagnosis, the Gleason score, the volume of metastatic disease, and the presence of bony symptoms.

In locally advanced M0 patients, the median OS is frequently reported to exceed 10 years (57).

12.9 Side-effects, QoL, and cost of hormonal therapy

The many deleterious side-effects of long-term ADT have been well known for years. Some can have a detrimental effect on QoL, especially in young men, while others may contribute to an increased risk of serious health concerns associated with ageing.

Many patients with PCa for whom long-term ADT is indicated are still young and physically and sexually active. Quality of life is an issue of paramount importance when considering the various hormonal treatment options. Thus, in selected patients, monotherapy with a non-steroidal anti-androgen (e.g. bicalutamide) is becoming more popular because it maintains normal (or even higher) serum testosterone levels and has a good tolerability profile.

*12.9.1 **Sexual function***

Loss of libido and erectile dysfunction are well-known side-effects of hormonal therapy. The management of erectile dysfunction is not specific.

*12.9.2 **Hot flashes***

Hot flashes are probably the most common side-effect of ADT. They appear 3 months after starting ADT, persist long term in most patients and can have a significant impact on QoL in some patients. Treatments include hormonal therapy and antidepressants.

12.9.2.1 Hormonal therapy

Oestrogen-receptor modulators or low-dose oestrogen therapies, e.g. DES, 0.5-1 mg/day, reduce the frequency and severity of hot flashes. Both treatments carry a risk of cardiovascular complications (94). Soya phytoestrogens have shown efficacy for hot flashes in breast cancer patients (95), but have not been evaluated in men. Progesterone-based treatments, such as megestrol acetate, medroxyprogesterone acetate and CPA, have also demonstrated efficacy, with 80% of patients showing an improvement with CPA (96) or chlormadinone (97).

12.9.2.2 Antidepressants

Antidepressants may have some efficacy against hot flashes, including venlafaxine (a non-specific selective noradrenaline and serotonin reuptake inhibitor), which has shown efficacy in breast cancer patients, and the

selective serotonin reuptake inhibitor, sertraline, which appears to be effective in men with PCa.

Recently, a randomised trial (n = 919) compared three drugs: venlafaxine, 75 mg daily, medroxyprogesterone, 20 mg daily, or CPA, 100 mg daily (98). After 6 months of LHRH, only 311 men had significant hot flushes and were randomized. Venlafaxine was clearly inferior compared to the hormonal agents, which showed similar efficacy to each other.

12.9.2.3 Other options

Other treatments have also been tested, including clonidine and veralipride, and even acupuncture (99). With a placebo effect influencing up to 30% of patients (100), few treatments are approved for the control of hot flashes in men with PCa. There is a lack of large, prospective, randomised controlled trials in this area.

12.9.3 ***Other systemic side-effects of ADT***

More recently, other systemic side-effects have been described and require increased attention, including bone problems, obesity and sarcopenia, lipid alterations and insulin resistance, metabolic syndrome, diabetes, and cardiovascular disease (101).

12.9.3.1 Non-metastatic bone fractures

Androgen deprivation therapy increases the risk of non-metastatic bone fracture due to increased bone turnover and decreased BMD in a time-dependent manner, and there is an increased risk of fracture of up to 45% relative risk with long-term ADT (102). This is an important side-effect, as hip fractures in men are associated with a significant risk of death (103). Increased exercise, calcium and vitamin D supplementation are protective. Bicalutamide monotherapy could also be a bone-protective method based on a small, prospective, randomised trial, including 103 patients comparing bicalutamide, 150 mg/day, or medical castration (104) (LE: 1b).

Bisphosphonates

Recently, bisphosphonates, such as pamidronate, alendronate or zoledronic acid, have been shown to increase BMD in the hip and spine by up to 7% in 1 year. The optimal regimen for zoledronic acid is unclear. One study recommends treatment every 3 weeks (105), while another trial has produced similar results with an annual injection (106). The optimal regimen is very important because of the risk of jaw necrosis, which may be both dose- and time-related (107). The initial BMD could be used to guide the choice of regimen (108). Thus, a 3-month injection might be given in osteoporotic patients for whom a yearly injection is likely to provide insufficient protection.

As previously observed in breast cancer, a significant benefit in OS has recently been demonstrated for biphosphonates in PCa, particularly oral first-generation clodronate versus placebo. After at least 10 years of follow-up, an absolute 8% increase in OS was observed at 8 years in a clodronate-treated group of PCa patients, who had an overall survival of 22% versus 14% in the placebo group (109). The benefit for OS applied only to M1 patients, but not to M0 patients. Although this is a post-hoc analysis and the results are surprising because clodronate has no bone protective effect in PCa, this study again highlights the potential impact of bone-targeted drugs and the need for continuous trials, e.g. the Zeus trial, which uses a more recent biphosphonate.

Denosumab

In 2009, a major advance in bone protection was made with the introduction of denosumab, a fully human monoclonal antibody against RANKL, which is a key mediator for osteoclast function, activation and survival. A total of 1,468 men with non-metastatic PCa receiving ADT were randomised to denosumab, 60 mg subcutaneous every 6 months, or placebo (110). The primary end-point was the percentage change in lumbar spine BMD at 2 years. Denosumab was associated with 5.6% increase in the lumbar BMD versus 1% decrease in the placebo arm. There were also significant BMD increases at the total hip, femoral neck and distal third of the radius. The vertebral fracture rate was less in the denosumab-treated group versus the placebo-treated group (1.5% vs 3.9%, p = 0.006). This benefit was similar whatever the age (< or > 70 years), the duration or type of ADT, the initial BMD, the patient's weight or the initial BMI. This benefit was not associated with any significant toxicity, as the rates of adverse events were the same in both groups, without any jaw osteonecrosis or delayed healing in vertebral fractures. Denosumab may therefore represent a major advance in bone protection.

In addition, this drug has been shown to postpone bone metastases in non-metastatic patients in a large RCT of 1,432 patients (111). Denosumab, 120 mg every 4 weeks, increased the time to bone metastasis-free survival by 4.2 months compared to placebo, but was accompanied by the side effects of jaw necrosis in 5% of treated patients versus 0% in the placebo arm and hypocalcaemia in 2% of treated patients versus less than 1% in the placebo arm. However, the increase in bone metastasis-free survival had no impact on overall

survival, which was 43.9 months in the denosumab group compared to 44.8 months in the placebo group. These results highlight the potential importance of targeting the bone microenvironment. However, the daily use of denosumab remains questionable because of related side effects and cost.

Lifestyle changes before starting long-term ADT
Patients should be encouraged to adopt lifestyle changes, e.g. increased physical activity, cessation of smoking, decreased alcohol consumption and normalisation of their body mass index (BMI). A precise evaluation of BMD should be performed by dual emission X-ray absorptiometry before starting long-term ADT. An initial low BMD (T-score > 2.5, or > 1 if other risk factors are present) indicates a high risk of subsequent non-metastatic fracture, suggesting the need for early preventive bisphosphonate therapy.

Obesity and sarcopenia
Obesity and sarcopenia are common and often occur early, during the first year of ADT. There is an expected increase in body fat mass by up to 10%, and a decrease in lean tissue mass by up to 3% (112). Both changes are linked to an increased risk of fracture.

12.9.3.2 Lipid levels
Lipid alterations are common and may occur as early as the first 3 months of treatment (112). Androgen deprivation therapy also decreases insulin sensitivity and increases fasting plasma insulin levels, which is a marker of insulin resistance. Once again, exercise must be recommended as a protective tool.

12.9.3.3 Metabolic syndrome
Metabolic syndrome is an association of independent cardiovascular disease risk factors, often associated with insulin resistance. The risk factors include:

- waist circumference > 102 cm;
- serum triglyceride > 1.7 mmol/L;
- blood pressure > 130/80 mmHg;
- HDL cholesterol < 1 mmol/L;
- glycaemia > 6.1 mmol/L.

The prevalence of metabolic syndrome is higher during ADT compared with untreated men (113).

12.9.3.4 Cardiovascular disease
Androgen deprivation therapy has been associated with an increased risk of diabetes mellitus, cardiovascular disease, and myocardial infarction in several studies (114).

Analysis of the RTOG 92-02 data has confirmed an increase in cardiovascular risk, which is unrelated to the duration of ADT. No increase in cardiovascular mortality was found (115). Similar findings were observed in the RTOG 94-08 trial (116). These observations have been much discussed because no increase in cardiovascular mortality has been reported in trials RTOG 8531, 8610, 9202, EORTC 30891 or EORTC 22863. However, an increase in cardiovascular mortality has been reported in patients suffering from previous congestive heart failure or myocardial infarction in a retrospective database analysis (117).

In summary, since 6 or less months of ADT may already be associated with increased cardiovascular morbidity the FDA issued a warning and a consensus paper from the American Heart, Cancer Society and Urological Associations was published (118). However, to date, the data on cardiovascular mortality remain inconsistent. Preventive advice is associated with non-specific measures, such as loss of weight, increased exercise, improved nutrition and the cessation of smoking.

12.10 Quality of life (QoL)

There is little data on QoL during hormone treatment. The only large, prospective, randomised study is a double-blind, placebo-controlled trial including 739 patients with M1 PCa, which compared orchiectomy + flutamide versus orchiectomy + placebo. The QoL was assessed in the first 6 months of treatment. Combined therapy resulted in a lower QoL, with statistically significant differences in two QoL parameters, namely more frequent diarrhoea and worse emotional functioning, compared with castration alone (119).

A prospective, non-randomised, observational study, which included 144 patients with locally advanced PCa or PSA failure after definitive local treatment, found that patients who received immediate ADT (by means of bilateral orchiectomy, LHRH agonist or CAB) reported a lower overall QoL (increased fatigue, emotional distress, and decreased physical functioning) than patients in the deferred hormone treatment arm (120) (LE: 2a).

A retrospective, non-randomised study included 431 patients with stage PCa who received orchiectomy or LHRH agonists as their primary therapy within 12 months of initial diagnosis. The study

assessed health-related quality of life (HRQoL) outcomes at 12-months' follow-up. Men receiving LHRH agonists reported more worry and physical discomfort and poorer overall health, and were less likely to believe themselves free of cancer than were orchiectomised patients. The stage at diagnosis had no significant independent effect on health outcome. However, the study was underpowered (121) (LE: 2b).

A recent, small, randomised, controlled trial evaluated the HRQoL of patients with non-localised PCa allocated to leuprorelin, goserelin, CPA or no treatment at 1-year follow-up. Both sexual and cognitive function significantly declined in men on all forms of androgen suppression, while emotional distress significantly increased in those assigned to CPA or no treatment (122) (LE: 1b).

Intermittent androgen deprivation may be associated with an improved overall QoL based on the normal testosterone levels during off-treatment periods. Until recently, the results were inconclusive, showing either no benefit, or only a marginal one, in QoL. However, recent results from the JPR7 trial have shown a clear benefit for QoL (74).

As for LHRH agonists, QoL has been evaluated in the previously mentioned studies of bicalutamide monotherapy using a specific non-validated questionnaire. At 12 months, bicalutamide showed a significant advantage over castration in the domains of physical capacity and sexual interest (not sexual function) (38) (LE: 1b).

A further post-hoc analysis, including only patients with sexual interest at study entry, found that significantly more patients receiving bicalutamide, 150 mg/day, maintained their interest in sex and felt that they were still sexually attractive (123,124), or had a preserved libido and erectile function compared to castration (125).

The most common side-effects during non-steroidal anti-androgen monotherapy are gynaecomastia and breast pain, which are caused by an imbalance in the androgen-to-oestrogen ratio within breast tissue. In bicalutamide studies, these events were reported by up to 66% and 73% of patients, respectively, and may have led to treatment cessation in 16.4% of patients.

12.11 Cost-effectiveness of hormonal therapy options

A recent formal meta-analysis and literature review evaluated the cost-effectiveness of various long-term androgen suppression options in advanced PCa (e.g. bilateral orchiectomy, DES, LHRH-agonist, non-steroidal anti-androgen monotherapy, and CAB using non-steroidal anti-androgens).

For the analysis, a sophisticated statistical model was generated, assuming the base case at entry to be a 65-year-old man with clinically evident local recurrence of PCa and no distant metastases, followed for a 20-year time horizon. The study concluded that, for men who can accept it, bilateral orchiectomy is the most cost-effective form of ADT providing a higher quality-adjusted survival, while CAB is the least economically attractive option, yielding small health benefits for a high relative cost. Furthermore, the greatest QoL gains and least costs may be obtained by starting ADT when symptoms from distant metastases have occurred (87) (LE: 1a).

Finally, once ADT is started, if a clear response is obtained (*see Section* 12.3.3), then IAD might be a useful way to lower treatment costs.

12.12 Conclusions and guidelines for hormonal therapy in prostate cancer	LE
In advanced PCa, androgen deprivation therapy (ADT) delays progression, prevents potentially catastrophic complications, and palliates symptoms effectively, but does not prolong survival.	1b
In advanced PCa, all forms of castration used as monotherapy (e.g. orchiectomy, LHRH and DES) have equivalent efficacy.	1b
Non-steroidal anti-androgen monotherapy (e.g. bicalutamide) is an alternative to castration in patients with locally advanced disease.	2a
In metastatic PCa, the addition of a non-steroidal anti-androgen to castration (CAB) results in a small advantage in OS over castration alone, but is associated with increased adverse events, reduced QoL, and high costs.	1a
In metastatic PCa, ADT should only be offered to carefully selected patients.	2a
In advanced PCa, immediate ADT (given at diagnosis) significantly reduces disease progression, as well as the complication rate due to progression itself, compared with deferred ADT (delivered at symptomatic progression). However, the survival benefit is at best marginal and not related to cancer-specific survival.	1b
Bilateral orchiectomy might be the most cost-effective form of ADT, especially if initiated after the occurrence of symptoms from metastatic disease.	3

13. MANAGEMENT OF PROSTATE CANCER IN OLDER MEN

13.1 Introduction

Prostate cancer is the most prevalent cancer in men, with a median age at diagnosis of 68 years. Two-thirds of prostate cancer-related deaths occur in men aged ≥ 75 years (1). Older men tend to have larger tumours of a higher grade than younger patients (2,3). Treatment decisions for older men should take into consideration the risk of dying from PCa (which depends on the grade and stage of the tumour), potential adverse effects of treatment, and patient preference. Interventions that might decrease health-related quality of life (HRQoL)

without prolonging survival should be avoided. Evidence suggests that in both the USA (4) and Europe (5) older patients are under-treated: only a minority of older adults with localised prostate cancer receive curative treatment. However, curative treatment should neither be denied where appropriate, nor limited to androgen deprivation therapy (ADT).

Life expectancy is a major determinant of the potential for benefit from therapy. The International Society of Geriatric Oncology (SIOG) Prostate Cancer Working Group recommends that the decision-making process for treating older men with PCa should be based on a systematic evaluation of health status, most importantly comorbidities, dependence status, and nutritional status (6). These factors influence patient survival and can also affect the ability to tolerate treatment-related side-effects (6).
For localised disease, treatment benefit is usually considered to be seen only beyond 10 years, which leads to a treatment frontier of 75 years. This should be reconsidered, given that Walter (7) has shown that survival probability is linked not only to legal age, but more importantly to overall health status. For example, a healthy 80-year-old senior can expect a median 10.8 years of survival, compared to 6.7 years for a vulnerable, and 3.3 years for a frail senior. At 85 years of age, healthy seniors can expect to survive 8 years. These figures date back 10 years, and are likely to have increased with life expectancy.

Comorbidity is a major predictor of PCa mortality. Tewari et al. demonstrated that comorbidity evaluated by the Charlson index was the strongest predictor of death from causes other than PCa in men with localised PCa treated with RP (8). This was recently confirmed in a cohort of patients from the Surveillance, Epidemiology and End Results (SEER) database, all of whom had treatment-resistant PCa. At 10 years, most men with a Charlson score ≥ 2 died from competing causes, irrespective of age or tumour aggressiveness (9). Currently the Cumulative Illness Score Rating-Geriatrics (CISR-G) is the best available tool for assessing the risk for death unrelated to PCa. Whereas the Charlson index considers only potentially lethal comorbid conditions, the CISR-G also rates nonlethal conditions according to their severity and level of control (10,11).

Level of dependence in daily activities is another factor that influences survival in senior adult patients (12,13). Dependence can be evaluated using the Activities of Daily Living (ADL) and Instrumental Activities of Daily Living (IADL) scales. The ADL scale rates an ability to accomplish basic activities of daily living, while the IADL scale rates activities that require a higher level of cognition and judgement (for example the ability to manage money or medication, or to use transportation or the telephone).

Malnutrition has also been shown to be associated with an increased mortality rate in senior adult patients (14). Nutritional status can be estimated by the variation of weight during the previous 3 months:

- good nutritional status < 5% of weight loss;
- risk of malnutrition - weight loss 5-10%;
- severe malnutrition - weight loss > 10%.

Evaluation of comorbidity, dependence and malnutrition is recommended by The SIOG Prostate Cancer Working Group in order to classify patients into one of 4 groups:

1. ‘Fit’ or ‘healthy’ older men should receive the same standard treatment as younger patients.
2. ‘Vulnerable’ patients (i.e. reversible impairment) should receive standard treatment after resolution of any geriatric problems through geriatric interventions.
3. ‘Frail’ patients (i.e. irreversible impairment) should receive an adapted treatment.
4. Patients who are ‘too sick’ with ‘terminal illness’ should receive only symptomatic palliative treatment (6).

“Fit” and “vulnerable” older men with localised PCa in the high-risk group defined by D`Amico et al. (18), with a chance of surviving for more than 10 years are likely to benefit from curative treatment. Older men in the low risk and possibly intermediate risk classification are most likely to benefit from a watchful-waiting approach. The urological approach in older men with PCa should be the same as in younger patients, based on existing recommendations (15-17). Older men with PCa should be managed according to their individual health status which is mainly driven by the severity of associated comorbid conditions and not according to chronological age.

13.2 Treatment-related complications

The risk of short-term postoperative complications appears to be related more to the severity of comorbidities than chronological age. Conversely, the risk of long-term incontinence after RP is more influenced by increasing age than comorbidity (19,20). External Beam Radiotherapy (EBRT) has similar outcomes in terms of cancer control and treatment related comorbidities in both older and younger patients, assuming a dose of $\geq$ 70Gy using intensity modulated radiotherapy (IMRT) or image guided radiotherapy (IGRT). Brachytherapy might be a suitable option in older patients, but survival benefit in older men with low risk disease has not been established. Urinary, bowel and erectile complications after brachytherapy increase significantly with

both increasing age and severity of comorbidities (15). For those with locally advanced disease, a combined modality of EBRT and long term hormonal treatment must be considered. The drawback of ADT in older patients has been discussed earlier (see Chapter 14). Cardiac status should be specially checked if ADT is considered, as it might be associated with increased morbidity, but not mortality. Comorbidity by itself could also be a discriminating factor, as suggested recently in localised high risk patients (21).

In patients with non-metastatic localised PCa unsuitable for curative treatment, immediate ADT should be used only in patients requiring symptom palliation (22,23) . In the case of locally advanced T3-T4 disease immediate ADT can be of benefit in patients with PSA > 50ng/mL and PSA doubling time of < 12 months (22,23). ADT is the first-line treatment in hormone-sensitive metastatic PCa. The SIOG Prostate Cancer Working Group recommends evaluation of bone mineral status and prevention of osteoporosis. All men receiving ADT should receive calcium and vitamin D supplementation. The routine use of biphosphonates to prevent skeletal complications in patients undergoing ADT is not recommended unless there is a documented risk for fracture or castration-resistant PCa with skeletal metastasis (6). However, in a recent randomised trial Denosumab was shown to improve metastases free survival in patients without distant metastases and rising PSA (29.5 months vs 25.2 months, p = 0.0028) and increase time to first bone lesion (33.2 months vs 29.5 months, p = 0.0032) (24).

In metastatic castration-resistant prostate cancer (CRPC), chemotherapy with docetaxel (75 mg/m^2 every 3 weeks) is the standard for fit and vulnerable older men. The tolerability of the docetaxel 3-weekly regimen has not been specifically studied in frail older men. In a retrospective analysis of 175 patients aged ≥ 75 years treated with docetaxel, patients with a good performance status responded to docetaxel therapy to a similar extent as younger patients. Docetaxel was generally well tolerated. The weekly regimen showed less febrile neutropenia than the 3-weekly regimen but a higher rate of fatigue, resulting in frequent treatment discontinuation (25). The place of weekly docetaxel in metastatic CRPC should be further evaluated. Palliative treatments in CRPC include palliative surgery, radiopharmaceuticals, EBRT, and medical treatments for pain and symptoms.

14. QUALITY OF LIFE OF PATIENTS WITH LOCALISED PROSTATE CANCER

14.1 Introduction

The increase in life expectancy of patients with localised PCa has made the quality of life after treatment a key issue for PCa survivors. The term 'health-related quality of life' (HRQoL) is typically used to refer to the impact

that disease and treatment have on a person's well-being and physical, emotional and social functioning, including daily functioning (1-4). HRQoL is a patient-centered outcome which is rated by the patient himself, particularly as physicians often underestimate the impact of disease and treatment on their patients' lives (5). In PCa, HRQoL is usually divided into PCa-specific and PCa-general issues. PCa-specific HRQoL refers to the disease-specific outcome of PCa, including urinary, bowel, and sexual functioning. PCa-general HRQoL refers to generic issues of well-being, including physical, social, emotional, and cognitive functioning, vitality/fatigue, pain, general health status, global quality of life and life satisfaction (6).

HRQoL is measured using standardised questionnaires, which collect patient-centric data and provide an objective assessment and perception of both generic and disease-specific domains. Several comprehensive HRQoL questionnaires have undergone validation and have been used to measure early stage PCa outcomes. The most frequently used questionnaires include the EPIC (Expanded Prostate Cancer Index Composite), the Symptom indexes constructed by Clark and Talcott, and the Prostate Module appendix for the EORTC-QLQ C30 (7-9).

Various forms of therapies have different impacts on HRQoL. A comparison of the most common contemporary therapies for localised PCa (radical prostatectomy, brachytherapy, external-beam radiation therapy and active surveillance) is necessary to inform patients about treatment options and to address individual patient preferences for the various possible outcomes. There is still very little objective data about HRQoL for PCa treatment, mainly because of a lack of prospective trials.

14.2 Active surveillance

Although active surveillance avoids treatment-related side effects, it carries an increased risk of psychological distress, which can have significant effects on the patient's HRQoL. There are certain risk factors for patients who may not do well on active surveillance. These factors include the patient's perception that the physician is making most of the decision-making, a poor physical health score, a high neuroticism (anxiety) score, and a high PSA value. All these factors were found to have significant positive associations with lower HRQoL scores in multivariate analysis (10). Anxiety and distress did not increase and remained low during the first 9 months of surveillance in men enrolled in the active surveillance PRIAS study (11). Additional research with a longer follow-up is needed to define the significance of negative effects of active surveillance on HRQoL (LE: 1b).

Data from an RCT on anxiety comparing WW and RP (13) found that depression, well-being and psychological status were not significantly different between treatment groups, even if they were systematically inferior in the treated group (LE: 1b).

14.3 Radical prostatectomy

Several trials have shown that RP has a significant negative effect on multiple QoL domains, including a lower sexual function score, lower urinary function and incontinence scores, and a lower physical HRQoL (13-16).

In the Prostate Cancer Outcomes Study (PCOS), 8.7% of men at 24 months were bothered by a lack of urinary control and 41.9% reported that sexual function was a moderate-to-big problem in their daily lives (17). Sexual function and interest are the two prostate-specific domains that decline most after surgery and remain most affected after 1 year (18). The recovery of sexual dysfunction and urinary incontinence occurs over 2 to 3 years (19-21). Sanda and colleagues (14) recently reported that urinary incontinence was at its worst by 2 months after surgery, after which time it improved in most patients. At 1 year after RP, 26% of patients reported that sexual function was a 'big problem', while 76% reported that urinary incontinence was a 'very small' problem or 'no problem at all' (LE: 2a).

Although certain advances have been made that help diminish these side effects, such as nerve-sparing RP or robotic-assisted radical prostatectomy (RALP), their impact on HRQoL remain controversial.

Preserving the neurovascular bundles reduces the incidence of impotence (14,22) and can also help to improve urinary function (21,22). Both RALP and open RP have demonstrated comparable functional outcomes and should therefore theoretically have similar HRQoL scores (24). Recently, Hu et al. (25) compared minimally invasive RP (all laparoscopic techniques) with traditional open RP using a dataset of nearly 2000 Medicare patients. The incontinence and erectile dysfunction rate were higher in the minimally invasive group compared with the open RP group (LE: 3). In a prospective, longitudinal study, Thornton et al. assessed changes in the cognitive, emotional, and interpersonal components of PCa-related QoL in 71 men who underwent RALP. Although some components of QoL returned to baseline by 1 year after surgery, there were enduring decreases in sexual intimacy, sexual confidence, and masculine self-esteem (26). More motivated patients

seemed to experience greater distress and were less satisfied (27). Other general HRQoL domains that may be affected after surgery included pain and energy (18). Several studies have shown that pain and energy worsen immediately post-RP but usually improve by 12 months (19,21,28).

A new methodology for reporting outcomes after RP was proposed recently: the so-called trifecta (29) and pentafecta (30). The new method combines major outcomes, including continence, potency and cancer control (trifecta) and peri-operative complications and positive surgical margins rates (pentafecta). Pentafecta rates reflect post-operative patient expectations and satisfaction more accurately and can be used in counselling patients with clinically localised PCa. The use of trifecta and pentafecta outcomes in post-operative HRQoL assessment needs further validation.

14.4 External-beam radiation therapy (EBRT) and low-dose rate (LDR) brachytherapy

Patients undergoing EBRT and I^{125} LDR brachytherapy may have urinary, sexual and bowel dysfunction after treatment (31). Both methods can result in irritative voiding symptoms, such as urgency, frequency, and urge incontinence, that negatively affect overall urinary function and HRQoL. The most predominant severe acute toxicity after LDR brachytherapy is urinary retention requiring catheterisation (32). Roeloffzen et al. (32,33) reported that acute urinary retention after LDR brachytherapy occurs in 8-10.2% of patients and has a significant negative impact on patients' HRQoL up to 6 years after treatment, in terms of both global QoL measures and urinary symptom scores (LE: 3).

A prospective multicentre study showed that the effects of EBRT on urinary symptoms had resolved at 12 months and improved over baseline at 24 months (14). In the same study, patients in the LDR brachytherapy group reported significant detriments in urinary irritation or obstruction and incontinence compared with baseline. Incontinence after LDR brachytherapy was reported by 4-6% of patients at 1-2 years after treatment. Eighteen percent of patients in the LDR brachytherapy group and 11% of those in the EBRT group reported moderate or worse distress from overall urinary symptoms at 1 year (14) (LE: 3).

It has been shown that both EBRT and LDR brachytherapy had a significant impact on the bowel and rectal HRQoL domains (14,34). Bowel/rectal problems appeared to have an overall impact close to that of the urinary v domain (35,36). The onset of symptoms occurred during or early after treatment, and sometimes persisted longer into follow-up. Sanda et al. reported rectal urgency, frequency, pain, fecal incontinence, or hematochezia-caused distress related to bowel function in 9% of patients at 1 year after EBRT or LDR brachytherapy (14). In a retrospective observational study of fecal incontinence in 143 men, who had received LDR brachytherapy for localised PCa, 13.2% (20) of patients at 2 years reported that fecal incontinence was impacting their ability to participate in daily activities (37). A multivariable analysis suggested that bowel and rectal symptoms were less profound after LDR brachytherapy than after EBRT (7) (LE: 2a).

Roeloffzen et al. (33) reported a statistically significant deterioration in HRQoL in patients treated with I125 LDR brachytherapy at 6 years for urinary symptoms, bowel symptoms, pain, physical functioning, and sexual activity. However, most of these changes were not clinically relevant. HRQoL scores returned to approximately baseline values at 1 year and remained stable up to 6 years after treatment. The only clinically relevant changes were seen for emotional functioning and sexual activity. Worse bowel and urinary function may play a stronger role than sexual function in predicting a patient's overall physical and emotional HRQoL (38). Contemporary treatment refinements, such as 3-D conformal or intensity-modulated radiotherapy (IMRT), may be able to reduce the impact of EBRT on bowel symptoms, but this has not yet been shown in a multicentre setting.

Recently, Sanda et al. showed that adjuvant androgen suppression exacerbated the adverse effects of external radiotherapy or brachytherapy on sexuality and vitality (14). The negative effects of adjuvant hormonal therapy have been shown in some other studies (31,39).

Among general domains, fatigue was commonly reported following EBRT. However, provided that fatigue was temporary, it did not appear to be emotionally distressing to most men (40,41). Men treated with interstitial LDR brachytherapy appeared to have only slight declines in general HRQoL (42). Physical and functional status declines have been reported in the first few months after implant, but pretreatment levels of function are regained by most men at 1 year after implant (43).

14.5 Comparison of HRQoL between treatment modalities

The limitations of all published studies assessing QoL include the lack of randomisation to treatment and therefore the presence of selection bias, which may influence outcomes. Thus, information regarding comparative outcome relies largely on results from non-randomised observational cohorts. Treatment comparison requires a long follow-up, as measures of quality of life may change with time. There are very few

trials investigating a direct comparison of different treatment modalities.

Most early studies addressing general HRQL issues (general physical function, role function, social function, emotional well-being, body pain, general health, or vitality/energy) have found few differences across treatments for clinically localised disease (6,44). In more recent longitudinal studies, both surgery- and radiotherapy-treated men have reported some declines in role function and vitality/energy shortly after treatment, with surgically treated men reporting the most dysfunction (28,40). However most men recovered function by 1 year after treatment.

The presence of comorbid psychiatric conditions (i.e. prior psychiatric history, alcohol abuse, drug abuse) and the experience of pain after treatment were considered to be certain risk factors for poor general HRQoL in men after treatment for localised prostate cancer (45-47).

The PCOS was the first reported prospective study presenting treatment-specific QoL outcomes for PCa patients at 5 years after initial diagnosis (17). The cohort consisted of men with newly diagnosed localised PCa treated with RP (n = 901) or EBRT (n = 286). At 5 years after diagnosis, overall sexual function declined in both groups to approximately the same level, mostly because of a continuing decline in erectile function among EBRT patients between years 2 and 5. However, erectile dysfunction was more prevalent in the RP group (79.3% vs 63.5%, respectively). Approximately 14-16% of RP and 4% of EBRT patients were incontinent at 5 years. Bowel urgency and painful haemorrhoids were more common in the EBRT group (LE: 2a).

Madalinska et al. evaluated the side effects of RP and EBRT in 278 patients from the ERSPC study at 6 and 12 months following treatment (35). RP patients reported significantly higher incidences of urinary incontinence (39- 49%) and erectile dysfunction (80-91%) than radiotherapy patients (6-7% and 41- 55%, respectively). Bowel problems (urgency) affected 30-35% of the EBRT group versus 6-7% of the RP group (LE: 2a).

Downs et al. measured the impact of LDR brachytherapy alone on general HRQoL and disease-specific HRQoL compared to patients treated with RP (48). The authors studied 419 men from the CaPSURE database, whose primary treatment was (LDR) brachytherapy [n = 92] or RP [n = 327].Patients treated with LDR brachytherapy or RP did not differ greatly in general HRQoL after treatment. Both treatment groups showed early functional impairment in most general domains, with scores returning to or approaching baseline in most domains at 18 to 24 months after treatment. Patients treated with LDR brachytherapy had significantly higher urinary function scores at 0 to 6 months after treatment (84.5%) than patients treated with RP (63.3%). Urinary bother scores were not significantly different (67.7% vs 67.4%, respectively). Both treatment groups showed decreases in sexual function that did not return to pretreatment levels (LE: 2a).

A multicentre study that compared all three treatments (RP, EBRT, LDR brachytherapy) in a longitudinal prospective cohort was conducted by Talcott et al. (7). In 417 men, the authors assessed urinary, bowel and sexual function from before primary treatment to 24 months afterwards. Urinary incontinence increased sharply after RP, while bowel problems and urinary irritation/obstruction occurred after EBRT and LDR brachytherapy. Sexual function severely worsened immediately after surgery and then improved, while sexual function continued to decline after both radiation treatments. It has been shown that a surgical patient, who is impotent at 3 or 12 months after surgery, can expect to have a realistic hope of improvement while impotent EBRT patients probably should not. There was no change in urinary function and little change in overall bowel function after 12 months. The data showed that a patient with bowel dysfunction at 12 months after EBRT may expect modest improvement, with diverging trends for individual symptoms. Diarrhoea will continue to subside, tenesmus and rectal urgency will change little, and episodes of rectal bleeding will become more prevalent (7) (LE: 2a).

A recent, prospective, multicentre study of 435 patients with a longer follow-up of 36 months was reported by Pardo et al. (49). The study confirmed that there was a long-term change in adverse effects, e.g. an increase in urinary-related adverse effects after EBRT or sexual adverse effects with LDR brachytherapy, which tended to reduce any differences between treatments over time. However, these changes were only slight. In accordance with other reports, the RP-treated group showed greater deterioration in urinary incontinence and sexual function, but improved urinary irritative-obstructive results compared with the LDR brachytherapy group. In patients with urinary irritative-obstructive symptoms at baseline, improvement was observed in 64% of those treated with nerve-sparing RP. Higher bowel worsening was observed in the ERBT group, with 20% of patients reporting bowel symptoms. Relevant differences between treatment groups persisted for up to 3 years of follow-up (49) (LE: 2a).

The American College of Surgeons Oncology Group phase III Surgical Prostatectomy Versus Interstitial Radiation Intervention Trial compared RP and LDR brachytherapy, but was closed after 2 years due to poor accrual. Crook et al. (50) recently reported the HRQoL at a mean of 5.3 years for 168 trial-eligible men, who either chose or were randomly assigned to RP or brachytherapy following a multidisciplinary educational session (50). There were no differences in bowel or hormonal domains. However, men treated with LDR brachytherapy scored slightly better in the urinary domain (91.8 vs 88.1; $p = 0.02$) and sexual (52.5 vs 39.2; $p = 0.001$) domain, and in patient satisfaction (93.6 vs 76.9; $p < 0.001$). It should be noted that treatment allocation was random in only 19% of cases (LE: 2a).

The quality of life of a patient's spouse or partner may also be reduced as a result of their spouse or partner receiving treatment for PCa. In a prospective multicentre study of more than 1200 patients and 625 spouses or partners (14), patients in the LDR brachytherapy group reported long-lasting urinary irritation, bowel and sexual symptoms and transient problems with vitality or hormonal function. The adverse effects of RP on sexual function were mitigated by nerve-sparing procedures. Distress associated with the patient's erectile dysfunction was reported by 44% of partners in the RP group, 22% of those in the EBRT group and 13% of those in the LDR brachytherapy group. After RP, urinary incontinence was observed, but urinary irritation and obstruction improved, particularly in patients with large prostates. Treatment-related symptoms were made worst by obesity, large prostate size, high prostate-specific antigen score and older age (LE: 2a).

Malcolm et al. (51) reported a single-institution study comparing the outcomes of surgery (RP, RALP), LDR brachytherapy and cryosurgical ablation of the prostate (CSAP) with a relatively short follow-up of 24 months (51). The HRQoL of patients treated with (LDR) brachytherapy and CSAP was associated with higher urinary function and higher bother score compared to open RP and RALP. LDR brachytherapy was associated with higher sexual function and higher bother score compared to all other treatment modalities. Unfortunately, the study used the UCLA-PCI questionnaire, which lacks items for evaluating irritative urinary symptoms often observed in patients after LDR brachytherapy (48). This may have significantly compromised the results of the HRQoL assessment (LE: 3).

In conclusion, many men treated for clinically localised PCa will experience some post-treatment problems that may impact their daily lives. Each patient therefore has to determine which side effect profile (34) is most acceptable to them when making a decision about treatment.

15. SUMMARY OF GUIDELINES ON PRIMARY TREATMENT OF PCA

Stage	Treatment	Comment	GR
T1a	Watchful waiting	Standard treatment for Gleason score ≤ 6 and 7 adenocarcinomas and < 10-year life expectancy.	B
	Active surveillance	In patients with > 10-year life expectancy, re-staging with TRUS and biopsy is recommended.	B
	Radical prostatectomy	Optional in younger patients with a long life expectancy, especially for Gleason score ≥ 7 adenocarcinomas	B
	Radiotherapy	Optional in younger patients with a long life expectancy, in particular in poorly differentiated tumours. Higher complication risks after TURP, especially with interstitial radiation.	B
	Hormonal	Not an option.	A
	Combination	Not an option.	C
T1b-T2b	Active surveillance	Treatment option in patients with cT1c-cT2a, PSA < 10 ng/mL, biopsy Gleason score ≤ 6, ≤ 2 biopsies positive, ≤ 50% cancer involvement of each biopsy.	B
		Patients with a life expectancy < 10 years.	
		Patients with a life expectancy > 10 years once they are informed about the lack of survival data beyond 10 years.	
		Patients who do not accept treatment-related complications.	

T1a-T2c	Radical prostatectomy	Optional in patients with pT1a PCa. Standard treatment for patients with a life expectancy > 10 years who accept treatment-related complications.	A
	Radiotherapy	Patients with a life expectancy > 10 years who accept treatment-related complications.	B
		Patients with contraindications for surgery.	
		Unfit patients with 5-10 years of life expectancy and poorly differentiated tumours (combination therapy is recommended; see below).	
	Brachytherapy	Low-dose rate brachytherapy can be considered for low risk PCa patients with a prostate volume ≤ 50 mL and an IPSS ≤ 12.	B
	Hormonal	Symptomatic patients, who need palliation of symptoms, unfit for curative treatment.	C
		Anti-androgens are associated with a poorer outcome compared to 'active surveillance' and are not recommended.	A
	Combination	For high-risk patients, neoadjuvant hormonal treatment and concomitant hormonal therapy plus radiotherapy results in increased overall survival.	A
T3-T4	Watchful waiting	Option in asymptomatic patients with T3, well-differentiated and moderately-differentiated tumours, and a life expectancy < 10 years who are unfit for local treatment.	C
	Radical prostatectomy	Optional for selected patients with T3a, PSA < 20 ng/mL, biopsy Gleason score ≤ 8 and a life expectancy > 10 years.	C
		Patients have to be informed that RP is associated with an increased risk of positive surgical margins, unfavourable histology and positive lymph nodes and that, therefore, adjuvant or salvage therapy such as radiation therapy or androgen deprivation might be indicated.	
	Radiotherapy	T3 with > 5-10 years of life expectancy. Dose escalation of > 74 Gy seems to be of benefit. A combination with hormonal therapy can be recommended.	A
	Hormonal	Symptomatic patients, extensive T3-T4, high PSA level (> 25-50 ng/mL), PSA-Doubling Time (DT) < 1 year.	A
		Patient-driven, unfit patients.	
		Hormone monotherapy is not an option for patients who are fit enough for radiotherapy.	
	Combination	Overall survival is improved by concomitant and adjuvant hormonal therapy (3 years) combined with external beam radiation.	A
		NHT plus radical prostatectomy: no indication.	B
N+, M0	Watchful waiting	Asymptomatic patients. Patient-driven (PSA < 20-50 ng/mL), PSA DT > 12 months. Requires very close follow-up.	B
	Radical prostatectomy	Optional for selected patients with a life expectancy of > 10 years as part of a multimodal treatment approach.	C
	Radiotherapy	Optional in selected patients with a life expectancy of > 10 years, combination therapy with adjuvant androgen deprivation for 3 years is mandatory.	C
	Hormonal	Standard adjuvant therapy in more than 2 positive nodes to radiation therapy or radical prostatectomy as primary local therapy. Hormonal therapy should only be used as monotherapy in patients who are unfit for any type of local therapy.	A
	Combination	No standard option. Patient-driven.	B

M+	Watchful waiting	No standard option. May have worse survival/more complications than with immediate hormonal therapy. Requires very close follow-up.	B
	Radical prostatectomy	Not a standard option.	C
	Radiotherapy	Not an option for curative intent; therapeutic option in combination with androgen deprivation for treatment of local cancer-derived symptoms.	C
	Hormonal	Standard option. Mandatory in symptomatic patients.	A

DT = doubling time; NHT = neoadjuvant hormonal treatment; IPSS = International Prostatic Symptom Score; PSA = prostatespecific antigen; TRUS = transrectal ultrasound; TURP =transurethral resection of the prostate

16. FOLLOW-UP: AFTER TREATMENT WITH CURATIVE INTENT

16.1 Definition

Curative treatment is defined as radical prostatectomy or radiotherapy, either by external beam radiation or an interstitial technique, or any combination of these. Alternative treatment options that are not fully established, such as HIFU, do not have a well-defined, validated PSA-cut-point to define biochemical failure but do generally follow the outlines given below.

16.2 Why follow-up?

The first question to be answered is: 'If failure after curative treatment is so common, are follow-up efforts worthwhile?' The answer to this question is definitely 'yes'. Recurrences will occur in a substantial number of patients who received treatment with intent to cure at various time points after the primary therapy.
The second question to be answered is: 'What is the reason for follow-up?' Reasons may vary depending on the treatment given, patient age, co-morbidity and the patient's own wishes. In general, patients who receive curative therapy may be followed-up for any of the following reasons:

- good responsible patient care;
- possibility of second-line treatment with curative intent;
- possibility of early hormonal therapy after failure;
- as part of a study protocol.

Chapter 18 discusses treatment options after failure of primary therapy.

16.3 How to follow-up?

The procedures indicated at follow-up visits vary depending on the clinical situation. The examinations discussed below are routinely used for the detection of PCa progression or residual disease. The PSA level, and eventually DRE, are the only tests that need to be carried out routinely. A disease-specific history should be mandatory at every follow-up visit and should include psychological aspects, signs of disease progression, and treatment-related complications. The examinations used for the evaluation of treatment-related complications must be individualised and are beyond the scope of these guidelines. The examinations used most often for cancer-related follow-up after curative surgery or radiation treatment are discussed below.

*16.3.1 **PSA monitoring***

The measurement of PSA level is a cornerstone in the follow-up after curative treatment. There is a difference in what can be expected after radical prostatectomy and radiotherapy, but PSA recurrence nearly always precedes clinical recurrence after either treatment, in some cases by many years (1-5). It is recommended that the finding of a single, elevated, serum PSA level should be re-confirmed before second-line therapy is started solely based on the PSA elevation.

*16.3.2 **Definition of PSA progression***

The level of PSA at which to define treatment failure differs between radical prostatectomy cases and radiation treated cases. Following radical retropubic prostatectomy, two consecutive values of 0.2 ng/mL or greater appear to represent an international consensus defining recurrent cancer (6,7). Other authors have argued for

an even higher cut-off of 0.4 ng/mL to better define patients with a high risk for clinical progression (5). It has been shown that patients with a PSA level between 0.1 ng/mL and 0.2 ng/mL after radical prostatectomy had neither clinical nor biochemical disease progression (8). Therefore, the use of an ultra-sensitive PSA assay is not justified for routine follow-up after radical prostatectomy (4). If ongoing randomised trials show that early adjuvant treatment after radical prostatectomy (given before PSA reaches > 0.2 ng/mL) improves survival, this issue should be reconsidered.

Following radiation therapy, until recently, the definition of biochemical relapse was three consecutive increases according to the recommendation of ASTRO from 1996 (9). At the 2006 RTOG-ASTRO Consensus conference a new definition of radiation failure was established with as the main aim to establish a better correlation between the definition and clinical outcome. The new definition of radiation failure is a rise of 2 ng/mL above the post-treatment PSA-nadir (lowest value) (10). This definition is applicable for patients treated with or without hormonal therapy.

After HIFU or cryotherapy, a variety of definitions for PSA-relapse have been used (11). Most of these are based on a cut-off of around 1 ng/mL, eventually combined with a negative post-treatment biopsy. As yet, none of these end-points have been validated against clinical progression or survival and therefore it is not possible to give firm recommendations on the definition of biochemical failure.

16.3.3 ***PSA monitoring after radical prostatectomy***

PSA is expected to be undetectable within 6 weeks after a successful radical prostatectomy (12). A persistently elevated PSA level means that PSA-producing tissue remains in the body. In patients treated with radical prostatectomy, this is generally thought to be residual cancer due to either micrometastases that were not detected or undetectable beforehand, or residual disease in the pelvis possibly due to positive surgical margins.

A rapidly increasing PSA level (high PSA velocity, short PSA doubling time) indicates distant metastases, while a later and slowly increasing concentration of PSA is most likely to indicate local disease recurrence. The time to PSA recurrence and tumour differentiation are also important predictive factors distinguishing between local and systemic recurrence (13,14). Both local treatment failure and distant metastases have been shown to occur with undetectable PSA levels. This is very rare and occurs almost only in patients with unfavourable pathology (undifferentiated tumours) (15,16).

This means that, in patients with a relatively favourable pathology (< pT3, pN0, Gleason score < 8), PSA measurement, together with the disease-specific history, could stand as the single test in follow-up after radical prostatectomy.

16.3.4 ***PSA monitoring after radiation therapy***

The PSA level falls slowly after radiotherapy compared with radical prostatectomy. The optimal cut-off value for a favourable PSA nadir after radiotherapy is somewhat controversial. Achieving a PSA nadir of less than 0.5 ng/mL seems to be associated with a favourable outcome (17). The interval before reaching the nadir PSA may be very long and can sometimes take up to 3 years or more. A PSA rising more than 2 ng/mL above the nadir PSA is the current definition of biochemical failure after radiotherapy (10). Also, after radiotherapy, the PSA doubling time has been shown to correlate to the site of recurrence; patients with local recurrence had a doubling time of 13 months compared to 3 months for those with distant failure (18).

16.3.5 ***Digital rectal examination (DRE)***

DRE is performed to assess whether or not there is any sign of local disease recurrence. It is very difficult to interpret the findings of DRE after curative therapy, especially after radiotherapy. A newly detected nodule should raise the suspicion of local disease recurrence.

As mentioned previously, a local disease recurrence after curative treatment is possible without a concomitant rise in PSA level (15,16). However, this has only been proven in patients with unfavourable pathology, i.e. those with undifferentiated tumours. Thus, PSA measurement and DRE comprise the most useful combination of tests as first-line examination in follow-up after radiotherapy or radical prostatectomy, but PSA measurement may well be the only test in cases with favourable pathology (19).

16.3.6 ***Transrectal ultrasonography (TRUS) and biopsy***

TRUS and biopsy have no place in the routine follow-up of asymptomatic patients and nowadays only rarely after biochemical failure. TRUS cannot stand alone as a diagnostic tool, but must usually be combined with biopsy to establish the presence of local disease recurrence. The purpose of the investigation is to confirm a histological diagnosis of local disease recurrence. It is only warranted if the finding of a local recurrence affects the treatment decision (see Section 16 for a more detailed discussion).

*16.3.7 **Bone scintigraphy***

The purpose of bone scintigraphy is to detect skeletal metastases. It is not recommended for the routine follow-up of asymptomatic patients, but may be indicated in individuals with elevated PSA levels for whom the findings will affect the treatment decision. It is also indicated in patients with symptoms arising from the skeleton, since metastatic disease may occur even if PSA is undetectable (15,16).

*16.3.8 **Computed tomography (CT) or magnetic resonance imaging (MRI)***

CT or MRI have no place in the routine follow-up of asymptomatic patients. They may be used selectively in the evaluation after biochemical failure before treatment decisions are made (see Chapter 18).

16.4 When to follow-up?

Most patients who fail treatment for PCa do so early, even if failure only becomes clinically obvious after years. The patient should therefore be followed-up more closely during the first years after treatment when the risk of failure is highest. PSA measurement, disease-specific history and DRE are recommended at the following intervals: 3, 6 and 12 months postoperatively, every 6 months thereafter until 3 years, and then annually. The purpose of the first clinic visit is mainly to detect treatment-related complications and to assist patients in coping with the new situation. Tumour or patient characteristics may allow alterations to this schedule. For example, patients with poorly differentiated and locally advanced tumours or with positive margins may be followed-up more closely than those with a well-differentiated, intracapsular or specimenconfined tumour. Obviously, advanced age or associated co-morbidity may make further follow-up in asymptomatic patients superfluous.

16.5 Guidelines for follow-up after treatment with curative intent

Recommendations	GR
In asymptomatic patients, a disease-specific history and a serum PSA measurement supplemented by DRE are the recommended tests for routine follow-up. These should be performed at 3, 6 and 12 months after treatment, then every 6 months until 3 years, and then annually.	B
After radical prostatectomy, a serum PSA level of more than 0.2 ng/mL can be associated with residual or recurrent disease.	B
After radiation therapy, a rising PSA level over 2 ng/mL above the nadir PSA, rather than a specific threshold value, is the most reliable sign of persistent or recurrent disease.	B
Both a palpable nodule and a rising serum PSA level can be signs of local disease recurrence.	B
Detection of local recurrence by TRUS and biopsy is only recommended if it will affect the treatment plan. In most cases TRUS and biopsy are not necessary before second-line therapy.	B
Metastasis may be detected by pelvic CT/MRI or bone scan. In asymptomatic patients, these examinations may be omitted if the serum PSA level is less than 20 ng/mL but data on this topic are sparse.	C
Routine bone scans and other imaging studies are not recommended in asymptomatic patients. If a patient has bone pain, a bone scan should be considered irrespective of the serum PSA level.	B

17. FOLLOW-UP AFTER HORMONAL TREATMENT

17.1 Introduction

A large proportion of patients treated with hormonal therapy have either metastatic or locally advanced tumours at diagnosis. This will affect the scheme of follow-up because biochemical failure is often associated with rapid symptomatic progression.

17.2 Purpose of follow-up

The main objectives of following-up these patients are to:

- monitor the response to treatment;
- ensure compliance with treatment;
- detect potential complications of endocrine therapy;
- guide the modalities of palliative symptomatic treatment at the time of CRPC.

It is important to be clear about which complementary investigations are helpful at different stages of the disease to avoid unnecessary patient examinations and excessive economic cost. In addition, strict recommendations for follow-up procedures are only useful if effective therapeutic strategies are available in cases of disease progression. To date, the issue of early versus late initiation of non-hormonal treatment in CRPC has still not been resolved, so follow-up should be performed on an individual basis. Based on current knowledge, it is not possible to formulate level 1 evidence guidelines for follow-up procedures following hormonal therapy.

17.3 Methods of follow-up

17.3.1 ***Prostate-specific antigen monitoring***

Prostate-specific antigen is a good marker for following the course of metastatic PCa. The initial PSA level can be a reflection of the extent of metastatic disease, although some poorly differentiated tumours do not secrete PSA. In recent decades, the PSA value has been used to predict the duration of response to endocrine treatment, based on either the initial pre-treatment value or the PSA decrease during the first 3-6 months. However, the prognostic value of the pre-treatment PSA value is variably assessed in the literature and should not be used alone to predict the duration of treatment response (1).

Treatment response may be assessed using the change in serum PSA level as a surrogate endpoint for survival in patients with newly diagnosed metastatic PCa after hormonal treatment has been initiated. Patients with the lowest absolute value of serum PSA (< 0.2 ng/mL) have been shown to have the best survival compared to patients with a value of 0.2-4.0 ng/mL or > 4.0 ng/mL (2). Similar results have been seen in other studies of locally advanced and metastatic PCa (3-5). The PSA response has been shown to be equally important in patients treated with hormonal therapy, following a rising PSA after treatments with curative intent (radical prostatectomy, radiation therapy). Patients with the best response also had the best survival (6,7).

Despite its usefulness in determining treatment response in individual patients, the role of PSA as a surrogate end-point in clinical trials is more controversial (8). After the initial phase of response to endocrine treatment, patients should be regularly monitored to detect and treat any complications of endocrine escape. Clinical disease progression occurs after a median interval of about 12-18 months of treatment in patients with stage M1 disease. It is well established that regular PSA control in asymptomatic patients allows the earlier detection of biochemical escape because a rise in PSA level usually precedes the onset of clinical symptoms by several months. However, it must be stressed that the PSA level is not the absolute marker of escape and should not be used alone as a follow-up test. Clinical disease progression (usually bone pain) with normal PSA levels has been reported to occur.

17.3.2 ***Creatinine, haemoglobin and liver function monitoring***

Creatinine monitoring has some value because it can detect upper urinary tract obstruction in cases of advanced cancer, which might need to be relieved by, for example, percutaneous nephrostomy or a JJ-stent.

Haemoglobin and liver function tests may suggest disease progression and/or toxicity of hormonal treatment, which can lead to interruption of hormonal treatment (i.e. liver toxicity from non-steroidal antiandrogens). It is important to remember that haemoglobin levels will decrease by about 20% with androgen deprivation (9).

Alkaline phosphatase and its bone-specific isoenzymes have the advantage of not being directly influenced by hormonal therapy compared with PSA. These markers may be used to monitor patients with stage M1b disease. It should be remembered that increases in serum alkaline phosphatase may be due to androgen-induced osteoporosis (10), and in this context, it may be helpful to determine the level of bone-specific alkaline phosphatase.

17.3.3 ***Bone scan, ultrasound and chest X-ray***

In routine practice, asymptomatic patients with a stable PSA level should not undergo a bone scan at regular intervals, because disease progression is more reliably detected by PSA monitoring, which also has a lower cost (11,12).

Moreover, it is also sometimes difficult to interpret bone scans. Thus, in an asymptomatic patient, the therapeutic approach is not modified by the appearance of a new site of uptake or deterioration of pre-existing lesions. Recently, the PCWG2 has clarified the definition of bone scan progression as the appearance of at least two new lesions (13).

Clinical or laboratory suspicion of disease progression indicates the need for a chest X-ray or renal and hepatic ultrasound. Imaging modalities must also be guided by symptoms. However, these examinations are not recommended for routine use in asymptomatic patients. In CRPC disease, follow-up examinations should be individualised with the aim of maintaining the patient's quality of life.

During long-term ADT, it may be necessary to introduce regular measurement of BMD (LE: 3), based on the initial T-score (14). Bone mineral density should be measured every 2 years if the initial T-score < 1.0, or every year if the T-score is between 1.0 and 2.5, in the absence of associated risk factors (LE: 4). Otherwise, active protective bone treatment should have started at the initiation of ADT (see Chapter 12).

17.4 Testosterone monitoring

Most PCa patients receiving LHRH analogues will achieve serum testosterone values at or below the castration level (< 20 ng/dL). However, about 13-38% of patients fail to achieve this therapeutic goal, while 2-17% of patients do not achieve a serum testosterone level below 50 ng/dL (15-17). Furthermore, up to 24% of men treated with LHRH analogues may experience testosterone surges (testosterone > 50 ng/dL) during long-term treatment upon re-administration of the agonist drug, which is described as the 'acute on-chronic effect' or 'breakthrough responses' (16,18).

In view of these findings, the measurement of serum testosterone levels, as well as serum PSA levels, should be considered as part of clinical practice for men on LHRH therapy. The timing of testosterone measurements is not clearly defined. The first evaluation of testosterone level can be recommended at 1 month after initiating LHRH therapy to check the nadir testosterone level achieved before re-administration of the agonist drug. A 6-month testosterone level assessment may be performed to evaluate the effectiveness of treatment and to ensure the castration level is being maintained. If it is not being maintained, switching to another LHRH agent or surgical orchiectomy can be attempted. In patients with a rising PSA and/or clinical signs of progression, serum testosterone must be evaluated in all cases to confirm a castrate-resistant state.

17.5 Monitoring of metabolic complications

Androgen deprivation therapy is beneficial in patients with prostate cancer, but has a greater range of complications than might be expected (see Chapter 12). The most common side-effects of low testosterone levels include hot flushes, lack of libido, erectile dysfunction, gynaecomastia and loss of bone mineral density. In addition, recent studies have suggested that men with low testosterone levels have a higher prevalence of metabolic complications (19), including insulin resistance, arterial stiffness, diabetes and metabolic syndrome. Research has shown that the metabolic syndrome is present in more than 50% of men undergoing long-term ADT, predisposing them to a higher cardiovascular risk (20). Men with metabolic syndrome are almost three times more likely to die of coronary heart disease and other cardiovascular diseases (21), which have now become the most common cause of death in prostate cancer patients, even exceeding prostate cancer mortality (22).

In view of these findings, a cardiology consultation may be beneficial in men with a history of cardiovascular disease and men older than 65 years prior to starting ADT. All patients should be screened for diabetes by checking fasting glucose and HbA1c (at baseline and then every 3 months [LE: 3]). In selected cases, glucose tolerance testing may be required. Men with impaired glucose tolerance and/or diabetes should be referred for an endocrine consultation. Patients on ADT should be given advice on modifying their lifestyle (e.g. diet, exercise, smoking cessation, etc.) and should be treated for any existing conditions, such as diabetes, hyperlipidaemia, and/or hypertension (23,24). The patient's GP or family physician should probably be more involved in those patients at risk of cardiovascular disease, including monitoring of fasting glucose, lipids profile and blood pressure, which is recommended in all patients receiving long-term ADT. Furthermore, the risk-to-benefit ratio of ADT must be considered in patients with a higher risk of cardiovascular complications, especially if it is possible to delay starting ADT (19,25).

Monitoring bone health is also important, particularly serum levels of Vitamin D and calcium. If needed, supplements should be given so that the patient receives a daily intake of at least 1200 mg/day of calcium and 1000 UI of vitamin D. Preventive therapy with biphosphonates or denosumab should be considered in patients who have an initial T-score of less than -2.5 on dual-energy X-ray absorptiometry (DEXA), which is the definition of osteoporosis. However, optimal bone monitoring using DEXA is still controversial and should

be prospectively evaluated. It is currently suggested that bone monitoring should be performed every 2 years after initiation of castration, provided there are no other risk factors (26), and every year if there are risk factors (27,28).

17.6 When to follow-up

After initiation of hormonal treatment, it is recommended that patients be followed-up at 3 and 6 months. These guidelines must be individualised, and each patient should be told to contact his physician in the event of troublesome symptoms.

17.6.1 ***Stage M0 patients***

If there is a good treatment response, i.e. symptomatic improvement, good psychological coping, good treatment compliance, and a serum PSA level of less than 4 ng/mL, follow-up visits are scheduled every 6 months.

17.6.2 ***Stage M1 patients***

If there is a good treatment response, i.e. good symptomatic improvement, good psychological coping, good treatment compliance, and a serum PSA level of less than 4 ng/mL, follow-up is scheduled every 3 to 6 months.

17.6.3 ***Castration-refractory PCa***

Patients whose disease progresses, or who do not respond according to the criteria mentioned above, warrant an individualised follow-up scheme.

17.7 Guidelines for follow-up after hormonal treatment

Recommendation	GR
Patients should be evaluated at 3 and 6 months after the initiation of treatment.	
As a minimum, tests should include serum PSA measurement, digital rectal examination (DRE), serum testosterone and careful evaluation of symptoms in order to assess the treatment response and the side-effects of the treatments given.	B
If patients undergo intermittent androgen deprivation, PSA and testosterone should be monitored in 3-month intervals during the treatment pause.	C
Follow-up should be tailored for the individual patient, according to symptoms, prognostic factors and the treatment given.	C
In patients with stage M0 disease with a good treatment response, follow-up is scheduled every 6 months, and should include as a minimum a disease-specific history, DRE and serum PSA determination.	C
In patients with stage M1 disease with a good treatment response, follow-up is scheduled for every 3 to 6 months. As a minimum, this should include a disease-specific history, DRE and serum PSA determination, and is frequently supplemented with haemoglobin, serum creatinine and alkaline phosphatase measurements. The testosterone level should be checked, especially during the first year.	C
Patients (especially with M1b status) should be advised about the clinical signs that could suggest spinal cord compression.	A
When disease progression occurs, or if the patient does not respond to the treatment given, the follow-up needs to be individualised.	C
In patients with suspected progression, the testosterone level must be checked. By definition, CRPC is based on the assumption that the patient is castrated (at least T < 50 ng/dL).	
Routine imaging of stable patients is not recommended.	B

18. TREATMENT OF BIOCHEMICAL FAILURE AFTER TREATMENT WITH CURATIVE INTENT

18.1 Background

Primary curative procedures, such as RP and radiotherapy, are well-established therapeutic options in the management of localised PCa. Technical advances in surgery and radiation therapy have improved therapeutic efficacy and decreased treatment-associated morbidity and toxicity, respectively. However, despite these improvements, there is still a significant risk of cancer recurrence after therapy. Between 27% and 53% of all patients undergoing RP or radiation therapy develop local or distant recurrences within 10 years of initial therapy and 16-35% of patients receive second-line treatment within five years of initial therapy (1-5,6).

18.2 Definitions

*18.2.1 **Definition of treatment failure***

Treatment failure was previously defined as recurrence on DRE or the development of metastatic disease. Currently, treatment failure is defined as a rising PSA level based on a study of Pound et al. (7), which showed that no patient followed for more than five years developed any recurrence without a concomitant rise in PSA.

The level of PSA that defines treatment failure differs between men who have undergone RP and men treated with radiotherapy. Following radical retropubic prostatectomy (RRP), there is an international consensus that recurrent cancer may be defined by two consecutive values of PSA > 0.2 ng/mL (6,8). However, the most appropriate definition of biochemical progression after RP remains uncertain. A retrospective analysis of 2782 men who had undergone RP for clinically localised PCa (9) was used to determine the best PSA cut-off point

for defining biochemical recurrence. Another study found that once PSA recurrence was detected, there was a subsequent increase in PSA in 49%, 62% and 72% of patients with PSA levels of 0.2 ng/mL, 0.3 ng/mL, and 0.4 ng/mL, respectively (9). These data indicate that only half of patients with a PSA of 0.2 ng/mL will show further progression and can therefore be managed initially by surveillance.

Similar data have been presented by Stephenson et al. (10). The study identified a PSA value of > 0.4 ng/mL as the best cut-off level to explain the development of distant metastasis among 10 candidates. This level was estimated using definitions developed from a retrospective review of 75 patients, who had developed distant metastases following RP. A cut-off of 0.4 ng/mL is therefore appropriate to define progression with clinical relevance, i.e. necessitating salvage treatment.

Following radiotherapy, three consecutive increases in PSA are considered to provide a reasonable definition of biochemical relapse, according to ASTRO (11). This new definition indicates a relapse if the PSA increase is > 2 ng/mL higher than the PSA nadir value, independent of the serum concentration of the nadir (12).

18.2.2 ***Definitions of recurrence***

A recurrence of CaP can be defined as:

- Following RP, PSA values > 0.2 ng/mL confirmed by two consecutive measures.
- Following radiotherapy, a PSA value of 2 ng/mL above the nadir after radiotherapy.

18.3 Local or systemic relapse

Once a PSA relapse has been diagnosed, it is of major importance to determine whether the recurrence has developed at local or distant sites. About 50% of patients who have undergone radical retropubic prostatectomy will have local disease, while the remainder will have either distantdisease alone, or distant and local disease (11).

Several important parameters help to differentiate between local or distant relapse:

- timing of the PSA increase after surgery;
- PSA velocity;
- PSA doubling time (PSA DT);
- pathohistological stage;
- Gleason score of the prostatectomy specimen.

PSA elevations developing within the first 2 years following surgery are more often associated with distant recurrences (12). It has been shown that a median PSADT of 4.3 months might be associated with distant relapse, whereas a median PSA DT of 11.7 months predicts local failure (13). According to a recent study (14), a PSA velocity of < 0.75 ng/mL/y was observed in 94% of patients with local recurrence, whereas 56% of patients with distant metastases demonstrated a PSA velocity of > 0.75 ng/mL/y. There is no indication to perform ultrasound-guided biopsies of the vesicourethral anastomosis to diagnose local relapse as this method has low sensitivity and low predictive accuracy in men with rising PSA levels < 1.0 ng/mL.

With radiotherapy, any continuously rising PSA following a nadir after radiation is an indicator for local recurrence, systemic metastatic spread or a combination of both (11,14-16). However, due to the well- known PSA bounce phenomenon, biochemical recurrence is defined by a PSA rise of 2 ng/mL above the PSA nadir according to ASTRO guidelines. After radiotherapy, a late and slowly rising PSA is a sign of local failure only.

Local recurrence of PCa is defined by:

- a prostatic biopsy demonstrating malignant cells at 18 months or longer after initial radiotherapy;

plus

- an associated rise in PSA, although prostate biopsy is only indicated if the patient is a candidate for a secondary local salvage therapy with curative intent;

plus

- no evidence of metastatic spread documented by CT or MR imaging and bone scintigraphy.

18.3.1 ***Definition of local and systemic failure***

The definitions of local and systemic failure are as follows:

- Local failure following RP is predicted with an 80% probability by a PSA increase at 3 years after RP, a PSA DT ≥ 11 months, a Gleason score ≤ 6, and stage ≤ pT3a pN0, pTx R1.
- Systemic failure following RP is predicted with > 80% accuracy by a PSA increase.
- At less than 1 year after RP, there is a PSA DT of 4-6 months, a Gleason score of 8-10, and stage pT3b, pTxpN1.

- Local failure after radiotherapy is documented by a positive prostatic biopsy and negative imaging studies.
- Prostatic biopsy after radiotherapy is necessary only if local procedures, such as salvage prostatectomy, are indicated in an individual patient.

18.4 Evaluation of PSA progression

Prior to an extensive diagnostic work-up in patients with PSA relapse following local treatment, men must be stratified into those who are candidates for salvage therapy and those who are not. Men must also be stratified into those who are candidates for local salvage treatment and those who might need systemic therapy. All diagnostic procedures should only be performed if the results will have therapeutic consequences.

In recent years, most patients with PSA progression following initial therapy with curative intent underwent physical and sonographic examinations, as well as radiology or biopsies of the prostatic fossa and the vesicourethral anastomosis to confirm the recurrence identified by serological studies. For patients with asymptomatic PSA-only progression, the yield is very low. Lange et al. (14) have shown that biochemical failure precedes clinical disease by 6-48 months.

In general, DRE is not useful in men with undetectable or very low PSA levels. In a recent study by Öbek et al. (17), it was shown that only 4/72 patients (5.5%) with a PSA recurrence following RP had an abnormal DRE.

Imaging studies are used to differentiate local from systemic relapse to help select the most appropriate treatment modality. However, it must be remembered that most imaging studies are probably not sensitive enough to identify the anatomical location of relapsing PCA at PSA levels < 0.5-1.0 ng/mL.

*18.4.1 **Diagnostic procedures for PSA relapse following RP***

Traditionally, bone scans and abdominal CT scans have been used to evaluate PSA elevations following primary treatment. However, both imaging studies have low sensitivity and specificity and can be safely omitted in the routine work-up of relapsing patients. A recent study (18) looked at bone scans in 144 patients, 122 of whom had undergone RP without hormone treatment, while 22 had received either neoadjuvant or adjuvant androgen-deprivation therapy (ADT). Bone scans in 93 patients with PSA recurrence identified metastatic disease in only 4.1% of men who had undergone RP and 27% of men who had been treated with ADT. The lowest PSA associated with positive findings was 46 ng/mL in the absence of adjuvant ADT, whereas the lowest PSA value was 15.47 ng/mL in patients who had received hormonal therapy.

The probability of a positive bone scan remains < 5% until the serum PSA reaches at least 40 ng/mL. Similar data have been achieved by other groups, which have demonstrated that patients with a true positive bone scan had an average PSA level of > 60 ng/mL and a PSA velocity of 22 ng/mL/year (19,20). Logistic regression analysis showed that PSA and PSA velocity were good predictors of bone scan results and PSA velocity for CT scan results. Of 132 patients with biochemical recurrence, 9.4% had a positive bone scan and 14% had a positive CT scan. However, there may be a slight difference between patients after radical retropubic prostatectomy and patients after radiation therapy, as shown by Johnstone et al. (21), who found that 5% and 30%, respectively, of bone scans, were positive.

In summary, bone scintigraphy and CT scans are of no additional diagnostic value, unless the PSA serum levels are higher than 20 ng/mL or the PSA velocity is more than 20 ng/mL/year.

Endorectal coil imaging is a useful technique to detect local recurrences after RP (22). In a series of 48 patients, local recurrence was correctly identified in 81%, with the mean PSA being 2 ng/mL at diagnosis.

The diagnostic accuracy of endorectal MRI (eMRI) was investigated in a series of 72 men with PSA relapse following RP (23). The mean total PSA was1.23 +/- 1.3 ng/mL, with men undergoing eMRI using a 1.5-Tesla system. The data were compared to standard references for local recurrence, including prostatectomy bed biopsy results, choline positron emission tomography results, PSA reduction or increase after pelvic radiotherapy, and PSA modification during active surveillance. Sensitivity, specificity, predictive positive value, negative predictive value and accuracy were 61.4%, 82.1%, 84.4%, 57.5% and 69.4% for unenhanced eMRI, and 84.1%, 89.3%, 92.5%, 78.1% and 86.1% for enhanced eMRI. The two evaluations showed a statistically significant difference in accuracy (chi(2) = 5.33, p = 0.02) and sensitivity (chi(2) = 9.00m, p = 0.0027).

Although eMRI appears to be very sensitive and predictive in identifying local recurrences following RP, it is currently not a routine imaging modality to be performed in every case, as local versus systemic relapse

must be differentiated at PSA levels < 0.5 ng/mL (see Section 18.6). At this PSA level, eMRI is not sufficiently sensitive or accurate.

Positron emission tomography (PET) has been successfully applied in many human cancers for early identification of local or systemic recurrences. In PCa, there are few, but promising, published data on the clinical efficacy of PET in detecting local recurrences after RP (23-25). However, it must be kept in mind that the uptake of ^{11}C-choline is not specific for PCa and may also be due to inflammatory intraprostatic lesions.

In a series of 31 patients with biochemical progression after RP, ^{11}C-acetate-PET demonstrated a high sensitivity and specificity for the detection of local recurrences when the PSA serum level was > 1 ng/mL (24). In another recent series of 43 patients with newly diagnosed CaP, there was a significant correlation between ^{11}C-choline uptake and the intraprostatic location of PCa in RP specimens (26). Similar results have been reported for the detection of locally recurrent PCa after radiation therapy (27). However, ^{11}C-PET was significantly less sensitive at detecting extraprostatic extension compared with MRI.

The most recent series evaluating the role of ^{11}C-choline PET/CT in men with biochemical recurrence after RP have shown that metastases were more likely to be identified at higher PSA levels. ^{11}C-choline PET/CT was able to locate metastases in 20-36% of men with PSA levels < 1 ng/mL, increasing to 63-83% of men with PSA levels > 3 ng/mL (28-31).

In 190 patients with PSA relapse following RP, Castelucci et al. (32) investigated how the ^{11}C-choline PET/CT detection rate was affected by:

- trigger PSA level (i.e. total PSA level at the time of the scan);
- PSA velocity (PSA VEL);
- PSA doubling time (PSA DT) (Table 20).

The study found that the mean PSA relapse was 4.2 ng/mL (median 2.1, range 0.2-25.4). Disease relapse was detected by ^{11}C-choline PET/CT in 74/190 patients (38.9%). The study also found that trigger PSA values were statistically different between PET-positive patients (median PSA 4.0 ng/mL) and PET-negative patients (median PSA 1.4 ng/mL) (p = 0.0001), with the optimal cutoff point for trigger PSA being 2.43 ng/mL. In 106 patients, PSA DT and PSA level values were statistically different between patients with PET-positive (p = 0.04) and PET-negative scans (p = 0.03).

Table 20: Relationship between different measurements of PSA and ^{11}C-choline PET/CT detection rate

PSA measurement	n	^{11}C-choline PET/CT detection rate (%)
Trigger PSA		
< 1 ng/mL	51	19
1 < PSA < 2 ng/mL	39	25
2 < PSA < 5 ng/mL	51	41
PSA > 5 ng/mL	49	67
PSA velocity		
< 1 ng/mL/y	33	12
1 < PSA VEL < 2 ng/mL/y	26	34
2 < PSA VEL < 5 ng/mL/y	19	42
PSA VEL > 5 ng/mL/y	28	70
PSA doubling time		
PSA DT > 6 mo	45	20
4 < PSA DT < 6 mo	20	40
2 < PSA DT < 4 mo	31	48
PSA DT < 1 mo	10	60

A recent publication from Giovacchini et al. (32) comprising 109 patients with rising PSA level and negative conventional imaging studies concluded that ^{11}C-choline PET/CT might be helpful in restaging PCA but it

should not be used to guide therapy. The authors found that only 12 of 109 patients (11%) had positive PET/CT findings. Scans were positive in 5%, 15%, and 28% of patients with PSA < 1ng/mL, between 1 and 2 ng/mL, and > 2ng/mL, respectively ($p < 0.05$). The use of ^{11}C-choline PET/CT in all men with a rising PSA level > 1 ng/mL would result in 85% incidence of unnecessary examinations, significant increase of medical costs, and no benefit for the individual patient.

Another retrospective study of 37 patients scheduled for salvage radiation therapy after RP (34) reported that about 13% of the patients demonstrated ^{11}C-choline PET/CT-positive lymph nodes outside the prostatic fossa, implicating an extension of the target volume. However, none of the lesions was verified histologically, and the mean PSA of choline-positive patients (1.1 ng/mL, range 0.5-1.8 ng/mL) was significantly higher than in ^{11}C-choline PET/CT-negative patients (0.4 ng/mL, range: 0.3-0.7 ng/mL).

The most recent review published by Picchio et al. (35) has concluded that the routine use of ^{11}C-choline PET/CT cannot be recommended for PSA values < 1 ng/mL. Its accuracy is correlated to PSA value, PSA DT, and other pathological features. The authors propose that ^{11}C-choline PET/CT may be proposed as a guide for individualised treatment of recurrence. A similar conclusion can be made from another recent study by Castellucci et al (32).

However, the indication to perform ^{11}C-choline PET/CT must be placed in the context of the above-mentioned clinical parameters. It therefore remains doubtful whether a patient with elevated PSA, rapid PSA DT and a prostatectomy Gleason score > 8 will receive therapy other than ADT based on the findings of ^{11}C-choline PET/CT.

In summary, the role and the diagnostic accuracy of ^{11}C-choline PET/CT in men with rising PSA following RP is dependent on the absolute PSA, PSA DT, and PS AV. The higher the PSA level and the faster PSA DT, the better the predictive value of this imaging modality. However, even in patients with PSA values > 2 ng/mL and negative imaging studies, ^{11}C-choline PET/CT is positive in only 28% of patients. There is therefore an urgent need for well-conducted and histologically controlled trials to explore the potential role of ^{11}C-choline PET/CT.

The role of choline PET/CT to detect local or systemic recurrences in men with PSA relapse following radiotherapy is unclear and based on very few studies (36,37). Thus, no final recommendations can be made. Its sensitivity and specificity with regard to the detection of lymph node metastases are less reliable, and the routine use of ^{11}C-PET cannot therefore be recommended, especially not for PSA values < 1 ng/mL.

It has been common practice to perform transrectal ultrasound (TRUS)-guided biopsies of the prostatic fossa, the anastomosis or the prostate gland to exclude local recurrence after radical retropubic prostatectomy or radiotherapy. However, according to available studies, routine biopsy of the vesicourethral anastomosis appears not to be justified based on a verification rate of only 54% (38-40). Only in the presence of a palpable lesion or a hypoechoic lesion on TRUS can the diagnostic yield of the biopsy be improved to approximately 80%. Furthermore, there is a strong correlation between the positive biopsy rate and PSA serum concentrations (38-40); 28% and 70% of the biopsies were positive if the PSA level was, respectively, below 0.5 ng/mL or greater than 2.0 ng/mL.
Thus, it is now commonsense that routine anastomotic biopsy is not indicated, and the use of PSA and PSA DT is sufficient for clinical practice. In addition, PSA-free survival in biopsy-proven recurrences does not differ significantly compared with PSA-only recurrences.

*18.4.2 **Diagnostic studies for PSA relapse following radiation therapy***

With regard to PSA relapses following radiation therapy, routine prostate biopsy should no longer be performed for the evaluation of PSA-only recurrences, according to an ASTRO consensus recommendation (15). However, prostate biopsy documenting local recurrence represents the main cornerstone in the decision-making process for salvage RP in patients with rising PSA levels following a nadir after radiation therapy (41). It is a general recommendation to wait about 18 months and three months following radiation therapy or seeds, and cryotherapy or high-intensity focused ultrasound (HIFU), respectively. Patients with rising PSA and viable cancer on biopsy 2 years after radiation therapy have true locally recurrent disease and might be candidates for salvage RP.

Recent studies have evaluated the role of eMRI, MRI spectroscopy and dynamic-contrast enhanced MRI in the identification of locally recurrent PCA following radiation therapy (42-44). These studies have demonstrated that locally recurrent PCA can be differentiated from benign nodules due to the low T2-weighted signal intensity. Endorectal MRI and MR spectroscopy were more sensitive than TRUS or TRUS-guided prostate biopsies

to detect viable PCa. Endorectal MRI has also contributed important information about the presence of extraprostatic extension and seminal vesicle invasion with a sensitivity of 86% and a specificity of 96%.

Endorectal MRI is therefore strongly recommended in the diagnostic work-up of men with PSA relapse after radiation therapy, who might be candidates for secondary local salvage therapy with curative intent.

*18.4.3 **Diagnostic procedures in patients with PSA relapse***

Following RP, CT scans of the pelvis and abdomen are of low sensitivity and specificity in patients with PSA levels < 20 ng/mL or a PSA velocity of < 2 ng/mL/y. Endorectal MRI or PET scans may help to detect local recurrences if PSA is > 1.0 ng/mL, but is not routine clinical practice for the early detection of local relapses.

Following radiation therapy, local recurrence is documented by a positive biopsy > 18 months after the procedure. Endorectal MRI is of valuable importance for men who are candidates for radical salvage prostatectomy.

18.5 Treatment of PSA-only recurrences

The timing and mode of treatment of PSA-only recurrence after RP or radiation therapy remains controversial. After RRP observation, the therapeutic options are:

- radiation therapy to the prostatic bed;
- (complete) androgen blockade (CAB);
- intermittent androgen deprivation (IAD);
- combination of antiandrogens with 5-α-reductase inhibitors;
- early chemohormonal approaches.

These same therapeutic options may be applied to PSA recurrences following radiation therapy. In addition, salvage prostatectomy, cryotherapy or brachytherapy may be indicated in carefully selected patients.

*18.5.1 **Radiation therapy for PSA-only recurrence after RP***

Three large RCTs in adjuvant radiation have now been published (45-48). All three trials showed a benefit with adjuvant radiotherapy of at least 15% at 5 years in biochemical recurrence-free survival.

The largest trial (EORTC-22911, n = 1005) (46) and the smallest trial (ARO-96-02, n = 307) (47) trial were powered to detect a benefit in biochemical disease recurrence-free survival, while metastasis-free survival was the primary endpoint of the third trial, SWOG-S8794 (n = 431) (47). The three trials had similar inclusion criteria; however, the EORTC trial also included pT2R1 patients, while the other two trials allowed only pT3 cancers with or without a positive resection margin. In all three trials, quite a high proportion of patients (63-68%) had a positive surgical margin.

It should be noted that the post-operative PSA level of men before they were randomised to adjuvant radiotherapy was different between the three trials. In the German ARO-96-02 trial, only men with a PSA < 0.1 ng/mL were eligible for randomisation. In the EORTC trial, 11% of men had a PSA level > 0.2 ng/mL prior to randomisation and 34% in the SWOG trial. Thus, a substantial number of patients in the EORTC and SWOG trials received ‘salvage‘ radiation therapy rather than adjuvant radiotherapy for a non-normalised PSA. It is therefore interesting that not all men in the non-adjuvant arms of the trials were treated with salvage radiotherapy by the time of a biochemical recurrence: delayed or salvage radiotherapy to the prostatic fossa was administered to 55% of men with a rising PSA level in the EORTC trial and to 33% of men in the SWOG trial. Thus, the trials were not able to evaluate whether adjuvant radiation was superior to salvage radiation as in the control arm, as at most only half of the men received radiation at the time of PSA recurrence.

Indeed, the authors of the EORTC trial suggested that salvage radiation may be equivalent to adjuvant therapy provided the PSA is lower than 1 ng/mL (46). However, only the SWOG trial was powered to address the effect of delayed radiation since it was the only trial with metastasis-free survival as the primary endpoint. In the SWOG trial, men in the control arm were less likely to receive salvage radiation (33%). However, it took a median follow-up of over 12 years before metastasis-free survival improve d in the adjuvant treatment arm suggesting that adjuvant therapy may not be helpful in men with a life expectancy < 10 years (45,47). Recently, it has been demonstrated that patients in the control group had a higher frequency of Gleason score 8-10 CaP and were more likely to not receive ADT at the time of PSA relapse.

There have been many studies on the use of radiation therapy for PSA-only recurrence following RRP. As a result there is a growing body of parameters predicting outcome that may help to differentiate between the

need for observation, radiation or hormonal therapy. As confirmed by various studies, the pre-radiation PSA level is critically important for optimal treatment results (41-44,49-53):

- Applying a pre-radiation cut-off of < 2.5 ng/mL, Wu et al. (49) and Schild et al. (50) reported disease-free survival rates of 53% and 76%, compared with 8% and 26%, respectively, for patients with PSA serum levels > 2.5 ng/mL.
- Forman et al. (51) demonstrated a disease-free survival rate of 83% versus 33% in patients with a PSA-only recurrence of < 2.0 ng/mL and greater than 2.0 ng/mL, respectively.
- Nudell et al. (52) even reported progression-free survival rates of 58% and 21% in patients having undergone radiation of the prostate bed if PSA serum levels were below 1.0 ng/mL or greater than 1.0 ng/mL, respectively.

Based on these data, ASTRO has published a consensus paper recommending a dose of at least 64 Gy when the PSA level is < 1.5 ng/mL after RRP (15). Furthermore, recent papers (53-58) have corroborated the data of early salvage radiation therapy demonstrating a significant difference in 5-year biochemical-free and overall survival rates in patients treated for PSA-recurrence only or for palpable local recurrence. In another study, Stephenson et al. (59) evaluated prognostic models to predict the outcome of salvage radiation therapy on a cohort of 1603 men with PSA progression after RP and operated on in 17 North American tertiary referral centres.

The authors identified a significant relationship between PSA serum concentration at the time of radiation therapy and therapeutic outcome: the 6-year biochemical-free survival was 48% in men with PSA < 0.5 ng/mL, but only 40%, 28%, and 18% in men with PSA levels of 0.51-1 ng/mL, 1.01-1.5 ng/mL and > 1.5 ng/mL, respectively.

For the SWOG and EORTC non-adjuvant radiotherapy arms, the median interval to salvage radiotherapy was 2 and 2.2 years, respectively. In the SWOG 8974 study, 23% of men had a PSA > 1.5 ng/mL prior to salvage radiation. In a subanalysis of the SWOG 8974 trial, Swanson et al. (60) showed that men in all categories of post-prostatectomy PSA level (< 0.2, 0.2-1.0, > 1.0 ng/mL) showed an improvement with salvage radiotherapy in metastasis-free survival. However, the therapeutic benefit was most evident in the presence of minimal PSA serum levels. These data suggest that, although less effective, salvage radiation treatment may help improve metastasis-free survival.

In a recent multi-institutional, matched-control analysis of adjuvant and salvage post-operative radiation for pT3-4N0 PCa, Trabulsi et al. (61) have demonstrated a biochemical recurrence-free survival advantage in favour of adjuvant radiotherapy versus salvage radiotherapy. Interestingly, in a multivariate Cox regression analysis, adjuvant versus salvage radiotherapy were not independent predictors in metastatic progression-free survival, when corrected for adverse clinical and pathological factors.

Recently, data on overall survival and salvage radiation have become available. In a group of men with a median follow-up of 9 years after prostatectomy, the benefit of salvage radiation for prostate cancer-specific mortality was seen particularly in men with a PSA DT of less than 6 months, who had been given salvage radiation to the prostate fossa within 2 years after a rise in PSA (62). This suggests that local disease control may prolong prostate cancer-specific survival in men formerly thought to be at risk for systemic disease progression and less likely to benefit from (salvage) radiation. It has been suggested that men with slowly progressing disease, even though still at risk of systemic progression, may not benefit from salvage radiotherapy because they have a low risk of development of lethal PCa. Certainly, longer follow-up is needed to answer this question.

However, more data are required from prospective randomised trials.

18.5.1.1 Dose, target volume, toxicity

The three randomised trials on adjuvant radiation therapy all used dosages less than 66 Gy, which is currently the most frequently used dose for adjuvant and salvage radiation. However, it is important to note that, as with dose escalation studies in primary radiation for PCa, an increased dose in the salvage setting may improve the biochemical response without worsening local toxicity (63,64). Dosages up to 70 Gy showed better biochemical recurrence-free rates at higher doses, with 66.8 Gy radiation found to be the dose required for 50% biochemical recurrence-free survival (TCD50). Even higher doses may be considered, particularly when using improved imaging techniques, such as fiducial markers (65). The finding that 9% of men develop a local recurrence after adjuvant radiation of 60 Gy provides support for an increase in dosage and target volume (60). Target volume delineation has been found to vary by up to 65% between different radiotherapists administering

adjuvant or salvage radiation to the prostatic fossa (66,67), despite the presence of guideline (68). It is therefore important not to overlook local toxicity. In the EORTC 22911 study, 3.1% of men had to interrupt adjuvant radiation because of local complaints, mainly diarrhoea. Although grade 3 or 4 toxicity is rare for either adjuvant or salvage radiation to the prostate fossa, it was almost doubled in the adjuvant arm of the EORTC 22911 study (2.6% vs 4.2%) and the SWOG S8794 study, particularly urethral stricture (relative risk [RR], 9) and incontinence (RR, 2.3).

*18.5.2 **Hormonal therapy***

Systemic failure following RP is predicted with > 80% accuracy by PSA relapse < 1 year, PSA DT of 4-6 months, Gleason score 8-10 and stage pT3b, pTxpN1. There is some evidence that early hormonal therapy may help to delay progression and possibly achieve a survival benefit (69,70).

18.5.2.1 Adjuvant hormonal therapy after RP

In the absence of randomised controlled trials for post-operative PSA recurrence, it is necessary to rely on retrospective data or to extrapolate data from other clinical settings, such as men with metastatic disease or locally advanced non-metastatic disease. It is uncertain whether or not such data are relevant to men with rising post-operative PSA levels.

Two randomised studies have compared immediate hormonal therapy (after diagnosis) with deferred hormonal therapy (on progression) in patients with PCa. The Medical Research Council study in locally advanced or asymptomatic metastatic PCa and the EORTC study in newly diagnosed PCa (T0-4N0M0) illustrate that, although immediate hormonal therapy after diagnosis can delay disease progression in men with PCa, it does not necessarily result in an improved cancer-specific survival (71,72).

The survival advantage for immediate (adjuvant) ADT after RP has only been proven in patients with positive-lymph-node PCa in a single randomised study (69,70). The updated results of this multicentre Eastern Cooperative Oncology Group study after a median follow-up of 11.9 years showed a significant improvement in overall survival, cancer-specific survival, and progression-free survival in lymph-node positive (N+) patients treated with immediate ADT (70).

Adjuvant bicalutamide, 150 mg, could decrease progression in men with locally advanced PCa, but did not result in an overall survival benefit (73). Several retrospective analyses from the Mayo Clinic showed that adjuvant hormonal therapy after RP had a positive effect on time to progression and cancer death in patients with pT3b and N+ PCa (74-76). However, a recent large series from the Mayo Clinic with a median follow-up of 10.3 years showed that adjuvant hormonal therapy in patients with surgically managed N+ PCa decreased the risk of biochemical recurrence and local recurrence, but did not significantly impact systemic progression or cancer-specific survival (77). A recent retrospective study with a median follow-up of 5.2 years showed that immediate and delayed hormonal therapy (at PSA recurrence) in patients with surgically managed N+ PCa provided similar outcomes (78).

An observational study showed that deferring immediate ADT in men with positive lymph nodes after RP may not significantly compromise survival. There was no statistically significant difference in survival with 90, 150, 180 and 365 days as the definition of adjuvant ADT. These results need to be validated in a prospective study (79).

18.5.2.2 Post-operative hormonal therapy for PSA-only recurrence

Androgen deprivation therapy

Although patients with post-operative PSA recurrence often undergo ADT before evidence of metastatic disease, the benefit of this approach is uncertain. A retrospective study including 1352 patients with post-operative PSA recurrence showed no significant difference in the time to clinical metastases with early ADT (after PSA recurrence, but before clinical metastases) versus delayed ADT (at the time of clinical metastases). However, upon risk stratification, early ADT could delay the time to clinical metastases in high-risk patients with a Gleason score > 7 and/or a PSA DT < 12 months. Androgen deprivation therapy had no overall impact on prostate cancer-specific mortality (80).

A recent retrospective study from the Mayo Clinic showed that adjuvant ADT (within 90 days of surgery) slightly improved the cancer-specific survival and systemic progression-free survival after RP in a large group of high-risk patients with PCa. However, the survival advantage was lost when ADT was delivered farther in the disease process, at the time of PSA recurrence or systemic progression. It should be emphasised that there was no overall survival advantage (83% for both groups) and that the difference in cancer-specific survival and systemic progression-free survival was only 3% and 5%, respectively (81). In a recent retrospective

study, including 422 patients with post-operative PSA recurrence, 123 developed distant metastasis, of whom 91 patients with complete data received deferred ADT at the time of documented metastasis after RP. The authors concluded that patients when closely followed after PSA recurrence may have an excellent response to deferred ADT and a long survival with a median failure time of 169 months from RP to death (82). However, these three studies are limited by their retrospective design and in assessing the side effects of long-term ADT. Evidence from well-designed, prospective, randomised studies is needed before the use of early hormonal therapy can be advocated in clinical practice.

Antiandrogens
Although gynaecomastia and breast tenderness were the most predominant side effects for the treatment of organ-confined and locally advanced PCa, the incidence of hot flushes, loss of libido and impotence was significantly lower than expected for luteinising hormone-releasing hormone (LHRH) agonists and CAB (83).

Antiandrogens may represent a viable alternative to other modes of androgen deprivation for the management of PSA-only recurrences, especially in young and otherwise healthy men. In a prospective, placebo-controlled, randomised trial of adjuvant bicalutamide, 150 mg, following RP in patients with locally advanced disease, the risk of objective progression of the disease was significantly reduced in patients receiving bicalutamide. However, overall survival did not differ between groups (84). Low-dose flutamide, 250 mg daily, is currently being investigated in men with PSA recurrence. Bicalutamide, 150 mg daily, has not yet been studied in this clinical setting (85).

Intermittent androgen deprivation
Intermittent androgen deprivation (IAD) has been examined as a potential alternative to CAD to:
- delay the time to androgen independence and hormone-refractory disease;
- minimise side-effects;
- reduce costs of prolonged therapy.

The Cochrane Collaboration revealed that there were no long-term data of large-scale randomised controlled trials that proved the superiority of IAD over CAD for survival. Limited information suggests that IAD may result in a slight reduction of adverse effects (86). However, in the setting of PSA-only recurrences, there are no prospective randomised trials and no clinical studies with sufficient data on long-term efficacy to justify the routine clinical application of IAD, despite its potential benefits. Summarising the series in which PSA-only recurrences were treated by IAD (87-91), PSA threshold levels at study-entry varied significantly, as did the PSA level at discontinuation of hormonal therapy. Only the study of 150 patients by Tunn et al. (91) had a sufficiently appropriate study design to allow the drawing of important clinical conclusions. Patients were started on IAD for 9 months when the post-prostatectomy PSA serum level was greater than 3.0 ng/ mL, and all patients reached a nadir of less than 0.5 ng/mL. Intermittent androgen deprivation was re-started when PSA increased to more than 3.0 ng/mL. After a mean follow-up of 48 months, and a mean duration of hormonal therapy of 26.6 months, none of the patients had progressed to hormone-refractory disease. In the meantime, IAD remains attractive to selected, closely monitored and well-informed patients with post-operative PSA recurrence.

Minimal androgen blockade
In some studies, finasteride and flutamide have been combined to manage PSA-only recurrences since both agents work additively by blocking the intraprostatic conversion of testosterone to dihydrotestosterone (DHT) and blocking the intracytoplasmic DHT receptor (92-94). In the latest report (93) including 73 patients, the application of finasteride (10 mg/day) and low-dose flutamide (250 mg/day) resulted in a mean PSA nadir of 1.35 ng/mL within 6 months. However, only 62% of the patients studied reached a PSA nadir of < 0.2 ng/mL. After a mean follow-up of 15 months, none of the patients had progressed to traditional hormonal therapy. However, longer follow-up of a larger patient cohort is needed, and randomised phase III trials using modern antiandrogens with fewer gastrointestinal and hepatic side-effects are mandatory.

Hormonal therapy after RP combined with radiotherapy and/or chemotherapy
The addition of hormonal therapy to salvage radiotherapy (n = 78) was not associated with any additional increase in cancer-specific survival (94). A recent phase II trial including 74 patients with post-operative PSA recurrence showed that combined treatment with salvage radiotherapy plus 2 years of maximum androgen blockade (castration + oral antiandrogen) had relatively minor long-term effects on quality of life (95). However, more efficacy data are needed and the potential increase in side effects should be considered when combining therapies. Results are eagerly awaited from a recently completed randomised controlled phase III study from the Radiation Therapy Oncology Group (RTOG-9061) comparing radiotherapy + placebo versus the

combination of radiotherapy + bicalutamide, 150 mg daily, in the post-operative setting.

Radiotherapy and Androgen Deprivation in Combination after Local Surgery is a recently started, large, randomised, controlled study, sponsored by the Medical Research Council. The study addresses the timing of radiotherapy (adjuvant vs early salvage) and the duration of hormonal therapy (none vs short-term vs long-term) used together with post-operative radiotherapy. The primary outcome measure will be cancer-specific survival. Secondary outcome measures will include overall survival, ADT administered outside the protocol, and reported treatment toxicity. The study also aims to assess the long-term effect of radiotherapy after RP on sexual, urinary and bowel function, and the long-term effect of ADT on sexual function and overall quality of life. Patients will be asked to complete four short questionnaires. These assessments will be done at baseline, 5 years and 10 years (96).

Currently, there is no indication for chemotherapy in patients with PSA-recurrence only. Chemotherapy should be considered as a treatment option for patients with castration-resistant PCa, but when to initiate a cytotoxic regime remains controversial (97).

18.5.3 ***Observation***

Observation until the development of clinically evident metastatic disease might represent a viable option for patients with a Gleason score < 7, PSA recurrence longer than 2 years after surgery, and a PSA DT longer than 10 months. In these patients, the median actuarial time for the development of metastasis will be 8 years, and the median time from metastasis to death will be another 5 years (7).

18.5.4 ***Management of PSA relapse after RP***

Recommendations	GR
Local recurrences are best treated by salvage radiation therapy with 64-66 Gy at a PSA serum level < 0.5 ng/mL.	B
For patients with presumed local recurrence who are too unfit or unwilling to undergo radiation therapy, expectant management can be offered.	B
PSA recurrence indicative of systemic relapse is best treated by early ADT resulting in decreased frequency of clinical metastases.	B
Luteinising hormone releasing hormone (LHRH) analogues/antagonists/orchiectomy or bicalutamide, 150 mg/day, can both be used when there is an indication for hormonal therapy.	A

18.6 Management of PSA failures after radiation therapy

In a recent review of the data of the Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE) comprising 2336 patients with PCa, Grossfeld et al. (98) demonstrated that 92% of patients initially irradiated received ADT for secondary treatment of PSA progression. In the absence of salvage procedures, the mean time interval from biochemical to clinical progression is approximately 3 years. Therapeutic options in these patients are ADT or local procedures, such as salvage RP, cryotherapy and interstitial radiation therapy (41,99-108). Salvage RRP has not, however, gained widespread acceptance because of its associated morbidity, namely incontinence, local recurrences and rectal injuries. However, in well-selected patients, the procedure may result in long-term disease-free survival.

18.6.1 ***Salvage radical prostatectomy***

Previously, most series reporting on salvage RP have included patients treated in the pre-PSA era without modern radiotherapeutic techniques, when local recurrences were usually detected at a late stage. Complications associated with the procedure were therefore quite high, with up to 65% of patients suffering from treatment-related morbidities. Up to 60% of patients who underwent salvage RP had to undergo anterior or total exenteration for locally extensive disease, associated with a high rate of local recurrences and a mean time to progression of only 1.3 years.

Recent reports analysing patients who were operated on during the past decade, have described far more optimistic outcomes after salvage RP. In the series examined by Gheiler et al. (103), 40 patients with a mean PSA of 14 ng/mL underwent salvage RP. When stratified by PSA < 10 ng/mL, the 3-year disease-specific survival was 68% and 26%, respectively. In the series reported by Garzotto and Wajsman (104), 24 patients underwent radical cystoprostatectomy or RP with neoadjuvant ADT. Neoadjuvant ADT was associated with a lower rate of positive surgical margins (21%) compared with patients in whom androgen deprivation failed and

who exhibited a positive surgical margin rate of 80%. The authors demonstrated that disease-specific survival correlated strongly with the surgical margin status. At a mean follow-up of 5 years, the disease-specific survival rate was 95% and 44% for those with negative and positive surgical margins, respectively. Vaidya and Soloway (105) demonstrated a low rate of complications, good post-operative continence and only one biochemical recurrence at 36 months after salvage RP.

Similar data have been achieved by Stephenson et al. (106), who reported on 100 consecutive patients undergoing salvage RP associated with a very low rate of peri-operative complications. The 5-year progression-free rates have improved, with results similar to those of standard RP in cases of similar pathological stages. In contemporary series, the 10-year cancer-specific survival and overall survival rates are 70-75% and 60-66%, respectively. In most contemporary series, organ-confined disease, negative surgical margins and the absence of seminal vesicle and/or lymph node metastases are favourable prognostic indicators associated with a better disease-free survival of approximately 70-80%, compared with 40-60% in patients with locally advanced PCa (107).

Recently, Heidenreich et al. (108) reported on the oncological and functional outcome of 55 patients who underwent radical salvage therapy for locally recurrent PCA after various types of modern state-of-the-art radiation therapy, performed in or after the year 2000. Forty (72.7%) and 15 (27.3%) patients demonstrated organ-confined and locally advanced PCa, respectively. Eleven patients (20%) and seven patients (14%) had lymph node metastases and positive surgical margins, respectively. On multivariate analysis, significant predictors of organ-confined PCa with negative surgical margins were:

- biopsy Gleason score prior to salvage RP ($p = 0.02$);
- < 50% positive biopsy cores ($p = 0.001$);
- PSA DT > 12 months ($p = 0.001$);
- low-dose brachytherapy ($p = 0.001$).

Urinary continence was achieved after a mean of 8 months in basically all men after low-dose-radiation brachytherapy, while incontinence persisted in about 20% of patients who underwent external beam radiation therapy or high-dose radiation brachytherapy. Salvage RP is a surgically challenging but effective secondary local treatment of radiorecurrent PCa with curative intent. The identified predictive parameters will help to select patients most suitable for salvage RP with long-term cure and good functional outcome.

18.6.1.1 Summary of salvage RP

In general, salvage RP should be considered only in patients with a low co-morbidity, a life expectancy of at least 10 years, an organ-confined PCa < T2, Gleason grade < 7, and pre-surgical PSA < 10 ng/mL. In all other patients, accurate pre-surgical staging is not easily defined after radiation therapy, increasing the risk not only for anterior and total extirpation procedures, but also for associated complications and decreased long-term disease-specific survival.

18.6.2 ***Salvage cryosurgical ablation of the prostate (CSAP) for radiation failures***

Salvage cryosurgery has been proposed as an alternative to salvage RP because it has the potential to have less morbidity but equal efficacy. However, there have only been a very few studies, with disappointing results. Pisters et al. (109) reported on 150 patients who had undergone CSAP for PSA recurrences following radiotherapy (n = 110) or other extensive pre-treatment (n = 40). After a mean follow-up of 13.5 months, 58% of patients exhibited biochemical failure, while only 31% demonstrated undetectable PSA serum levels. The complications associated with salvage CSAP were significant, and occurred in virtually all patients, with the main complications being urinary incontinence (73%), obstructive symptoms (67%), impotence (72%) and severe perineal pain (8%). After 1-year follow-up, incontinence resolved in most patients, with persistent significant incontinence in 22% of patients.

According to a recent study by Cespedes et al. (110), the risk for urinary incontinence and impotence at least 12 months after CSAP are as high as 28% and 90%, respectively. In addition, 8-40% of patients complained about persistent rectal pain, and an additional 4% of men had undergone surgical procedures for the management of treatment-associated complications.

With regard to oncological outcome, recent studies demonstrated that a durable PSA-response can be achieved in about 50% of patients with a pre-cryosurgery PSA of < 10 ng/mL (111). In a recent multicentre study, the contemporary results of CSAP in 279 patients treated at a large number of centres, participating in the Cryo On-Line Data Registry, were analysed (112). Pre-treatment PSA was 7.6 +/- 8.2 ng/mL and the Gleason score was 7.5 +/- 1.1 (median 7). Patients were followed for 21.6 +/- 24.9 months and 47 were

followed for longer than 5 years. The 5-year actuarial biochemical disease-free rate was 54.5% +/- 4.9% (Phoenix). As predicted, based on the preservation of some prostatic tissue, 83% +/- 3.5% of patients had a detectable PSA level > 0.2 ng/mL at 5 years. Positive biopsies were observed in 15 of the 46 patients (32.6%) who underwent prostate biopsy after salvage cryotherapy. The incontinence rate (requiring pad use) was 4.4%. The rectal fistula rate was 1.2% and 3.2% of patients underwent transurethral prostate resection to remove sloughed tissue.

Quite recently, a case-matched control study between RSP and CSAP was performed among men with radiorecurrent PCa. The authors compared the oncological outcome of both salvage treatment options after a mean follow-up of 7.8 and 5.5 years for the radical salvage prostatectomy group and the cryosurgery group, respectively. RSP resulted in a statistically significant biochemical disease-free survival at 5 years of 61% versus 21% for the cryosurgery procedure. Also, the 5-year overall survival was significantly superior for the RSP group (95% vs 85%, $p < 0.001$) (113).

*18.6.3 **Salvage brachytherapy for radiation failures***

The experience with salvage brachytherapy for radiation failures is very limited. There is only one study that includes a representative number of patients and a mean follow-up of 64 months (114). Grado et al. (114) treated 49 patients with transperineal TRUS-guided brachytherapy and reported 3- and 5-year disease-free survival rates of 48% and 43%, respectively. Beyer (115) reported a 5-year biochemical freedom from relapse in 34-53% of patients, with local cancer control achieved in 98% of patients. However, the complication rate was quite severe:

- 27% became incontinent;
- 14% needed palliative transurethral resection due to acute urinary retention;
- 4% developed rectal ulcers;
- 2% required permanent colostomy.

Burri et al. (116) reported on the long-term outcomes and toxicity after salvage brachytherapy with palladium-103 or iodine-125 for local failure after initial radiotherapy for PCa in 37. Median follow-up was 86 months (range, 2-156). The median dose to 90% of the prostate volume was 122 Gy (range, 67-166). The 10-year biochemical disease-free survival and cancer-specific survival were 54% and 96%, respectively. There were three grade 3 toxicities and one grade 4 toxicity (10.8%). In conclusion, careful patient selection for salvage brachytherapy may result in improved outcomes and reduced toxicity.

In a similar approach, Moman et al. (117) retrospectively evaluated the outcome and toxicity after salvage iodine-125 implantation in 31 patients with locally recurrent PCa after primary iodine-125 implantation and external beam radiotherapy. The mean follow-up was 9 years (SD +/-4). Freedom from biochemical failure after 1-year follow-up was 51% and after 5 years was 20%. Fourteen (45%) patients died of PCa after a mean (+/- SD) follow-up of 73 (+/-39) months. Grade 1, 2, or 3 toxicity of the genitourinary tract was reported in 29%, 58% and 3% of the patients, respectively, in the acute phase, and in 16%, 39%, and 19%, respectively, in the late phase. Grade 1, 2, or 3 toxicity of the gastrointestinal tract was reported in 45%, 10%, and 0% of the patients, respectively, in the acute phase, and in 48%, 3%, and 6%, respectively, in the late phase. In conclusion, freedom from biochemical failure after salvage iodine-125 implantation for locally recurrent PCa after radiotherapy is limited, and both genitourinary and gastrointestinal toxicity occur frequently.

*18.6.4 **Observation***

Patients with signs of local recurrence only (i.e. low-risk patients with late recurrence and a slow PSA rise), who are not opting for second-line curative options, are best managed by observation alone. A retrospective cohort analysis of hormonal therapy versus watchful waiting (WW) in 248 men with PSA failure after radiotherapy showed no advantage for hormonal therapy in the subgroup of men with a PSA DT of > 12 months after radiotherapy. The 5-year metastasis-free survival rate was 88% with hormonal therapy versus 92% with WW ($p = 0.74$) (118).

*18.6.5 **High-intensity focused ultrasound (HIFU)***

The experience of HIFU for the treatment of locally recurrent PCa after radiation therapy is limited to a few retrospective studies. Zacharakis et al. (119) investigated the oncological and functional outcome of HIFU in a cohort of 31 men with biopsy-proven locally recurrent PCa following EBRT. The mean (range) pre-operative PSA level was 7.73 (0.20-20) ng/mL. The patients were followed for a mean (range) of 7.4 (3-24) months. Side effects included stricture or intervention for necrotic tissue in 11 patients (35%), urinary tract infection or dysuria syndrome in eight (26%) and urinary incontinence in two (6%). Rectourethral fistula occurred in two men (7%). Overall, 71% had no evidence of disease following salvage HIFU.

Using a similar approach, Murat et al. (120) evaluated the safety and efficacy of salvage HIFU in 167 patients with local PCA recurrence after EBRT and to determine prognostic factors for optimal patient selection. Local cancer control was achieved with negative biopsy results in 122 (73%) patients. The median PSA nadir was 0.19 ng/mL. The mean follow-up period was 18.1 months (range, 3-121 months). Seventy-four patients required no hormonal therapy. The actuarial 5-year overall survival rate was 84%. The actuarial 3-year progression-free survival was significantly lower in three situations:

- worsening of the pre-EBRT stage with 53%, 42%, and 25% for low-, intermediate-, and high-risk patients, respectively;
- an increase in the pre-HIFU PSA;
- use of ADT during PCa management.

In multivariate analyses, the risk ratios for intermediate- and high-risk patients were 1.32 and 1.96, respectively. The risk ratio was 2.8 if patients had been treated with ADT. No rectal complications were observed. Urinary incontinence accounted for 49.5% of the urinary sphincter implantations required in 11% of patients.

Urinary incontinence and the development of rectourethral fistula are the most significant complications of salvage HIFU therapy (119-121). About 30% of men develop some type of incontinence, with significant urinary incontinence treated with an artificial urinary sphincter in about 10% of patients. The oncological control rate after a short median follow-up of about 2 years is 30-40%.

18.6.5.1 Salvage HIFU therapy

Ahmed et al. (122) evaluated the outcome of whole-gland HIFU in 84 patients with radiorecurrent CaP following external beam radiation therapy. After a mean follow-up of 19.8 months, the 1- and 2-year progression-free survival rates were 59% and 43%, respectively. Four men developed rectourethral fistula and another 20% needed to undergo surgical treatment for subvesical outlet obstruction.

Berge et al. (123) evaluated the health-related quality of life using the Los Angeles Prostate Cancer Index questionnaire in 61 patients following HIFU for radiorecurrent, clinically organ-confined CaP. The mean time between treatment and quality of life evaluation was 17.5 months The treatment of localised radiorecurrent PCa by salvage HIFU is associated with clinically significant reductions in urinary and sexual function domains, but not in mental domains.

18.6.6 ***Guidelines for the management of PSA relapse after radiation therapy***

Recommendations	**GR**
Local recurrences may be treated by salvage RP in carefully selected patients, who presumably demonstrate organ-confined disease, i.e. PSA < 10 ng/mL, PSA DT > 12 months, low-dose-radiation brachytherapy, biopsy Gleason score < 7.	B
Cryosurgical ablation of the prostate and interstitial brachytherapy are alternative procedures in patients not suitable for surgery.	B
High-intensity-focused ultrasound may be an alternative option. However, patients must be informed about the experimental nature of this treatment modality due to the short follow-up periods reported.	
In patients with presumed systemic relapse, ADT may be offered.	B

18.7 Guidelines for second-line therapy after treatment with curative intent

Recommendations	GR
Presumed local failure after radical prostatectomy	
Patients with presumed local failure only may be candidates for salvage radiotherapy. This should be given with at least 64 Gy and preferably before PSA has risen above 0.5 ng/mL.	B
Other patients are best offered a period of watchful waiting (active monitoring), with possible hormonal therapy later on.	
Presumed local failure after radiotherapy	
Selected patients may be candidates for salvage RP and patients should be informed about the higher risk of complications, e.g. incontinence and erectile dysfunction.	C
Salvage RP should only be performed in experienced centres.	
Other patients are best offered a period of watchful waiting (active monitoring), with possible hormonal therapy later on.	
Presumed distant failure	
There is some evidence that early hormonal therapy may be of benefit in +/- local failure, delaying progression, and possibly achieving a survival benefit in comparison with delayed therapy. The results are not without controversy.	B
Local therapy is not recommended except for palliative reasons.

19. CASTRATION-RESISTANT PCA (CRPC)

19.1 Background

Cancer of the prostate is a heterogeneous disease. Our knowledge of the mechanisms involved in androgen independence, which is now known as castration-resistant prostate cancer (CRPC), remains incomplete (1-4), but is starting to become clearer (5,6). In the past, it was thought that androgen ablation provides a selective advantage androgen-independent cells that grow and eventually comprise most of the tumour. An alteration in normal androgen signalling is thought to be central to the pathogenesis of androgen-independent PCa (7).

It is thought that androgen independence (now called castration resistance) is mediated through two main, overlapping, mechanisms, which are androgen-receptor (AR)-independent and AR-dependent.

*19.1.1 **Androgen-receptor-independent mechanisms***

Androgen-receptor-independent mechanisms may be associated with the deregulation of apoptosis through the deregulation of oncogenes. High levels of bcl-2 expression are seen with greater frequency as PCa progresses.The regulation of microtubule integrity may be a mechanism through which bcl-2 induces its anti-apoptotic effect (8,9). Indeed, most active chemotherapeutics in CRPC work by inhibiting microtubule formation. The tumour suppressor gene p53 is more frequently mutated in androgen-independent PCa. Over-expression of bcl-2 and p53 in prostatectomy specimens has been shown to predict an aggressive clinical course (10-12). Clinical trials are underway to target the bcl-2 pathway (13), as the MDM2 oncogene (14) and the PTEN (phosphatase and tensin homolog) suppressor gene may also be involved (15).

19.1.2 ***AR-dependent mechanisms***

Direct AR-dependent mechanisms comprise the main pathway. Ligand-independent AR activation has been suspected, such as the tyrosine kinase activated pathway (IGF-1, KGF, EGF). Epidermal growth factor (EGF) is a potent mitogen of prostate stromal and epithelial cells. It is produced in high levels locally and acts as a paracrine stimulator. In AR-independent tumours, autocrine stimulation may become more important, which could allow unregulated growth (16).

Androgen receptor amplification and overexpression are observed in one-third of CRPC tissues (17,19) and may lead to AR hypersensitivity. Androgen receptor mutations may lead to a functional change in AR function (3,4,16). At the same time, there is an intracellular increase in androgens from in-situ conversion (20,21). This increase may be secondary to an increase in the intracellular enzymes involved in intracellular androgen synthesis (22).

Because AR mutations are found in only a subpopulation of tumour cells, they are unlikely to be responsible for the entire spectrum of the AR-independent state (23). The AR mutations might be related to the selective pressure of anti-androgens (23). The recent discovery of gene fusion between the androgen-driven TMPRSS2 and the EGR-ETS oncogene family (24) raises the question of oncogene regulation through androgen regulation pathways. In gene fusion, an androgen-responsive element from an androgene-regulated gene becomes associated with genes that are usually not androgen-regulated, so that they too become subject to androgen regulation. Currently, their implication in CRPC is hypothetical. Even in castrated patients, metastatic tissues have repeatedly shown high levels of androgens, suggesting a high level of intracrine synthesis (22,25). It is possible that a high intraprostatic cholesterol level can activate specific androgen pathways (1).

19.2 Definition of relapsing prostate cancer after castration

The previously term, 'hormone-refractory prostate cancer' referred to a very heterogeneous disease. It included different patient cohorts with significantly different median survival times (Table 21).

Table 21: Estimated natural mean survival of patients with HRPC presenting with different clinical scenarios

Patient characteristics	**Estimated mean survival**
Asymptomatic PSA	
No metastases	20-36 months
Minimal metastases	18-27 months
Extensive metastases	9-12 months
Symptomatic PSA	
Minimal metastases	14-16 months
Extensive metastases	9-12 months

The precise definition of recurrent or relapsed PCa remains controversial and several groups have recently published practical recommendations for defining CRPC (25-26).

Various different terms have been used to describe prostate cancers that relapse after initial hormonal ablation therapy, including HRPC, androgen-independent cancers and hormone-independent cancers (1). Over the course of the past 5 to 8 years, the term castration-resistant prostate cancer (CRPC) has become more used than the term hormone refractory or androgen independent. This is based predominantly on the implications of recent findings suggesting that advancing prostate cancer is not uniformly refractory to further hormonal manipulation and that androgens and the progression of disease are frequently dependent on - not independent of - androgen-AR interactions. The castrate-resistant, but still hormone-sensitive, PCa (CRPC) has been clearly characterised, with new drugs targeting either the AR, such as MDV3100, or androgen synthesis, via the CYP 17 inhibition like abiraterone acetate or TAK700 (*see below* Section 17.8.5.2) (27). Table 22 lists the key defining factors of CRPC.

Table 22: Definition of CRPC

Castrate serum levels of testosterone (testosterone < 50 ng/dL **or** < 1.7 nmol/L)
Three consecutive rises of PSA, 1 week apart, resulting in two 50% increases over the nadir, with a PSA > 2 ng/mL
Anti-androgen withdrawal for at least 4 weeks for flutamide and for at least 6 weeks for bicalutamide*
PSA progression, despite consecutive hormonal manipulations†

** Either anti-androgen withdrawal or one secondary hormonal manipulation should have been done in order to fulfil the criteria for CRPC if patients have been treated with antiandrogens in the context of maximum androgen blockade or step up therapy following PSA progression after failure of LHRH treatment.*
† Progression of osseous lesions: progression or appearance of two or more lesions on bone scan or soft tissue lesions using RECIST (Response Evaluation Criteria in Solid Tumours) and with nodes ≥ 2 cm in diameter.

19.3 Assessing treatment outcome in androgen-independent PCa

In general, the therapeutic outcome should be assessed using the guidelines for the evaluation of treatment response in solid tumours, recently published by the RECIST group (Response Evaluation Criteria In Solid Tumours) (28). However, 80-90% of patients do not have bi-dimensionally measurable disease. Patients with primarily soft tissue cancers often have a different prognosis to those with only osseous metastases.

Osteoblastic bone metastases remain difficult to quantify accurately. Magnetic resonance imaging (MRI) might be useful for assessing axial metastases (29). Since the cause of death in PCa patients is often unreliable, a more valid end-point might be overall survival (OS) rather than a disease-specific one (30).

*19.3.1 **PSA level as marker of response***

Many contemporary studies use PSA as a marker of response, even though there is no consensus about the magnitude and duration of a decline in PSA level. Although PSA is used as a rapid screening tool to test new agents for activity, there is conflicting evidence about the role of PSA as a response marker. Both the vaccine trials, Sipuleucel-T (Provenge) (31) and the TRICOM (PROSTVAC) study (32), demonstrated a significant OS benefit without any PSA change, raising questions about the value of PSA response for non-hormonal non-cytotoxic drugs (33).

In addition, wide fluctuations have been seen in PSA values due to a transient effect of drugs on PSA production. The effect of drugs on PSA expression should be considered when interpreting PSA response data, which should be viewed together with other clinical data (34-41).

Nevertheless, it has been reproducibly shown that ≥ 50% PSA decline in pre-treatment PSA following therapy carries a significant survival advantage (42,43). Kelly et al. (42) reported a statistically significant survival advantage in 110 patients with ≥ 50% PSA decline (> 25 months) versus those without a ≥ 50% PSA decline (8.6 months). Smith et al. (43) showed that a PSA decline ≥ 50% for at least 8 weeks resulted in a longer mean survival time of 91 weeks versus 38 weeks in patients showing a smaller PSA reduction.

An improved PSA response was also associated with prolonged survival in the TAX 327 study, with a median survival of 33 months when the PSA was normalised (< 4 ng/mL) versus 15.8 months for an abnormal PSA. This study also showed that a PSA response was not a surrogate marker for survival; even though the same PSA response rate was found in both docetaxel arms (45%), improved survival only occurred with the 3-weekly docetaxel regimen. According to the most recent evaluation of the TAX 327 and SWOG 99-16 studies, a PSA detection of ≥ 30% is associated with a significant survival benefit (44,45).

*19.3.2 **Other parameters***

The evaluation of molecular markers is just beginning. It includes a possible correlation between the positive findings of reverse transcriptase-polymerase chain reaction (RT-PCR) and poor survival (46), though these data must be corroborated before any clinical recommendations can be made. Another, probably more interesting, tool is the circulating tumour cell count (CTC count), which has been developed in parallel with abiraterone. The CTC count has been clearly related to survival in several trials (47-49) and may become a surrogate marker for survival. The FDA has recently approved an assay for CTC.

In patients with symptomatic osseous lesions, pain reduction or complete pain relief may be used as parameters to assess palliative therapeutic response (50). In a landmark analysis of TAX 327, PSA response

and pain response, but not QoL response, were independently associated with survival (51).

*19.3.3 **Trial end-points***

An increasing number of investigators advocate subjective end-points. However, investigators should currently apply the following:

- Use clearly defined end-points in trials, sufficiently powered to answer the hypothesis.
- Report each response parameter individually, rather than as a complete or partial response.
- Only use PSA response with other clinical parameters of response.
- Consider QoL end-points independently in symptomatic patients.

However, in everyday practice, the evaluation of treatment response must be based on symptom improvement, prolonged survival, or other pre-defined targets.

*19.3.4 **Recommendations for assessing therapeutic response***

The Prostate Cancer Working Group 2 recommends that investigators measure early-response outcomes by the changes in the individual disease manifestations present initially for both cytotoxic and non-cytotoxic drugs with the same methods used at enrolment (25). If a protocol defines a composite end-point for progression, the specified progression in any measure (with the exception of early changes in PSA or pain) overrides a change or improvement in other measures.

Recommendations	LE	GR
For PSA: Recognise that a favourable effect on PSA may be delayed for 12 weeks or more, even for a cytotoxic drug. Monitor PSA by cycle but plan to continue through early rises for a minimum of 12 weeks, unless there is other evidence of progression. Ignore early rises (prior to 12 weeks) in determining PSA response.	1a	A
Bone disease; Record outcome as new lesions or no new lesions. • First scheduled reassessment: no new lesions: continue therapy. • New lesions: perform a confirmatory scan 6 or more weeks later Confirmatory scan: no new lesions: continue therapy • Additional new lesions: progression Subsequent scheduled reassessments: no new lesions: continue. New lesions: progression.		
In non-osseous metastases from CRPC, assessment should adhere to the RECIST criteria.	1b	A
In patients with advanced symptomatic metastatic CRPC, the therapeutic response can be best assessed by improvement of symptoms. Document pain and analgesia at entry with a lead-in period and measure repeatedly at 3- to 4-week intervals. Perform serial assessments of global changes in HRQoL, urinary or bowel compromise, pain management, additional anticancer therapy Ignore early changes (12 weeks) in pain or HRQoL in absence of compelling evidence of disease progression. Confirm response or progression of pain or HRQoL end-points 3 weeks later.	1b	A

HRQoL = health-related Quality of life; RECIST = Response Evaluation Criteria in Solid Tumours.

19.4 Androgen deprivation in castration-resistant PCa

The existence of androgen-resistant PCa shows that disease progression occurs despite castration. The castration levels of testosterone must therefore be documented and a serum testosterone level < 50 ng/dL (1.7 nmol/L) should be documented at initial relapse on hormonal therapy (52).

Continued testicular androgen suppression in CRPC has a minimal overall effect. The recommendation to continue androgen deprivation therapy (ADT) with LHRH analogues, despite PSA progression, is based on the data of Manni et al. (53). This study demonstrated significantly lower survival rates in patients without complete androgen blockade (CAB). However, these data have been challenged by two trials that showed only a marginal survival benefit for patients remaining on LHRH analogues during second- and third-line therapies (54,55).

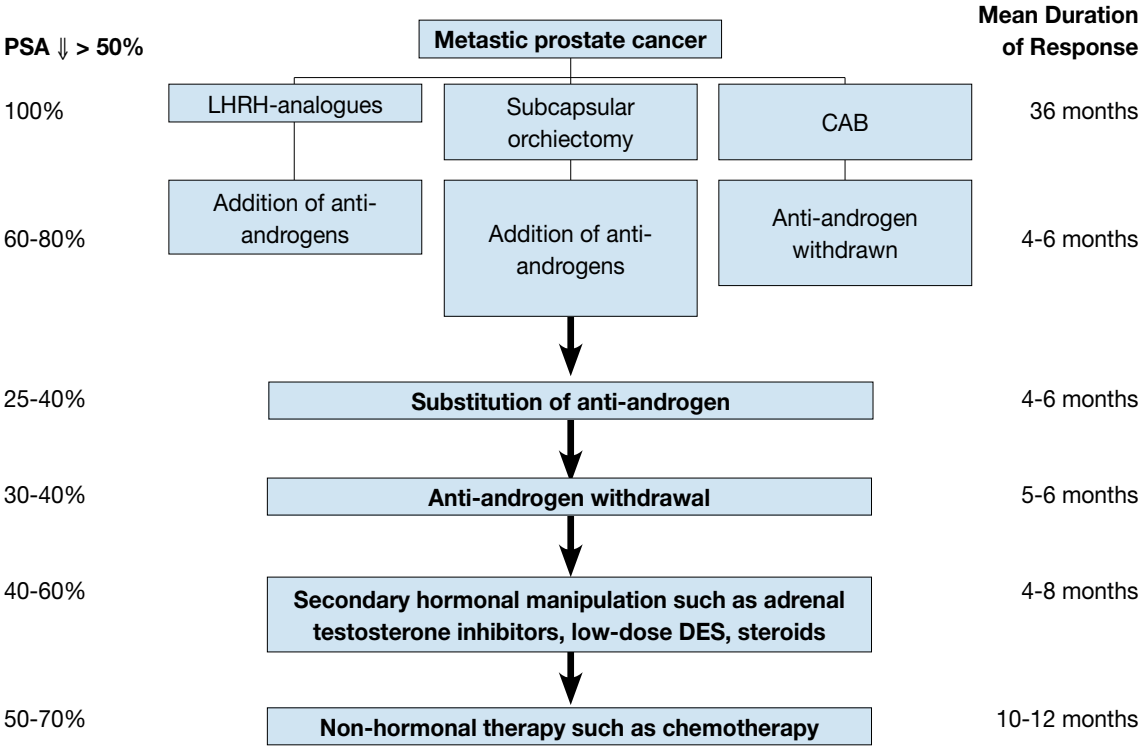
However, in the absence of prospective data, the modest potential benefits of a continuing castration outweigh the minimal risk of treatment. Androgen suppression should therefore be continued indefinitely in these patients.

19.5 Secondary hormonal therapy

For the patient with progressive disease after ADT, there are many therapeutic options. They include anti-

androgen withdrawal, addition of anti-androgens, anti-androgen replacement, oestrogenic compounds, adrenolytic agents, and novel approaches (56). Figure 1 summarises the treatment modalities and expected responses.

Figure 1: Flowsheet of the potential therapeutic options after PSA progression following initial hormonal therapy



LHRH = luteinising hormone releasing hormone; CAB = complete androgen blockade; DES = diethylstilboesterol.

19.6 Anti-androgen withdrawal syndrome

In 1993, Kelly and Scher (57) reported clinical and PSA responses in men who discontinued flutamide therapy upon the development of progressive disease. The anti-androgen withdrawal syndrome was a critical discovery in understanding the biology of androgen independence, interpreting clinical trials, and treating patients (58-61).

Approximately one-third of patients respond to anti-androgen withdrawal, as indicated by a ≥ 50% PSA decrease, for a median duration of approximately 4 months (Table 22). Anti-androgen withdrawal responses have also been reported with bicalutamide and megestrol acetate (62-67). Recently, in the SWOG 9426 trial, PSA progression despite CAB was reported in a subgroup of 210 patients with a tumour stage of M0 or M1 (68). A response was observed in 21%, even though there was no radiographic response. Median progression-free survival (PFS) was 3 months, with 19% (all M0) having 12 months' or greater PFS. Factors associated with increased PFS and OS were a longer period of non-steroidal use, lower PSA at baseline and M0-stage. These results were obtained with patients on CAB following androgen withdrawal treatment. No data were available on the withdrawal effect following second-line anti-androgen treatment.

In conclusion, androgen withdrawal should be systematically considered as a first-line modality in relapsing patients, even if its efficacy is limited (LE: 2).

Table 23: Frequency and duration of PSA response following anti-androgen withdrawal

Anti-androgen	No. of patients	> 50% decrease in PSA No. of patients (%)	Duration (months)
Flutamide	57	16 (28%)	4.0
Flutamide	82	12 (15%)	3.5
Flutamide	39	11 (28%)	3.7
Flutamide	21	7 (33%)	3.7
Bicalutamide	17	5 (29%)	5.0
Combined results	210	44 (21%)	3 (median)

19.7 Treatment alternatives after initial hormonal therapy

Except in patients with non-castration testosterone levels, it is difficult to predict which subset of patients is most likely to respond to secondary hormonal strategies.

19.7.1 ***Bicalutamide***

Bicalutamide is a non-steroidal anti-androgen with a dose response, with higher doses producing a greater reduction in PSA level (69). The largest cohort so far is based on 52 CRPC patients treated with bicalutamide, 150 mg (70). A palliative effect was clear and a 20% PSA response (at least 50% decrease) was observed, without any link to the palliative effect. Based on the affinity of dihydrotestosterone (DHT) for the androgen receptor, a large randomised trial (TARP) is ongoing comparing the effectiveness of bicalutamide 50 mg combined with either dutasteride or placebo in non-metastatic CRPC (71). The addition of an anti-androgen, such as bicalutamide or flutamide, to gonadal suppression at the time of PSA failure appears to result in declining PSA in only a few patients (72,73).

19.7.2 ***Switching to an alternative anti-androgen therapy***

There has been recent interest in another simple modality: the alternative anti-androgen therapy (74). After CAB was stopped in 232 progressing patients (76% being M1b), a withdrawal effect was observed in 31 men (15.1%). A second-line hormonal treatment was performed by giving an alternative non-steroidal drug (i.e. initial flutamide was replaced by bicalutamide and vice versa). An overall > 50% decline in PSA was observed in 83 men (35.8%), irrespective of any previous withdrawal effect, which lasted more than 6 months. The higher the PSA at the start of second-line therapy, the shorter was the progression-free survival and the lower was the PSA response rate.

19.7.3 ***Anti-androgen withdrawal accompanied by simultaneous ketoconazole***

The adrenal glands secrete approximately 10% of circulating androgen in humans. Some tumour cells in androgen-independent states must retain androgen sensitivity, as a clinical response is induced by a further decrease in circulating androgen levels following bilateral adrenalectomy or administration of drugs inhibiting adrenal steroidogenesis. Aminoglutethimide, ketoconazole and corticosteroids act mainly via this mechanism (75-79) to produce a PSA response in about 25% of patients for about 4 months. The simultaneous addition of ketoconazole to anti-androgen withdrawal, produced a significantly increased PSA response (32% vs 11%) and a longer time to PSA progression (8.6 vs 5.9 months) compared to anti-androgen withdrawal alone (79).

19.7.4 ***Oestrogens***

Prostate cancer usually expresses oestrogen receptors, which are upregulated after androgen ablation in animal models. In-vitro oestrogens can activate mutant androgen receptors isolated from androgen-independent PCa, while high-dose oestrogens have achieved objective salvage responses. This may be due to the mitotic arrest of direct cytotoxic effects on the cells, perhaps through an apoptotic mechanism (80,81). Recently, diethylstilboestrol (DES) (82-84) achieved a positive PSA response between 24% and 80%, with an overall estimated survival of 63% at 2 years. However, even at low doses of DES, about one-third (31%) of patients developed deep venous thrombosis and 7% experienced myocardial infarction.

19.7.5 ***The future for agents targeting the androgen receptor and endocrine pathways***

In the last 2 years, potential drugs have appeared in early phase I/II trials in CRPC and should be considered as potential major new tools, provided the randomised phase III trials confirm the early results. Furthermore, they confirm that the castrate-resistant status is far from meaning an hormonal-resistant status (see above Section 19.4).

19.7.5.1 MDV3100

The first agent, MDV3100, is a novel anti-androgen which blocks AR transfer to the nucleus, in contrast to currently available drugs where AR is able to transfer to the nucleus. This means that no agonist-like activity should ever occur. At the ASCO 2009 meeting, a phase I/II trial on 140 CRPC was reported (85). In this dose-finding study, a PSA decline > 50% was seen in 57% chemo-naïve patients, and in 45% chemo-refractory patients. Based on these results, a large phase III trial has been recently launched in metastatic CRPC patients after chemotherapy, on more than 1000 patients, with OS being the primary end-point.

At the GU ASCO 2012 the final results of the AFFIRM study were presented demonstrating a significant survival benefit of 4.8 months in patients undergoing MDV3100 treatment as compared to placebo. The median survival was 18.4 months versus 13.6 months ($p < 0.0001$) in the MDV3100 and the placebo group, respectively. The relative risk reduction of death was 37%. The median progression-free was 8.3 months versus 3.0 months ($p < 0.0001$) (86).

19.7.5.2 Abiraterone acetate

The second agent is the CYP17 inhibitor, abiraterone acetate. In CRPC patients, this drug is able to decrease PSA > 50% in 85% chemo-naïve patients (87), by 50% after docetaxel (88,89), and even by 33% after ketoconazole (89). In chemo-naïve patients, a PSA decline of > 90% is seen in up to 40% of patients (87).

The largest cohort so far is based on 96 chemo-naïve men included in a phase I/II trial. At a dose of 1000 mg, a PSA decline > 50% was observed in 67% and > 90% in 19% of patients. A partial response (RECIST-based) was seen in 37% of patients. The median time to progression was about 1 year (6). These very promising results have led to two large phase III trials: one in chemo-refractory patients (n = 1158), the other in chemo-naïve patients (n = 1000, accrual completed). In both trials, OS is the primary endpoint. In the post-chemotherapy trial (COU-301), patients with disease progression after docetaxel-based therapy were randomly assigned to receive abiraterone plus prednisone or prednisone plus placebo, with treatment continuing until disease progression or death. The results from the study demonstrated a significant improvement in overall survival in favour of abiraterone from 10.9 to 14.8 months, with a hazard ratio of 0.646. The PSA response proportion to abiraterone/prednisone was 38% versus 10% in this study, while grade 3 to 4 adverse events leading to discontinuation occurred in 10% of those treated with abiraterone and 13% of those treated with placebo. This study is a confirmation that CRPC remains hormone-driven, even in advanced stages of the disease and represents an outstanding opportunity for the future treatment of CRPC (90).

19.8 Non-hormonal therapy (cytotoxic agents)

Several proven chemotherapeutic options are available for metastatic disease in CRPC (Table 24). Multiple trials are underway, using very different approaches through all the known pathways. A detailed review is far beyond the scope of these guidelines (5), as most drugs are experimental, except perhaps docetaxel.

A significant improvement in median survival of about 2, 2.5 months occurred with docetaxel-based chemotherapy compared to mitoxantrone + prednisone therapy (91,92). In the SWOG 99-16 trial, pain relief was similar in both groups, although side-effects occurred significantly more often with docetaxel than with mitoxantrone.

Table 24: PSA response rates, mean survival, time to progression, and pain reduction in the large, prospective, randomised phase III trials of chemotherapy in patients with CRPC

Study	n	PSA decrease > 50%	Decrease in pain	Survival (months)	Time to progression
TAX 327					
Mitoxantrone, 3 weekly, 12 mg/m^2, Prednisone 5 mg BID		32%	22%	16.5	-
Docetaxel, 3 weekly, 75 mg/m^2 Prednisone 5 mg BID		45%[1]	35%[3]	18.9[1]	-
Docetaxel, weekly, 30 mg/m^2 Prednisone 5 mg BID		48%[1]	31%	17.4	-
SWOG 99-16					
Mitoxantrone, 3 weekly, 12 mg/m^2	336	50%[1]	-	17.5[2]	6.3 months[1]

Docetaxel/EMP, 3 weekly, 60 mg/m^2, EMP 3x280mg/day	338	27%	-	15.6	3.2 months
CALGB 9182					
Hydrocortisone	123	38%[4]	-	12.3	2.3 months
Mitoxantrone/HC, 3 weekly, 12 mg/m^2	119	22%	-	12.6	3.7 months[4]
Tannock et al.					
Prednisone	81	22%	12%	-	43 weeks[1]
Mitoxantrone/Pred, 3 weekly, 12 mg/m2	80	33%	29%[2]	-	18 weeks

EMP = estramustine; HC = hydrocortisone; Pred = prednisone. [1]p < 0.000; [2]p = 0.001; [3]p = 0.01; [4]p < 0.03.

19.8.1 Timing of chemotherapy in metastatic CRPC

The timing of chemotherapy varies in metastatic CRPC. It is advisable to start it immediately in symptomatic patients, if possible every 3 weeks, as this schedule is associated with an improvement in survival. However, a weekly regimen will result in the same symptom improvement and must be considered in patients unable to receive the optimal regimen (LE: 1b), as it is more effective than best supportive care (93). In asymptomatic patients, timing is not so clear and must be discussed individually.

Several poor prognostic factors have been described, such as a PSA level > 114 ng/mL, PSA doubling time (PSA-DT) < 55 days, or the presence of visceral metastases (94). A better risk group definition has been recently presented, based on the TAX 327 study cohort. The predictive factors were visceral metastases, pain, anaemia (Hb < 13 g/dL), bone scan progression, and prior estramustine before docetaxel. Patients were categorised into three risk groups: good risk (0-1 factor), intermediate (2 factors) and high risk (3-4 factors), leading to three different median OS: 25.7, 18.7 and 12.8 months, respectively (46) . In addition, two independent studies have suggested that improved survival can be predicted by C-reactive protein (CRP) levels < 8 mg/L (hazard ratio [HR], 2.96) (95,96). Age by itself is not a contraindication to docetaxel (97).

Currently, the only indication for chemotherapy in CRPC non-metastatic patients is inside clinical trials and patients should be advised to participate.

19.8.2 Mitoxantrone combined with corticosteroids

Mitoxantrone combined with corticosteroids (98,99) has been extensively studied primarily in patients with symptomatic osseous lesions due to CRPC. In the CALGB 9182 study (99), 244 patients with symptomatic metastatic CRPC were randomised to receive either mitoxantrone + hydrocortisone, 12 mg/m^2 every 3 weeks, or hydrocortisone alone. No differences were observed with regard to survival, PSA response, and median time to progression. However, the QoL was significantly improved in the combination arm. In another trial (99), 161 men with painful osseous metastases due to CRPC were randomised to receive mitoxantrone + prednisone versus prednisone alone. There was a significant benefit in pain reduction in the combination group (29%) versus prednisone alone (12%, p = 0.01). Furthermore, the duration of palliation was longer in patients who received mitoxantrone (43 weeks vs 18 weeks, p < 0.0001). There were no significant differences with regard to PSA response and median survival time. However, again, QoL was improved significantly due to pain reduction.

19.8.3 Alternative combination treatment approaches

Encouraging results have been seen with alternative treatments evaluated in prospective clinical phase II trials (100-103), including pegylated doxorubicin, vinorelbine, a combination of paclitaxel, carboplatin + estramustine, a combination of vinblastine, doxorubicin + radionuclides, and a combination of docetaxel + mitoxantrone. The lack of representative randomised phase III trials and unknown long-term efficacy are major problems associated with all these studies.

19.8.4 Estramustine in combination therapies

The synergy observed for estramustine combined with other drugs that target microtubule action has generated promising results in prospective clinical trials.

Estramustine + vinblastine is the most studied estramustine combination. Although different doses of estramustine and vinblastine have been used in prospective randomised trials, significant PSA and measurable responses have been reported in three separate studies. Although time to progression and frequency of ≥ 50% PSA decrease was significantly higher in the estramustine + vinblastine treatment arm, median survival

did not differ significantly between the estramustine and the estramustine + vinblastine arms (104). A recent meta-analysis (105) concluded that the addition of estramustine to chemotherapy increased the time to PSA progression and OS. However, there was a significant increased risk of thromboembolic events, up to 7% (106), requiring systematic prevention with coumadin.

19.8.5 ***Oral cyclophosphamide***

Intravenous cyclophosphamide has been tested in many trials. However, there is currently interest in oral cyclophosphamide, which seems to be less toxic than intravenous cyclophosphamide and may have greater activity. A study of oral cyclophosphamide + oral etoposide in 20 patients was similarly encouraging (107,108).

19.8.6 ***Cisplatin and carboplatin***

Cisplatin and carboplatin have activity as single agents against PCa. They also have a well-documented synergy with etoposide or paclitaxel in vitro in other malignancies, such as lung and ovarian cancer. As estramustine is also synergistic with these drugs, combinations of these three agents are now being tested. A combination of estramustine, etoposide and cisplatin (or carboplatin) has significant activity against poorly differentiated CRPC. A combination of estramustine, etoposide and paclitaxel has produced high response rates (102,109).

19.8.7 ***Specific bone targets***

Bone is a primary target for prostatic metastatic cells, leading to a rational for bone-protective drugs, preventing cancer cells from colonising and developing bone. Besides zoledronic acid and denosumab (see above Section 12.7.1), there are other promising drugs, mainly those targeting the endothelin-1 axis. The first of these agents (atrasentan) resulted in clear biological responses, but questionable clinical results (110), possibly secondary to an inappropriate trial design. However, the proof of principle has been made, and second-generation blockers (zibotentan) are under development after initially encouraging phase II trials (111), with large phase III trials in CRPC, either without metastases (> 1000 patients), with metastases (> 500 patients), or with docetaxel (> 1000 patients). Phase 3 trials in patients with CRPC are currently assessing docetaxel with or without atrasentan (NCT00134056) or zibotentan (ENTHUSE M1C; NCT00617669). However, recent results from the ENTHUSE M1 trial (NCT00554229) showed no significant improvement in OS with zibotentan monotherapy in men with mildly symptomatic CRPC (112). Moreover, it has been announced that the ENTHUSE M0 trial of zibotentan monotherapy in patients with non-metastatic CRPC has been discontinued after failing to meet the primary OS end-point. Phase 3 results for zibotentan/docetaxel treatment of bone-metastatic CRPC are still pending.

19.8.8 ***Salvage chemotherapy***

Since all patients who receive docetaxel-based chemotherapy for CRPC will progress, there have been many clinical trials investigating the role of salvage chemotherapy. The results suggest the most appropriate approaches are cabazitaxel (113), intermittent docetaxel chemotherapy (114,115), and potentially molecular-targeted therapy (116,117).

Several groups have used second-line intermittent docetaxel in patients who had clearly responded to first-line docetaxel (114,115,118). In general, a PSA response can be achieved in about 60% of patients with a median time to progression of about 6 months, while treatment-associated toxicity is minimal and similar to that of first-line docetaxel. Another, recently identified approach is molecular-targeted therapy (116,117,119-122) though more research is needed in larger groups of patients.

Platinum-based chemotherapeutic regimes have been investigated in patients with CRPC. Although the platinum complex, satraplatin, has shown activity against CRPC and some promise in clinical trials, the FDA rejected it for CRPC in 2008 (119).

Many new drugs, such as gefitinib, bevacizumab (phase III trial CALB 90401 ongoing), oblimersen (phase II trial EORTC 30021), and also a vaccine, G-Vax (122), have been tested in phase II/III trials without any positive impact on the primary end-point. The G-VAx trial was stopped prematurely because of a significantly higher mortality in the treatment arm as compared to the docetaxel control arm.

Positive results have been recently published from a prospective, randomised, phase III trial comparing the therapeutic efficacy of the taxane derivate, cabazitaxel, + prednisone versus mitoxantrone + prednisone in 755 patients with castration-resistant PCa, who had progressed after or during docetaxel-based chemotherapy (123). Patients received a maximum of 10 cycles of cabazitaxel (25 mg/m2) and mitoxantrone (12 mg/2), respectively. In both treatment arms, patients also received 10 mg prednisone daily for the entire treatment period. Overall survival was the primary endpoint and PFS, treatment response and safety were secondary endpoints. Patients in the cabazitaxel arm experienced a significantly increased OS of 15.1 versus 12.7 months ($p < 0.0001$) in the mitoxantrone arm. The cabazitaxel treatment arm also showed significant improvement

in PFS (2.8 vs 1.4 months, p < 0.0001), as well as in the objective response rate according to RECIST criteria (14.4% vs 4.4%, p < 0.005) and the PSA response rate (39.2% vs 17.8%, p < 0.0002).Treatment-associated WHO grade 3-4 side-effects developed significantly more often in the cabazitaxel arm, particularly haematological (68.2% vs 47.3%, p < 0.0002) and non-haematological toxicities (57.4% vs 39.8%, p < 0.0002) (113). Because of this and the risk of neutropenic sepsis associated with cabazitaxel, this drug should be administered by physicians with expertise in handling neutropenia and sepsis, possibly with granulocyte colony-stimulating factor.Whether cabazitaxel can be substituted for front-line docetaxel is the subject of a prospective phase III trial.

Recommendations on hormonal therapy
According to the positive results of this prospective randomised clinical phase III trial (LE: 1), cabazitaxel should be considered in the management of progressive CRPCA following docetaxel therapy.
Based on this second positive trial, in patients with relapse following first-line docetaxel chemotherapy both Cabazitaxel and Abiraterone are regarded as first-choice options for second-line treatment

19.9 Palliative therapeutic options: bone targeted therapies in CRPC

CRPC is usually a debilitating disease, often affecting the elderly male. A multidisciplinary approach is often required with input from medical oncologists, radiation oncologists, urologists, nurses, psychologists and social workers (124).

*19.9.1 **Painful bone metastases***

Most patients with CRPC have painful bone metastases. External beam radiotherapy is highly effective (125), even as single fraction (126). The two radioisotopes, strontium-89 and samarium-153, can partially or completely decrease bone pain in up to 70% of patients, but should not be given too late when pain is intractable. Early use can give rise to myelosuppression, making subsequent chemotherapy more difficult (127), even though a recent phase I trial has demonstrated manageable haematological toxicity with repeated administration of docetaxel and samarium-153. The use of samarium-153 as consolidation therapy, following a clear docetaxel response, may also help with initially painful bone metastases (128). Palliative treatment with another radioisotope emitter, radium-233, has shown very promising phase II results in patients with painful bone metastases in terms of palliation and OS, and only a mild haematological toxicity (129). Recently, survival results of the randomised phase 3 trial in men with CRPC and symptomatic bone metastases ineligible for or post-progresion to docetaxel with 223Ra (Alpharadin) (NCT00699751) have been reported at the ESMO 2011 meeting.The trial showed a survival advantage for alpharadine versus placebo (11.2 months versus 14.0 months HR 0.695; 95% CI, 0.552-0.875 P = .00185) met its primary endpoint of improved OS. Full data are awaited (130).

*19.9.2 **Common complications due to bone metastases***

Common complications due to skeletal metastases include bone pain, vertebral collapse or deformity pathological fractures and spinal cord compression. Osteoporosis may also cause fractures and should be prevented (see above). Cementation is an effective treatment of painful fracture, clearly improving both pain and QoL (131). However, it is still important to offer standard palliative surgery, which can be very effective at managing osteoblastic metastases (132,133). Impending spinal cord compression is an emergency. It must be recognised early and patients educated to recognise the warning signs. Once suspected, high-dose corticosteroids must be given and an MRI performed as soon as possible. A systematic neurosurgery consultation should be planned to discuss a possible decompression (134). Otherwise, external beam radiotherapy, with or without systemic therapy, is the treatment of choice.

*19.9.3 **Bisphosphonates***

Recently, bisphosphonates have been used to inhibit osteoclast-mediated bone resorption and osteoclast precursors in CRPC to provide effective treatment of skeletal complications and to reduce pain or provide total pain relief. In the largest single phase III trial (135), 643 patients who had CRPC with bone metastases were randomised to receive zoledronic acid, 8 mg or 4 mg every 3 weeks for 15 consecutive months, or placebo. At 15 and 24 months of follow-up, patients treated with only 4 mg of zoledronic acid had fewer skeletal-related events compared to the placebo group (44% vs 33%, p = 0.021) and fewer pathological fractures (13.1% vs 22.1%, p = 0.015). Furthermore, the time to first skeletal-related event was longer in the zoledronate group, so improving QoL. Patients were initially randomised to 4 or 8 mg of zoledronic acid, but the 8 mg dosage was later modified to 4 mg because of toxicity.

Currently, bisphosphonates can be proposed to patients with CRPC bone metastases to prevent skeletal

complications, even if the best dosing interval is unclear. At present, it is every 3 weeks or less. The toxicity, e.g. jaw necrosis, of these drugs, especially aminobisphosphonate, must always be kept in mind (135). Patients should have a dental examination before starting a bisphosphonate. The risk of jaw necrosis is increased by a history of trauma, dental surgery or dental infection, as well as intravenous long-term bisphosphonate administration (136).

Pain due to osseous metastases is one of the most debilitating complications of CRPC. Bisphosphonates have proven to be highly effective in reducing bone pain, but so far this has been investigated in small, open trials only. This data show that bisphosphonates seem to have a low side-effect profile which make them an ideal medication for palliative therapy of advanced CRPC (137-139). Bisphosphonates should be considered early in the management of symptomatic CRPC. Critical issues of palliation must be addressed when considering additional systemic treatment, including management of pain, constipation, anorexia, nausea, fatigue and depression, which often occur (i.e. palliative external beam radiation, cortisone, analgesics and anti-emetics).

19.9.4 ***RANK ligand inhibitors***

Denosumab is a fully human monoclonal antibody directed against RANKL, a key mediator of osteoclast formation, function, and survival. Denosumab efficacy against CRPC bone metastases was initially assessed in a phase 2 study. Fifty patients with increased urinary NTX levels despite previous treatment with zoledronic acid were randomised to either continue on intravenous bisphosphonates or receive subcutaneous denosumab. Denosumab normalised NTX levels more frequently than continuing bisphosphonate treatment (140).The efficacy and safety of denosumab (n = 950) compared with zoledronic acid (n = 951) in patients with metastatic CRPC was assessed in a phase III trial. Denosumab was superior to zoledronic acid in delaying or preventing skeletal related events (SREs), as shown by time to first on-study SRE (pathological fracture, radiation or surgery to bone, or spinal cord compression) of 20.7 versus 17.1 months, respectively (HR 0.82; p = 0.008). Denosumab also extended time to first and subsequent on-study SRE (HR 0.82; p=0.008). Both urinary NTX and BAP were significantly suppressed in the denosumab arm compared with the zoledronic acid arm ($p < 0.0001$ for both). This was the last of three pivotal trials exploring denosumab treatment of bone metastases, which formed the basis of the recent FDA approval of denosumab for preventing SREs in patients with bone metastases from solid tumours.

19.10 Summary of treatment after hormonal therapy

(Until results from randomised controlled trials on novel agents MDV3100 and abiraterone become available, there are no significant changes in the treatment of prostate cancer after hormonal therapy [27]).

Recommendations	GR
It is recommended to stop anti-androgen therapy once PSA progression is documented.	B
No clear-cut recommendation can be made for the most effective drug for secondary hormonal.	
manipulations because data from randomised trials are scarce.	C

Comment: Four to six weeks after discontinuation of flutamide or bicalutamide, an eventual anti-androgen withdrawal effect will be apparent.

19.11 Recommendations for cytotoxic and pre/post-docetaxel therapy in CRPC

Recommendations	GR
Patients with CRPCa should be counselled, managed and treated in a multidisciplinary team.	
In non-metastatic CRPCa, cytotoxic therapy should only be used in a clinical trial setting.	B
In patients with a PSA rise only, two consecutive increases of PSA serum levels above a previous reference level should be documented.	B
Patients should not be started on cytotoxic therapy unless their testosterone serum levels are below 50 ng/dL.	B
Patients should not be started on cytotoxic therapy unless their PSA serum levels are > 2 ng/mL. to assure correct interpretation of therapeutic efficacy.	B
Prior to treatment, the potential benefits of cytotoxic therapy and expected side-effects should be discussed with the patient.	C
In patients with metastatic CRPCa who are candidates for cytotoxic therapy, docetaxel at 75 mg/m^2 every 3 weeks is the drug of choice since it has shown a significant survival benefit.	A

In patients with symptomatic osseous metastases due to CRPCa, either docetaxel or mitoxantrone with prednisone or hydrocortisone are viable therapeutic options. If not contraindicated, docetaxel is the preferred agent based on the significant advantage in pain relief.	A
In patients with relapse following first-line docetaxel chemotherapy Cabazitaxel and Abiraterone are regarded as first-choice option for second-line treatment.	A
Second-line docetaxel can be offered to previously responding docetaxel-treated patients. Otherwise treatment is to be tailored to the individual patient. In case patients are not eligible for cabazitaxel or abiraterone, docetaxel is an option.	A
In men with CRPC with symptomatic bone metastases, ineligible for or progressing to docetaxel treatment with 223Ra (Alpharadin) has shown a survival benefit (141).	A

19.12 Recommendations for palliative management of CRPC

Recommendations	GR
Patients with symptomatic and extensive osseous metastases should be informed that further medical treatment will not extend life.	A
Management of these patients has to be directed at improvement of QoL and mainly pain reduction.	A
Effective medical management with the highest efficacy and a low frequency of side-effects is the major goal of therapy.	A
Bisphosphonates may be offered to patients with skeletal masses (mainly zoledronic acid has been studied) to prevent osseous complications. However, the benefits must be balanced against the toxicity of these agents, in particular jaw necrosis must be avoided.	A
Denosumab may be offered since it has been shown to delay/prevent SREs (pathologic fracture, radiation or surgery to bone, or spinal cord compression) also extending time to first and subsequent on-study SRE. Prior to treatment, the patient must be counseled about the potential benefits and side-effects (toxicity), in particular jaw necrosis.	A
In the management of painful osseous metastatses, early use of palliatative treatments such as radionuclides, external beam radiotherapy and adequate use of analgescis is recommended.	B
In patients with neurological symptoms, spinal surgery or decrompressive radiotherapy might be indicated as ermergency interventions.	A

20. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

3D-US	three-dimensional ultrasound
ADT	androgen-deprivation therapy
AS	active surveillance
ASCO	American Society of Clinical Oncology
ASTRO	American Society for Therapeutic Radiology and Oncology
AUA	American Urological Association
BDFS	biochemical disease-free survival
BMD	bone mineral density
bNED	actuarial biochemical freedom from disease
CAB	complete (or maximal or total) androgen blockade
CPA	cyproterone acetate
CRT	conformal radiotherapy
CSAP	cryosurgical ablation of the prostate
CSS	cancer-specific survival
CT	computed tomography
DES	diethylstilboestrol
DRE	digital rectal anticipation
DHT	dihydrostestosterone
DSS	disease-specific survival
EBRT	external beam radiation therapy
ECOG	Eastern Cooperative Oncology Group
eLND	extended lymph node dissection
ELND	elective lymph node dissection
e-MRI	endorectal MRI
EORTC	European Organisation for Research and Treatment of Cancer
EPC	Early Prostate Cancer Trialists' Group
EPCP	Early Prostate Cancer Programme
EPE	extraprostatic extension
ER-®	oestrogen receptor-®
ESRPC	European Randomized Screening for Prostate Cancer
FACT-P	Functional Assessment of Cancer Therapy-prostate
FNAB	fine-needle aspiration biopsy
FSH	follicle-stimulating hormone
GI	gastrointestinal
GR	grade of recommendation
GU	genitourinary
HD EBRT	high-dose EBRT
HDR	high-dose rate
HIFU	high-intensity focused ultrasound
HR	hazard ratio
HRPC	hormone-refractory prostate cancer
HRQoL	health-related quality of life
HT	hormonal therapy
IAD	intermittent androgen deprivation
IGRT	image-guided radiotherapy
IMRT	intensity modulated radiotherapy
IPSS	International Prostatic Symptom Score
LDAT	long-term ADT
LDR	low-dose rate (LDR)
LE	level of evidence
LET	linear energy transfer
LH	luteinising hormone
LHRH	luteinising hormone-releasing hormone
LHRHa	luteinising hormone-releasing hormone analogue
LND	lymph node dissection
LRP	laparoscopic radical prostatectomy
MRC	Medical Research Council

MRI	magnetic resonance imaging
MRSI	magnetic resonance spectroscopy imaging
NHT	neoadjvant hormonal therapy
NIH	National Institutes of Health
NVB	neurovascular bundle
OR	odds ratio
OS	overall survival
PAP	prostate acid phosphatase
PCa	prostate cancer
PET	positron emission tomography
PFS	progression-free survival
PIN	prostatic intraepithelial neoplasia
PIVOT	Prostate Cancer Intervention Versus Observation Trial: VA/NCI/AHRQ Cooperative StudiesProgram #407
PLCO	Prostate, Lung, Colorectal and Ovary
PSA	prostate-specific antigen
PSA-ACT	PSA complexed to antichymotrypsin
PSADT	PSA doubling time
PSAV	PSA velocity
PSMA	prostate-specific membrane antigen for messenger RNA
QoL	quality of life
QUALYs	quality of life adjusted gain in life
RALP	robot-assisted radical prostatectomy
RITA	radio-frequency interstitial tumour ablation
RP	radical prostatectomy
RRP	radical retropubic prostatectomy
RTOG	Radiation Therapy Oncology Group
SEER	Surveillance, Epidemiology, and End Results
SLN	sentinel lymph node
SPCG-4	Scandinavian Prostate Cancer Group Study Number 4
STAD	short-term androgen deprivation
SVI	seminal vesicle invasion
SWOG	South West Oncology Group
TNM	Tumour Node Metastasis
TZ	transition zone
TRUS	transrectal ultrasound
TURP	transurethral resection of the prostate
UICC	Union Against Cancer
USPIO	ultra-small super-paramagnetic iron oxide particles
VACURG	Veterans Administration Co-operative Urological Research Group
WHO	World Health Organization
WW	watchful waiting

Conflict of interest

All members of the Prostate Cancer Guidelines working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on
Renal Cell Carcinoma

TABLE OF CONTENTS PAGE

1. INTRODUCTION

The EAU Guideline Group for renal cell carcinoma (RCC) have prepared these guidelines to help urologists assess the evidence-based management of RCC and to help them incorporate the guidelines recommendations into their clinical practice. Publications concerning RCC are mostly retrospective analyses, which include some larger multicentre studies and well-designed controlled studies. As only a few randomised controlled trials are available, there is some lack of data with a strong evidence base. In recent years, a number of randomised studies have been performed, mostly concerning the medical treatment of metastasised RCC resulting in high evidence-based recommendations.

Where possible, a level of evidence (LE) and/or grade of recommendation (GR) have been assigned (1). Recommendations are graded in order to provide transparency between the underlying evidence and the recommendation given (Tables 1 and 2).

There is clearly a need for re-evaluation at regular intervals by the RCC Guideline Group of the information provided in these guidelines. It has to be emphasised that the current guidelines contain information for the treatment of an individual patient according to a standardised general approach. The information should be considered as providing recommendations without legal implications.

The current document provides a full text update, with a summary of the amendments provided below.

1.1 Summary of the 2010 RCC guidelines update

A new chapter “Other renal tumours” has been added which discusses other tumours of the kidney with the exception of renal pelvic carcinoma. The content of the other chapters has been completely revised based on the findings of a structured literature search.

1.2 Methodology

Structured literature searches using an expert consultant were designed for each section of this document. Searches were carried out in the Cochrane Library database of Systematic Reviews, the Cochrane Library of Controlled Clinical Trials, Medline, and Embase on the Dialog-Datastar platform. The controlled terminology of the respective databases was used and both MesH and EMTREE were analysed for relevant entry terms.

The search strategies covered the last 3 years for Medline and Embase. Prior to publication of this document an update search was carried out.

Also other data sources were consulted such as the Database of Abstracts of Reviews of Effectiveness (DARE) as well as relevant reference lists from other guidelines producers (National Institute for Clinical Excellence [NICE], American Urological Association [AUA]).

Publication history information: The RCC Guidelines were first published in 2000, with partial updates in 2001 and 2007 followed by a full text update in 2009, and a partial update in 2010.

Table 1: Level of evidence

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials.
1b	Evidence obtained from at least one randomised trial.
2a	Evidence obtained from one well-designed controlled study without randomisation.
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study.
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports.
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities.

Modified from Sackett et al. (1).

Table 2: Grade of recommendation

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial.
B	Based on well-conducted clinical studies, but without randomised clinical trials.
C	Made despite the absence of directly applicable clinical studies of good quality.

Modified from Sackett et al. (1).

2. EPIDEMIOLOGY AND AETIOLOGY

Renal cell carcinoma represents 2-3% of all cancers (1), with the highest incidence occurring in Western countries. Generally, during the last two decades until recently, there has been an annual increase of about 2% in incidence both worldwide and in Europe, though in Denmark and Sweden a continuing decrease has been observed (2). In 2006, it was estimated that there were 63,300 new cases of RCC and 26,400 kidney cancer-related deaths within the European Union (3). In Europe, overall mortality rates for RCC have increased up until the early 1990s, with rates generally stabilising or declining thereafter (4). There has been a decrease in mortality since the 1980s in Scandinavian countries and since the early 1990s in France, Germany, Austria, the Netherlands, and Italy. However, in some European countries (Croatia, Estonia, Greece, Ireland, Slovakia), mortality rates still show an upward trend with increasing rates (4).

Renal cell carcinoma is the commonest solid lesion within the kidney and accounts for approximately 90% of all kidney malignancies. It comprises different RCC types with specific histopathological and genetic characteristics (5). There is a 1.5:1 predominance of men over women, with peak incidence occurring between 60 and 70 years of age. Aetiological factors include lifestyle factors such as smoking, obesity, and hypertension (6-10). Having a first-degree relative with kidney cancer is also associated with an increased risk of RCC (11,12). The most effective prophylaxis is to avoid cigarette smoking and obesity.

Due to the increased detection of tumours by imaging techniques such as ultrasound and computed tomography (CT), the number of incidentally diagnosed RCCs has increased. These tumours are more often smaller and of lower stage (13-15).

2.1 Conclusion

Several verified risk factors have been identified including smoking, obesity and hypertension. Cigarette smoking is a definite risk factor for RCC (LE: 2a).

2.2 Recommendation

	GR
The most important primary prevention for RCC is to eliminate cigarette smoking and to avoid obesity.	B

3. DIAGNOSIS AND STAGING

3.1 Symptoms

Many renal masses are asymptomatic and non-palpable until the late stages of the disease (1). Currently, more than 50% of RCCs are detected incidentally by using imaging to investigate a variety of non-specific symptom complexes (2-4) (LE: 2b). The classic triad of flank pain, gross haematuria, and palpable abdominal mass is now rare (6-10%) (5,6) (LE: 3).

Paraneoplastic syndromes are found in approximately 30% of patients with symptomatic RCCs (Table 3) (LE: 4). A few symptomatic patients present with symptoms due to metastatic disease, such as bone pain or persistent cough (1,7) (LE: 2b).

Table 3: Most common paraneoplastic syndromes

Hypertension
Cachexia
Weight loss
Pyrexia
Neuromyopathy
Amyloidosis
Elevated erythrocyte sedimentation rate
Anaemia

Abnormal liver function
Hypercalcaemia
Polycythaemia

3.1.1 ***Physical examination***

Physical examination has only a limited role in diagnosing RCC. However, the following findings should initiate radiological examinations:

- palpable abdominal mass;
- palpable cervical lymphadenopathy;
- non-reducing varicocele;
- bilateral lower extremity oedema, which suggests venous involvement.

3.1.2 ***Laboratory findings***

The most commonly assessed laboratory parameters are serum creatinine, glomerular filtration rate, haemoglobin, erythrocyte sedimentation rate, alkaline phosphatase, lactate dehydrogenose (LDH), and serum corrected calcium (1,8,9) (LE: 4).

Separate bilateral renal function should be estimated in the following situations (10-12) (LE: 2b):

- When renal function is clinically important, e.g. in patients with a solitary kidney tumour or bilateral tumours;
- When renal function is compromised, as indicated by an increased concentration of serum creatinine;
- In patients at risk of future renal impairment from co-morbid disorders, e.g. diabetes, chronic pyelonephritis, renovascular disease, stone or renal polycystic disease.

3.2 Radiological investigations

Most renal tumours are diagnosed by abdominal ultrasound or CT performed for various reasons (LE: 4). Imaging can be used to classify renal masses into solid or cystic.

3.2.1 ***Presence of enhancement***

For solid renal masses, the most important criterion for differentiating malignant lesions is the presence of enhancement (13) (LE: 3). The traditional approach for detection and characterisation of renal masses is to use ultrasound, CT, or magnetic resonance imaging (MRI). Most renal masses can be diagnosed accurately by using imaging alone. Contrast-enhanced ultrasound can be helpful in specific cases (e.g. chronic renal failure with relative contraindication for iodinated or gadolinium contrast media (14-16) (LE: 3).

3.2.2 ***Computed tomography or magnetic resonance imaging***

Computed tomography or MRI are used to characterise a renal mass. Imaging must be performed both before and after administration of intravenous contrast material to demonstrate enhancement. In CT imaging, enhancement in renal masses is determined by comparing Hounsfield unit (HU) readings from before and after contrast administration. A change of 20 HU or greater is strong evidence of enhancement (17) (LE: 3). To maximise differential diagnosis and detection, the evaluation should include images from the nephrographic phase, because this phase allows optimum depiction of renal masses that typically do not enhance to the same degree as renal parenchyma.

Abdominal CT allows diagnosis of RCC and provides information on:

- function and morphology of the contralateral kidney (10) (LE: 3);
- primary tumour extension with extrarenal spread;
- venous involvement;
- enlargement of locoregional lymph nodes;
- condition of adrenal glands and the liver (LE: 3).

Abdominal contrast-enhanced CT angiography is a useful tool in selected cases to obtain detailed information about the kidney vascular supply (18). If CT results are indeterminate, MRI may provide additional information to:

- demonstrate enhancement in renal masses;
- investigate locally advanced malignancy;
- investigate venous involvement if there is a badly defined extension of inferior vena cava tumour thrombus on CT scan (19-22) (LE: 3).

Magnetic resonance imaging is also indicated in patients with an allergy to intravenous contrast and in

pregnancy without renal failure (23,24) (LE: 3). Evaluation of the tumour thrombus can also be performed with Doppler ultrasound (25) (LE: 3).

*3.2.3 **Other investigations***

Renal arteriography and inferior venacavography have only a limited role in the work-up of selected patients with RCC (LE: 3). In patients with any sign of impaired renal function, an isotope renogram and total renal function evaluation should be considered in order to optimise the treatment decision, e.g. the need to preserve renal function (10-12) (LE: 2a). The true value of positron emission tomography (PET) in the diagnosis and follow-up of RCC remains to be determined and currently PET is not a standard investigation (26,27) (LE: 1b).

*3.2.4 **Metastatic RCC investigations***

Chest CT is the most accurate investigation for chest staging (25,28-34) (LE: 3). However, at the very least, routine chest radiography, as a less accurate alternative to chest CT imaging, must be done for metastatic evaluation (LE: 3). There is a consensus that most bone and brain metastases are symptomatic at diagnosis so that a routine bone or brain CT scan is not generally indicated (35,36). However, if indicated by clinical or laboratory signs and symptoms, other diagnostic procedures may be used, such as a bone scan, brain CT, or MRI (37,39) (LE: 3).

*3.2.5 **Bosniak classification of renal cystic masses***

For the evaluation of renal cystic masses, the Bosniak classification classifies renal cysts into five categories based on CR imaging appearance in an attempt to predict the risk of malignancy (38) (LE: 3). The Bosniak system also advocates treatment for each category (Table 4).

Table 4: The Bosniak classification of renal cysts (38**)**

Bosniak category	**Features**	**Work-up**
I	A simple benign cyst with a hairline-thin wall that does not contain septa, calcification, or solid components. It measures water density and does not enhance with contrast material.	Benign
II	A benign cyst that may contain a few hairline-thin septa. Fine calcification may be present in the wall or septa. Uniformly high-attenuation lesions of < 3 cm, which are sharply marginated and do not enhance.	Benign
IIF	These cysts might contain more hairline-thin septa. Minimal enhancement of a hairline-thin septum or wall can be seen. There may be minimal thickening of the septa or wall. The cyst may contain calcification that might be nodular and thick, but there is no contrast enhancement. There are no enhancing soft-tissue elements. This category also includes totally intrarenal, non-enhancing, high-attenuation renal lesions of ≥ 3 cm. These lesions are generally well-marginated.	Follow-up. A small proportion are malignant.
III	These lesions are indeterminate cystic masses that have thickened irregular walls or septa in which enhancement can be seen.	Surgery or follow-up. Malignant in > 50% lesions.
IV	These lesions are clearly malignant cystic lesions that contain enhancing soft-tissue components.	Surgical therapy recommended. Mostly malignant tumour.

3.3 Renal biopsy

Renal tumour biopsies are increasingly being used in diagnosis, in follow-up surveillance, and in ablative therapies (40-45) (LE: 3). In most series, a core biopsy demonstrates high specificity and high sensitivity for the presence of malignancy (40-44), though it should be noted that 10-20% of biopsies are non-conclusive.

Biopsy aims to determine eventual malignancy, type, and grade of the evaluated renal mass.
A percutaneous mass biopsy is rarely required for large renal masses scheduled for nephrectomy.
The positive predictive value of imaging findings is so high that a negative biopsy result does not alter management (45) (LE: 3).

Biopsy is also indicated in metastatic patients before starting systemic therapy (46) (LE: 3).

3.4 Histological diagnosis

The histological diagnosis in RCC is established after surgical removal of renal tumours or after biopsy specimen examinations (40-42). The Fuhrman classification system for nuclear grade (grade 1, 2, 3 and 4) in RCC (47,48) has been the most generally accepted classification, and is an important, independent prognostic factor for RCC (LE: 3).

According to the World Health Organization (WHO) (49) there are at least three major histological subtypes of RCC:

- clear cell (cRCC, 80-90%);
- papillary (pRCC, 10-15%);
- chromophobe (chRCC, 4-5%) (LE: 3).

These RCC types can be differentiated by histological and molecular genetic changes (Table 5) (LE: 3). Papillary RCC can further be divided into two different subtypes: type 1 and type 2 with an adverse clinical course (Table 5) (50,51) (LE: 3).

Table 5: Major histological subtypes of RCC

Histological subtype	Percentage of RCC	Histological description	Associated molecular genetic changes
Clear cell (cRCC)	80-90%	Most cRCC are composed predominantly of cells containing clear cytoplasm, although eosinophilic cytoplasm predominates in some cells. The growth pattern may be solid, tubular, and cystic.	Identified by the specific deletion of chromosome 3p and mutation of the VHL gene. Other changes are duplication of the chromosome band 5q22, deletion of chromosome 6q, 8p, 9p, and 14q.
Papillary (pRCC)	10-15%	Most pRCCs have small cells with scanty cytoplasm, but also basophilic, eosinophilic, or pail-staining characteristics. A papillary growth pattern predominates, although there may be tubular papillary and solid architectures. Necrotic areas are common. Papillary RCC can be divided into two different subtypes: type 1 with small cells and pale cytoplasm and type 2 with large cells and eosinophilic cytoplasm, the latter having a worse prognosis.	The most consistent genetic alterations are trisomies of chromosomes 3q, 7, 8, 12, 16, 17, and loss of the y chromosome.
Chromophobe (chRCC)	4-5%	The cells of chRCC may have pail or eosinophilic granular cytoplasm. Growth usually occurs in solid sheets.	The genetic characteristic is a combination of loss of chromosomes 1, 2, 6, 10, 13, and 17.

3.5 Conclusion

The proportion of small and incidental renal tumours has significantly increased in most countries, though a large number of patients with RCC still present with clinical symptoms, such as palpable mass, haematuria, and paraneoplastic and metastatic symptoms (LE: 3). Accurate staging of RCC with abdominal and chest CT or MRI is obligatory (LE: 3). Chest CT is the most sensitive approach for chest staging. There is no role for routine bone scan or CT of the brain in the standard clinical work-up of asymptomatic patients.

Recently, there has been an increasing indication for fine-needle biopsy for evaluation and ablative therapies in small renal tumours (40-45) (LE: 3).

3.6 Recommendations

	GR
In a patient with one or more laboratory or physical findings, the possible presence of RCC should be suspected.	B
A plain chest x-ray can be sufficient for assessment of the lung in low-risk patients, but chest CT is most sensitive.	A
Abdominal CT and MRI are recommended for the work-up of patients with RCC and are the most appropriate imaging modalities for Tumour Node Metastasis (TNM) classification prior to surgery.	A
In high-risk patients for bone metastases (raised alkaline phosphatase or bone pain), further evaluation using an imaging approach should be done.	A
Evaluation of renal function is recommended.	B
Percutaneous biopsy is always indicated before ablative- and systemic therapy without previous histopathology.	B
Percutaneous biopsy is recommended in surveillance strategies to stratify follow-up.	B

4. CLASSIFICATION AND PROGNOSTIC FACTORS

4.1 Classification

The TNM stage classification system is generally recommended for clinical and scientific use (1). However, the TNM classification requires continuous improvements (2). The 2009 version has introduced significant changes based on recent prognostication literature (Table 6).

- The pT1 substratification, introduced in 2002, has been validated by several studies and is no longer a matter of controversy (3-5) (LE: 3). Even though it has been less extensively studied, the tumour size stratification of T2 tumours has been recently introduced within the 2009 TNM classification.
- Since the 2002 version of the TNM classification, tumours with renal sinus fat invasion have been classified as pT3a. However, accumulating data suggest that renal sinus fat invasion carries a worse prognosis than perinephric fat invasion and therefore should not be included in the same pT3a stage group (LE: 3) (6-8).
- Many studies have suggested that adrenal invasion has a very poor prognostic value and that RCCs with this feature should be classified as pT4 tumours (9,10) (LE: 3). This change has been introduced in the latest TNM version (1).
- In previous TNM classifications, the pT3b group included both renal vein and inferior vena cava invasions. As the result of many studies into the independent prognostic value of vena cava compared to renal vein invasion alone (11-13), these two groups have now been separated in the latest version of the TNM classification (1).
- The accuracy of the N1-N2 subclassification has been questioned (14) (LE: 3). For adequate M-staging of patients with RCC, accurate pre-operative imaging (currently, chest and abdominal CT) should be performed (15,16) (LE: 4).

4.2 Prognostic factors

Factors influencing prognosis can be classified into: anatomical, histological, clinical, and molecular.

*4.2.1 **Anatomical factors***

Anatomical factors include tumour size, venous invasion, renal capsule invasion, adrenal involvement, lymph node, and distant metastasis. These factors are commonly gathered together in the universally used TNM staging classification system (Table 6).

Table 6: The 2009 TNM staging classification system (1)

T - Primary tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
T1	Tumour ≤ 7 cm in greatest dimension, limited to the kidney
T1a	Tumour ≤ 4 cm in greatest dimension, limited to the kidney
T1b	Tumour > 4 cm but ≤ 7 cm in greatest dimension
T2	Tumour > 7 cm in greatest dimension, limited to the kidney
T2a	Tumour > 7 cm but ≤ 10 cm in greatest dimension
T2b	Tumours > 10 cm limited to the kidney
T3	Tumour extends into major veins or directly invades adrenal gland or perinephric tissues but not into the ipsilateral adrenal gland and not beyond Gerota's fascia

	T3a	Tumour grossly extends into the renal vein or its segmental (muscle-containing) branches or tumour invades perirenal and/or renal sinus (peripelvic) fat but not beyond Gerota's fascia
	T3b	Tumour grossly extends into the vena cava below the diaphragm
	T3c	Tumour grossly extends into vena cava above the diaphragm or invades the wall of the vena cava
T4	Tumour invades beyond Gerota's fascia (including contiguous extension into the ipsilateral adrenal gland)	
N - Regional lymph nodes		
NX	Regional lymph nodes cannot be assessed	
N0	No regional lymph node metastasis	
N1	Metastasis in a single regional lymph node	
N2	Metastasis in more than 1 regional lymph node	
M - Distant metastasis		
M0	No distant metastasis	
M1	Distant metastasis	
TNM stage grouping		
Stage I	T1	N0 M0
Stage II	T2	N0 M0
Stage III	T3	N0 M0
	T1, T2, T3	N1 M0
Stage IV	T4	Any N M0
	Any T	N2 M0
	Any T	Any N M1

A help desk for specific questions about TNM classification is available at http://www.uicc.org/tnm.

*4.2.2 **Histological factors***

Histological factors include Fuhrman grade, RCC subtype, sarcomatoid features, microvascular invasion, tumour necrosis, and invasion of the collecting system. Fuhrman nuclear grade is the most widely accepted histological grading system in RCC (17). Although affected by intra- and inter-observer discrepancies, it is an independent prognostic factor (18). Recently, it has been suggested that a simplified two- or three-strata Fuhrman grading system could be as accurate as the classical four-tiered grading scheme (19,20) (LE: 3).

According to the WHO classification (21), three major histological subtypes of RCC exist: conventional (clear cell) (80-90%), papillary (10-15%) and chromophobe (4-5%). In univariate analysis, there is a trend towards a better prognosis for patients with chromophobe versus papillary versus conventional (clear cell) RCC (22,23). However, the prognostic information provided by the RCC subtype is lost when stratified to tumour stage (23,24) (LE: 3).

Among papillary RCCs, two subgroups with different outcomes have been identified (25):
Type 1 are low-grade tumours with a chromophilic cytoplasm and a favourable prognosis.
Type 2 are mostly high-grade tumours with an eosinophilic cytoplasm and a great propensity for developing metastases (LE: 3).

The RCC type classification has been confirmed at the molecular level by cytogenetic and genetic analyses (26-28) (LE: 2b).

*4.2.3 **Clinical factors***

Clinical factors include patient performance status, localised symptoms, cachexia, anaemia, and platelet count (29-32) (LE: 3).

*4.2.4 **Molecular factors***

Numerous molecular markers being investigated include: carbonic anhydrase IX (CaIX), vascular endothelial growth factor (VEGF), hypoxia inducible factor (HIF), Ki67 (proliferation), p53, PTEN (phosphatase and tensin homolog) (cell cycle), E-cadherin, and CD44 (cell adhesion) (33,34) (LE: 3). To date, none of these markers has been shown to improve the predictive accuracy of current prognostic systems and their use is therefore not recommended in routine practice. Finally, even though gene expression profiling seems a promising method, it has not helped so far to identify new relevant prognostic factors (35).

*4.2.5 **Prognostic systems and nomograms***

Post-operative prognostic systems and nomograms that combine independent prognostic factors have been developed and externally validated (36-42). These systems may be more accurate than TNM stage or Fuhrman grade alone for predicting survival (LE: 3). An important advantage of nomograms is their ability to measure predictive accuracy (PA), which enables all new predictive parameters to be objectively evaluated. Before being adopted, every new prognostic variable or system should be able to demonstrate that its PA is superior to conventional post-operative histo-prognostic schemes (43). Recently, new pre-operative nomograms with excellent PAs have been designed (44,45). Table 7 summarises the current most relevant prognostic systems.

4.3 Conclusion

In patients with RCC, TNM stage, nuclear grade according to Fuhrman, and RCC subtype (WHO, 2004; (21)), should be performed because they contribute important prognostic information (LE: 2). Prognostic systems should currently be used in a metastatic setting and are still investigational in localised disease (LE: 2).

4.4 Recommendations

	GR
The current TNM classification system is recommended because it has consequences for prognosis and therapy.	B
The Fuhrman grading system and classification of RCC subtype should be used.	B
A stratification system should be used in a metastatic setting for selecting the appropriate first-line treatment.	B
In localised disease, the use of integrated prognostic systems or nomograms is not routinely recommended, even though these systems can provide a rationale for enrolling patients into clinical trials.	B
No molecular prognostic marker is currently recommended for routine clinical use.	B

Table 7: Summary of the anatomical, histological, and clinical variables included in the most commonly used prognostic models for localised and metastatic RCC

Prognostic Models		Variables												
		TNM Stage	ECOG PS	Karnofsky PS	RCC related symptoms	Fuhrman grade	Tumor necrosis	Tumor size	Delay between diagnosis and treatment	LDH	Corrected calcium	Hemoglobin	Neutrophil count	Platelet count
Localised RCC	UISS	X	X			X								
	SSIGN	X				X	X	X						
	Post operative Karakiewicz's nomogram	X			X	X		X						
Metastatic RCC	MSKCC prognostic system			X					X	X	X	X		
	Heng's model			X					X		X	X	X	X

ECOG PS = Eastern Cooperative Oncology Group performance status; LDH = lactate dehydrogenase; MSKCC = Memorial Sloan Kettering Cancer Center; PS = performance status; RCC = renal cell carcinoma; SSIGN = Stage Size Grade Necrosis; TNM = tumour node metastasis; UISS = University of California Los Angeles integrated staging system.

5. OTHER RENAL TUMOURS

Detailed morphological studies, which use contemporary immunohistochemical and molecular techniques, have resulted in the current classification of renal epithelial neoplasms, as outlined in the 2004 WHO monograph (1). The common clear cell (cRCC), papillary (pRCC) and chromophobe RCC (chRCC) types account for 85-90% of the renal malignancies. The remaining 10-15% of renal tumours include a variety of uncommon, sporadic, and familial carcinomas, some of which have recently been described, and a group of unclassified carcinomas.

5.1 Bellini duct carcinoma (collecting-duct carcinoma)

Collecting-duct carcinoma is a very rare type of RCC, often presenting at an advanced stage of disease. Up to 40% of patients have metastatic spread at initial presentation and most patients die within 1–3 years from the time of primary diagnosis. To date, the largest case series (n = 81) to consider outcome showed that regional lymph node metastases were present in 44% of patients at diagnosis and distant metastases were present in 32%. The survival rate was 48% at 5 years and 14% at 10 years (2-4).

5.2 Sarcomatoid RCC

Sarcomatoid RCC represents high-grade transformation in different RCC types, without being a distinct histological entity. Sarcomatoid changes in RCC carry a worse prognosis (5).

5.3 Unclassified RCC

Unclassified RCC is a diagnostic category for RCC that cannot be assigned to any other category of RCC-type carcinoma (1).

5.4 Multilocular cystic RCC (cRCC)

There are no strict histopathological criteria for this subtype. In the WHO 2004 classification (1), multilocular cRCC is an independent entity, but it is essentially a well-differentiated cRCC. This subtype accounts for up to about 3.5% of surgically treated kidney tumours (6). To date, metastases of this tumour have not been

described (6,7). According to the Bosniak classification, which is based on imaging criteria, multilocular cRCC presents as a Bosniak type II or III cystic lesion (8-10). However, this type of Bosniak lesion can also be due to a mixed epithelial and stromal tumour of the kidney (MESTK), a cystic nephroma, or a multilocular cyst, all of which are benign lesions. In many cases, a pre-operative biopsy and intra-operative frozen-section analysis does not lead to a correct diagnosis. Fortunately, all these tumours are treated with the same operative strategy. For this reason, if technically feasible, a nephron-sparing procedure is the procedure of choice for a complex multicystic renal mass with enhanced density is observed (LE: 3) (GR: B) (6,7,9,10).

5.5 Papillary adenoma

Papillary adenomas are tumours with papillary or tubular architecture of low nuclear grade and 5 mm in diameter or smaller (1). Because they are so small, they are only found incidentally in a nephrectomy specimen.

5.6 Renal medullary carcinoma

Renal medullary carcinoma is a devastating malignancy that primarily affects young men with sickle cell trait. It is also extremely rare, comprising approximately 2% of all primary renal tumours in young people aged 10 to 20 years old. Metastatic disease is seen at presentation in 95% of patients (2,11,12).

5.7 Translocation carcinoma

Renal translocation carcinomas are uncommon tumours, which usually occur in children and young adults. Most translocation carcinomas (about 90%) involve the transcription factor E3 (TFE3) located on Xp11.2 and seem to follow a relatively indolent course, despite often being at an advanced stage at presentation (2). Another rare group of RCCs that show a translocation (t (6; 11) (p21; q12)) has also been reported (2,13).

5.8 Mucinous tubular and spindle cell carcinoma

This tumour is associated with the loop of Henle. Most mucinous tubular and spindle-cell carcinomas behave in a low-grade fashion (1,2,14).

5.9 Carcinoma associated with end-stage renal disease

Cystic degenerative changes (acquired cystic kidney disease [ACKD]) and a higher incidence of RCC are typical features of ESKD (end-stage kidney disease). The incidence of ACKD is about 50% in patients undergoing dialysis, but also depends on the duration of dialysis, gender (three times more common in men), and the diagnostic criteria of the method of evaluation. RCCs of native end-stage kidneys are found in about 4% of patients. The lifetime risk of developing RCCs is at least 10 times higher than in the general population. Compared with sporadic RCCs, the RCCs associated with ESKD and ACKD are characterised by multicentricity and bilaterality, being found in younger patients (mostly male), and by less aggressive behaviour. In transplanted patients, however, it is usually quite aggressive, probably as a result of immunosuppression (15-20).

Although the histological spectrum of tumours within ACKD is similar to that in sporadic RCC, the most predominant form is pRCC, being found in 41-71% of ACKD-associated RCC versus 10% in sporadic RCC. The remaining tumours are mostly cRCC (2,19,20). Tickoo et al. (21) recently described two new renal tumours associated with ESKD: ‘acquired cystic disease-associated RCC‘ and ‘clear-cell pRCC‘. To date, these entities have not generally been accepted. The malignant potential of RCCs in ESKD is still a matter of discussion compared to sporadic RCCs. Patients with ESKD should undergo an annual ultrasound evaluation of the kidneys (16-19).

5.10 Metanephric tumours

Metanephric tumours are divided into metanephric adenoma, adenofibroma, and metanephric stromal tumour. These are very rare benign tumours and surgical excision is sufficient (1).

5.11 Renal epithelial and stromal tumours

Renal epithelial and stromal tumours (REST) is a new concept that brings together two benign mixed mesenchymal and epithelial tumours: cystic nephroma and mixed epithelial and stromal tumours (22). Imaging reveals that most REST cystic lesions are Bosniak type III and less frequently Bosniak type II or IV (8,10). Even though aggressive behaviour has been reported in very few cases, both neoplasms are generally considered to be benign and surgical excision as curative (22).

5.12 Oncocytoma

Renal oncocytomas are benign tumours (1) that comprise about 3-7% of all renal tumours (23). Imaging characteristics alone are unreliable when differentiating between oncocytoma and RCC. Histopathological diagnosis remains the reference standard (24). Although only a percutaneous biopsy can lead to a pre-

operative diagnosis, it has a low specificity for oncocytoma because oncocytotic cells are also found in cRCC, the granular-cell variant of RCC, and in the eosinophilic variant of pRCC (type 2) (25). 'Watchful waiting' can be considered in selected cases of histologically verified oncocytoma (LE: 3) (GR: C) (25,26).

5.13 Hereditary kidney tumours

Hereditary kidney tumours can be found as part of the following entities: Von Hippel-Lindau syndrome, hereditary pRCC, Birt-Hogg-Dubé syndrome, hereditary leiomyomatosis, tuberous sclerosis, and constitutional chromosome 3 translocation (1,27).

5.14 Mesenchymal tumours

Mesenchymal tumours include different types of sarcomas and are relatively rare, except for angiomyolipoma.

*5.14.1 **Angiomyolipoma***

Angiomyolipoma (AML) is a benign mesenchymal tumour composed of a variable proportion of adipose tissue, spindle and epitheloid smooth muscle cells, and abnormal thick-walled blood vessels. It can occur sporadically, which is four times more likely in women. It also occurs in tuberous sclerosis, when it is multiple, bilateral, larger, and likely to cause spontaneous haemorrhage. It accounts for approximately 1% of surgically removed tumours. Ultrasound, CT, and MRI often lead to diagnosis due to the presence of adipose tissue. Biopsy is rarely useful. Pre-operatively, it may be difficult to differentiate between tumours composed predominantly of smooth muscle cells and epithelial tumours. Epithelioid AML is a potentially malignant variant of AML (1).

The main complications of renal AML are retroperitoneal bleeding or bleeding into the urinary collection system, which can be life-threatening (28). The bleeding tendency is related to the angiogenic component of the tumour that includes irregular and aneurysmatic blood vessels (28). The major risk factors for bleeding are tumour size, the grade of angiogenic component of the tumour, and the presence of tuberous sclerosis (28,29).

Primary indications for intervention include symptoms such as pain, bleeding, or suspected malignancy. Prophylactic intervention is justifiable for:

- large tumours (the recommended threshold of intervention is ≥ 4 cm wide (28,30);
- females of childbearing age;
- patients in whom follow-up or access to emergency care may be inadequate (29) (LE: 3) (GR: C).

Most cases of AML can be managed by conservative nephron-sparing approaches, though some cases of AML may require complete nephrectomy (29) (LE: 3). Of the standard surgical interventions, selective arterial embolisation (SAE) and radiofrequency ablation (RFA) can be used (28,31). Although SAE is effective at controlling haemorrhage in the acute setting, it has limited value in the longer-term management of AML (31).

5.15 New histological entities

New histological entities have recently been described, for which there currently is very little clinical data. The entities include:

- thyroid-like follicular tumour/carcinoma of the kidney (32);
- RCC associated with neuroblastoma (1);
- renal angiomyoadenomatous tumour (33);
- tubulocystic carcinoma (34);
- clear cell pRCC (2);
- oncocytic pRCC (2);
- follicular renal carcinoma (2);
- leiomyomatous RCC (2).

Table 8: Summary of other renal tumours with indication of malignant potential and recommendation for treatment (GR: C)

Entity	Malignant potential	Treatment
Sarcomatoid variants of RCC	High	Surgery
Multilocular clear cell RCC	Low, no metastasis	Surgery, NSS*
Papillary adenoma	Benign	Observation
Carcinoma of the collecting ducts of Bellini	High, very aggressive	Surgery, in M+ discussable

Renal medullary carcinoma	High, very aggressive	Surgery
Translocation carcinoma	Intermediate	Surgery, NSS
Mucinous tubular and spindle cell carcinoma	Intermediate	Surgery, NSS
Carcinoma associated with end-stage renal disease	Variable	Surgery
Metanephric tumours	Benign	Surgery, NSS
Renal epithelial and stromal tumours (REST)	Low	Surgery, NSS
Oncocytoma	Benign	Observation/surgery
Hereditary kidney tumours	High	Surgery, NSS
Angiomyolipoma	Benign	Consider treatment when > 4 cm
Unclassified RCC	Variable	Surgery, NSS

**NSS = nephron-sparing surgery*

5.16 Summary

A variety of renal tumours exists, of which about 15% are benign. All kidney lesions have to be examined (e.g. imaging, biopsy, etc.) and judged regarding the likelihood of malignant behaviour.

5.17 Recommendations

	LE	GR
Except for angiomyolipomas, most of these less common renal tumours cannot be differentiated from RCC on the basis of radiology and should therefore be treated in the same way as RCC.	3	C
Bosniak cysts ≥ type III should be surgically treated. When possible, a nephron-sparing procedure should be performed in Bosniak type III.	3	C
In oncocytomas verified on biopsy, follow-up is an option.	3	C
In angiomyolipomas, treatment (surgery, thermal ablation, and selective arterial embolisation) can be considered when the tumour > 4cm. When possible, a nephron-sparing procedure should be performed.	3	C
In advanced uncommon types of renal tumours, a standardised oncological treatment approach does not exist.	4	C

6. TREATMENT OF LOCALISED RCC

6.1 Nephron-sparing surgery (partial tumour resection)

Nephron-sparing surgery (partial tumour resection) for localised RCC has a similar oncological outcome to that of radical surgery (1-5). However, in some patients with localised RCC, nephron-sparing surgery is not suitable because of:

- locally advanced tumour growth;
- partial resection is not technically feasible because the tumour is in an unfavourable location;
- significant deterioration of a patient's general health.

In these situations, the gold standard curative therapy remains radical nephrectomy, which includes removal of the tumour-bearing kidney. Complete resection of the primary tumour by either open (6,7) or laparoscopic surgery (8-13) offers a reasonable chance of curing the disease.

*6.1.1 **Associated procedures***

6.1.1.1 Adrenalectomy

Adrenalectomy is not indicated in the following situations (14-22):

- Pre-operative tumour staging (CT, MRI) shows a normal adrenal gland;
- Intra-operative findings do not give any indication of a nodule within the adrenal gland suspicious of metastatic disease;
- There is no evidence of direct invasion of the adrenal gland by a large upper pole tumour.

6.1.1.2 Lymph node dissection

An extended or radical lymph node dissection does not appear to improve long-term survival following tumour nephrectomy (23). Thus, for staging purposes, the lymph node dissection can be limited to the hilar region. In patients with palpable or CT-detected enlarged lymph nodes, resection of the affected lymph nodes should be performed to obtain adequate staging information.

6.1.1.3 Embolisation

There is no benefit in performing tumour embolisation before routine nephrectomy (24-26). In patients who are unfit for surgery, or who present with non-resectable disease, embolisation can control symptoms such as gross haematuria or flank pain (27-31). Embolisation prior to the resection of hypervascular bone or spinal metastases can reduce intra-operative blood loss (32-34). In selected patients with painful bone or paravertebral metastases, embolisation can help to relieve symptoms (35).

6.1.1.4 Conclusions

- Patients with low-stage RCC (T1) should undergo nephron-sparing surgery. Radical nephrectomy is no longer the gold standard treatment in these cases (1-5) (LE: 2b).
- Adrenalectomy is not recommended, provided a pre-operative CT scan shows the adrenal gland is normal and the intra-operative findings do not suggest intra-adrenal metastatic spread or a direct invasion of the adrenal gland by a larger upper pole tumour (14-22) (LE: 3).
- Extended lymphadenectomy does not improve survival in RCC patients and should be restricted to staging purposes with dissection of palpable and enlarged lymph nodes (23) (LE: 1b).
- RCCs with tumour thrombi have a higher stage and grade of disease (LE: 2b). Distant and lymph node metastases are twice as common in these patients (LE: 3). The increase in biological aggressiveness of the disease has a larger influence on clinical prognosis than the cranial extension of an intracaval thrombosis (36-40) (LE: 3).

6.1.1.5 Recommendations

	GR
Surgical therapy is the only curative therapeutic approach for the treatment of RCC. For T1 tumours, nephron-sparing surgery should be performed whenever possible. Extended lymphadenectomy does not improve survival and can be restricted to staging purposes.	A
Adrenalectomy (together with nephrectomy) is not needed in most patients, except when there is a large upper pole tumour and direct invasion of the adrenal gland is likely or when a normal adrenal gland cannot be excluded.	B
Embolisation can be a beneficial palliative approach in patients unfit for surgery and suffering from massive haematuria or flank pain.	C

6.1.2 ***Indications for nephron-sparing surgery***

Standard indications for nephron-sparing surgery are divided into the following categories:

- absolute – anatomical or functional solitary kidney;
- relative – functioning opposite kidney is affected by a condition that might impair renal function in the future;
- elective – localised unilateral RCC with a healthy contralateral kidney.

Relative indications include hereditary forms of RCC, which carry a high risk of developing a tumour in the contralateral kidney.

For elective indications, nephron-sparing surgery for tumours limited in diameter (T1a) provides recurrence-free and long-term survival rates similar to those observed after radical surgery (1-5,41,42) (LE: 2b). For larger tumours (T1b), partial nephrectomy has demonstrated feasibility and oncological safety in carefully selected patients (43-47).

6.1.3 ***Complications***

- The complication rates observed with nephron-sparing surgery are slightly higher but still very tolerable when compared with radical nephrectomy (48) (LE: 1b).
- Nephron-sparing surgery carried out for absolute rather than elective indications carries an increased complication rate and a higher risk of developing locally recurrent disease, probably due to the larger tumour size (49-51) (LE: 3).

6.1.4 ***Prognosis***

- In patients with a sporadic solitary renal tumour of up to 4-5 cm maximum diameter and a normal contralateral kidney, long-term renal function is better preserved with a nephron-sparing approach than with nephrectomy (52).
- There is a strong indication that, due to better preservation of renal function, nephron-sparing surgery

results in an improved overall survival when compared with radical nephrectomy (53-55) (LE: 3).
- If the tumour is completely resected, the thickness of the surgical margin does not impact on the likelihood of local recurrence (56-58) (LE: 3).

*6.1.5 **Conclusions***

- Nephron-sparing surgery has a slightly higher complication rate compared with radical surgery.
- However, nephron-sparing surgery is a safe procedure from the oncological point of view. Whenever technically feasible, nephron-sparing surgery is therefore considered to be the standard of care for T1a/b stage RCC (1-5,41-47).
- In the long term, a nephron-sparing approach results in improved preservation of renal function, decreased overall mortality, and reduced frequency of cardiovascular events (53-55).

*6.1.6 **Recommendations***

	GR
Whenever technically feasible, nephron-sparing surgery is the standard procedure for solitary renal tumours up to a diameter of 7 cm.	A
A minimal tumour-free surgical margin following partial resection of RCC is sufficient to avoid local recurrence.	B
There is an increased risk of intrarenal recurrences in larger-size (> 7 cm) tumours treated with nephron-sparing surgery, or when there is a positive margin. Follow-up should be intensified in these patients.	C

6.2 Laparoscopic surgery

Since its introduction, laparoscopic nephrectomy for RCC has become an established surgical procedure worldwide. Whether done retro-peritoneally or trans-peritoneally, the laparoscopic approach must follow established open surgical oncological principles.

*6.2.1 **Laparoscopic radical nephrectomy***

Laparoscopic radical nephrectomy is the standard of care for patients with T2 tumours and smaller renal masses not treatable by nephron-sparing surgery (59-63). Long-term outcome data indicate that laparoscopic radical nephrectomy has equivalent cancer-free survival rates to those of open radical nephrectomy (10,12,13,61,62,64-68).

6.2.1.1 Conclusions

- Laparoscopic radical nephrectomy appears to have a lower morbidity compared to open surgery, though this is based on only a few studies using a standardised quality-of-life evaluation (69) (LE: 3).
- Tumour control rates appear equivalent for T1-T2 tumours (10,12,13,61,62,64-68) (LE: 3).

6.2.1.2 Recommendations

	GR
Laparoscopic radical nephrectomy is recommended in T2 renal cell cancer.	B
Laparoscopic radical nephrectomy should not be performed in patients with T1 tumours for whom partial resection is indicated.	B

*6.2.2 **Partial laparoscopic nephrectomy***

In experienced hands and selected patients, laparoscopic partial nephrectomy is an alternative to open nephron-sparing surgery. The optimal indication for laparoscopic nephron-sparing surgery is a relatively small and peripheral renal tumour (4).

During laparoscopic partial resection, the intra-operative ischaemia time is longer than with open partial nephrectomy (4,70,71). Long-term renal function depends on the duration of the intra-operative ischaemia time (72).

Laparoscopic nephron-sparing surgery has a higher complication rate compared to open surgery. However, the oncological outcome in available series with limited follow-up appears to be similar to the outcome achieved with open nephron-sparing surgery (4,73,74).

In patients with a solitary kidney, laparoscopic partial nephrectomy results in a prolonged warm ischaemia time and a higher complication rate. Temporary or permanent dialysis is more likely to be necessary (4,72,75).

6.2.2.1 *Robotic-assisted partial nephrectomy*

Robotic-assisted partial nephrectomy is a novel technique that is still undergoing evaluation (76-80).

6.2.2.2 *Conclusion*

Partial nephrectomy by laparoscopic surgery is technically feasible (LE: 2b).

6.2.3 ***Recommendations***

	GR
Open partial nephrectomy currently remains the standard of care.	C
Laparoscopic partial nephrectomy should be performed by experienced surgeons.	C
Open partial resection is recommended for renal masses in a solitary kidney.	C

6.3 Therapeutic approaches as alternative to surgery

6.3.1 ***Surveillance***

In patients presenting with small renal masses, who undergo active surveillance, there appears to be no correlation between local tumour progression and an increased risk of metastatic disease. Both short- and intermediate-term oncological outcomes indicate that it is an appropriate strategy to initially monitor small renal masses followed, if required, by treatment for progression (73,81,82).

6.3.2 ***Percutaneous approaches***

Suggested alternatives to the surgical treatment of RCC have included image-guided percutaneous and minimally invasive techniques, e.g. percutaneous RFA, cryoablation, microwave ablation, laser ablation, and high-intensity focused ultrasound ablation (HIFU) (LE: 2b).

Possible advantages of these and other techniques include reduced morbidity, out-patient therapy, and the ability to treat high-risk surgical candidates (LE: 2b).

Indications for minimally invasive techniques, including RFA, are:

- small, incidentally found, renal cortical lesions in elderly patients;
- patients with a genetic predisposition for developing multiple tumours;
- patients with bilateral tumours;
- patients with a solitary kidney at high risk of complete loss of renal function following surgical tumour resection (LE: 2b).

Contraindications to the above-mentioned procedures include:

- poor life expectancy of < 1 year;
- multiple metastases;
- low possibility of successful treatment due to size or location of tumour. In general, tumours > 3 cm or tumours in the hilum, near the proximal ureter or the central collecting system are not typically recommended for ablative techniques via a percutaneous approach.

Absolute contraindications include:

- irreversible coagulopathies;
- severe medical instability, such as sepsis.

6.3.2.1 *Radiofrequency ablation and cryoablation*

Of all the available ablative techniques, RFA and cryoablation are the most intensively investigated approaches in terms of how practical they are to use, complication rate, and oncological safety.

Before an ablative approach, a pre-treatment biopsy to clarify the histology of the renal mass should be carried out. The available literature indicates that the pathology is unknown in a significantly higher proportion of patients undergoing RFA (40%) versus 25% in patients undergoing cryotherapy.

Compared to RFA, cryoablation is more likely to be performed laparoscopically. The laparoscopic approach is more effective but has a higher complication rate. Repeat ablation is necessary more frequently following RFA. Local tumour progression is significantly higher with RFA. Cancer-specific survival rates for cryotherapy and RFA are poorer than survival rates for surgical procedures (83-86).

6.3.2.2 *Conclusions*

- Radiofrequency and cryoablation are the only minimally invasive approaches for the treatment of small renal tumours with medium follow-up data.

- Although the oncological efficacy is not yet known, currently available data strongly suggest that cryoablation, when performed laparoscopically, results in fewer re-treatments and improved local tumour control compared with RFA (LE: 3).
- For both RFA and cryoablation, recurrence rates are higher than with nephron-sparing surgery (83-86) (LE: 3).

6.3.2.3 Recommendations

	GR
Patients with small tumours and/or significant co-morbidity who are unfit for surgery should be considered for an ablative approach, e.g. cryotherapy and radiofrequency ablation.	A
Pre-treatment biopsy has to be carried out as standard.	C
Other image-guided percutaneous and minimally invasive techniques, such as microwave ablation, laser ablation, and high-intensity focused ultrasound ablation are still experimental in character. The experience obtained with radiofrequency ablation and cryoablation should be considered when using these related techniques.	B

6.4 Adjuvant therapy

Current evidence that adjuvant tumour vaccination might improve the duration of the progression-free survival of selected subgroups of patients undergoing nephrectomy for T3 renal carcinomas needs further confirmation regarding the impact on overall survival (87-91) (LE: 1b). Prognostic algorithms might identify patients likely to derive the largest clinical benefit from adjuvant vaccination therapy.

*6.4.1 **Conclusion***

Adjuvant therapy with cytokines does not improve survival after nephrectomy (LE: 1b).

*6.4.2 **Recommendation***

	GR
Outside controlled clinical trials, there is no indication for adjuvant therapy following surgery.	A

6.5 Surgical treatment of metastatic RCC (tumour nephrectomy)

Tumour nephrectomy is curative only if surgery can excise all tumour deposits. For the majority of patients with metastatic disease, tumour nephrectomy is palliative and other systemic treatments are necessary. In a meta-analysis of two randomised studies, comparing nephrectomy combined with immunotherapy versus immunotherapy only, an increased long-term survival was found in patients subjected to tumour nephrectomy (92). Nephrectomy in patients with metastatic disease is indicated for patients who are both suitable for surgery and have good performance status (93). At present, only limited data are available addressing the value of cytoreductive nephrectomy combined with targeting agents.

*6.5.1 **Conclusion***

Tumour nephrectomy in combination with interferon-alpha (IFN-alpha) improves the survival of patients with metastatic RCC (mRCC) and good performance status (LE: 1b).

*6.5.2 **Recommendation***

	GR
Tumour nephrectomy is recommended for metastatic RCC patients with good performance status when combined with IFN-alpha.	A

6.6 Resection of metastases

Complete removal of metastatic lesions contributes to an improvement of clinical prognosis. Immunotherapy, where there has been complete resection of metastatic lesions or isolated local recurrences, does not contribute to an improvement in clinical prognosis (93-97) (LE: 2b).

*6.6.1 **Conclusion***

There is a definite role for metastasectomy in patients with RCC in order to improve the clinical prognosis

(LE: 3). Therefore; the possibility of metastasectomy has to be continuously re-evaluated, even together with a targeted systemic therapy.

6.6.2 ***Recommendation***

	GR
In patients with synchronous metastatic spread, metastasectomy should be performed where disease is resectable and the patient has a good performance status. The clinical prognosis is worse in patients who have surgery for metachranous metastases.	B
Metastasectomy should be performed in patients with residual and resectable metastatic lesions previously responding to immunotherapy and/or a limited (solitary lesion) number of metachranous metastases in order to improve the patient's prognosis.	B

6.7 Radiotherapy for metastases in RCC

Radiotherapy can be used for selected symptomatic patients with non-resectable brain or osseous lesions who do not respond to systemic treatment approaches (98,99).

6.7.1 ***Conclusion***

Radiotherapy of metastases from RCC can induce a significant relief from symptoms with pain reduction, e.g. a single bony deposit (LE: 2b).

6.7.2 ***Recommendation***

	GR
In individual cases, radiotherapy for the treatment of brain metastases (whole brain irradiation or stereotactic approach) and osseous lesions can induce a relief from symptoms due to mRCC (100,101).	B

7. SYSTEMIC THERAPY FOR METASTATIC RCC

7.1 Chemotherapy

Since RCCs develop from the proximal tubules, they have high levels of expression of the multiple-drug resistance protein, P-glycoprotein, and are therefore resistant to most chemotherapies. Chemotherapy seems to be moderately effective only if 5-fluorouracil (5FU) is combined with immunotherapeutic agents (1).

*7.1.1 **Conclusion***

Only 5FU in combination with immunotherapy seems to be effective in patients with mRCC (LE: 3).

Recommendation

	GR
Chemotherapy as monotherapy should not be considered effective in patients with mRCC.	B

7.2 Immunotherapy

*7.2.1 **Interferon-alpha monotherapy and combined with bevacizumab***

In randomised studies, IFN-alpha has proven superiority for survival over hormonal therapy in patients with mRCC (2). Interferon-alpha provided a response rate of 6-15%, together with a 25% decrease in the risk for tumour progression and a modest survival benefit of 3-5 months compared with a placebo-equivalent (3,4). The positive effect of IFN-alpha is particularly important in mRCC patients with clear-cell histology, good-risk Motzer criteria and lung metastases only (4). In a prospective randomised study, IFN-alpha showed equivalence in efficacy to the combination IFN-alpha + IL2 + 5FU (5).

A combination of bevacizumab + IFN-alpha recently demonstrated increased response rates and progression-free survival in first-line therapy compared to IFN-alpha monotherapy (6). All recent randomised studies comparing anti-angiogenic drugs in a first-line setting to IFN-alpha monotherapy have demonstrated a superiority for either sunitinib, bevacizumab + IFN-alpha or temsirolimus (6-9).

Table 9: MSKCC (Motzer) criteria to predict survival of patients with advanced RCC; depending on the presence or absence of 5 distinct risk factors (3)

Risk factors[1]	Cut Point Used
Karnofsky performance status	< 80
Time from diagnosis to treatment with IFN-alpha	< 12 months
Hemoglobin	< Lower limit of laboratory's reference range
Lactate dehydrogenase	> 1.5 x the upper limit of laboratory's range
Corrected serum calcium	> 10.0 mg/dL (2.4 mmol/L)

[1]Favourable (low) risk, 0 risk factor; intermediate, 1-2 risk factors; poor (high) risk ≥ 3 risk factors.

7.2.1.1 Conclusions

- Interferon-alpha monotherapy is no longer recommended as first-line therapy for mRCC (LE: 1b).
- Interferon-alpha monotherapy still has a role only in selected cases (good performance status, clear-cell type, lung metastases only) (LE: 2).

*7.2.2 **Interleukin-2***

Interleukin-2 (IL-2) has been used to treat mRCC since 1985 with response rates ranging from 7-27% (9-11).

The optimal IL-2 regimen is not clear, but long-term (> 10 years) complete responders have been achieved with high-dose bolus IL-2 (12). The toxicity of IL-2 is substantially higher than that of IFN-alpha. Only clear cell type RCC responds to immunotherapy. Interleukin-2 has not been validated in controlled randomised studies compared with best supportive care (4).

7.2.2.1 Conclusions

- Interleukin-2 has more side-effects than INF-alpha.
- High-dose IL-2 gives durable complete responders in a limited number of patients.
- Interleukin-2 can be considered as monotherapy in selected patients with a good prognosis profile.

7.2.2.2 Recommendations

	GR
Monotherapy with IFN-alpha or high-dose bolus IL-2 can only be recommended as a first-line treatment for mRCC in selected cases with clear-cell histology and good prognostic factors.	A
Bevacizumab + IFN-alpha is recommended as first-line therapy in low- and intermediate-risk patients. Only selected patients with mRCC, revealing a good risk profile, and clear-cell subtype histology, show clinical benefit from immunotherapy with IL-2.	B
Cytokine combinations, with or without additional chemotherapy, do not improve overall survival compared with monotherapy.	A

7.3 Angiogenesis inhibitor drugs

Recent advances in molecular biology have led to the development of several novel agents for the treatment of mRCC (Table 9).

In sporadic clear cell RCC, HIF accumulation due to von Hippel Landau (VHL) inactivation, results in overexpression of VEGF and PDGF (platelet-derived growth factor), both of which promote neo-angiogenesis (13-15). This process substantially contributes to the development and progression of RCC. At present, several targeting drugs have been approved both in the USA and in Europe for the treatment of mRCC:

- sorafenib (Nexavar®);
- sunitinib (Sutent®);
- bevacizumab (Avastin®) combined with IFN-alpha;
- pazopanib (Votrient®);
- temsirolimus (Torisel®);
- everolimus (Afinitor®).

Several other new agents targeting angiogenesis are under investigation, as well as combinations of these new agents with each other or with cytokines.

*7.3.1 **Sorafenib***

Sorafenib is an oral multikinase inhibitor with activity against Raf-1 serine/threonine kinase, B-Raf, vascular

endothelial growth factor receptor-2 (VEGFR-2), platelet-derived growth factor receptor (PDGFR), FMS-like tyrosine kinase 3 (FLT-3) and c-KIT. A phase III trial compared sorafenib and placebo after failure of a prior systemic immunotherapy or in patients unfit for immunotherapy. The trial reported a 3-month improvement in progression-free survival in favour of sorafenib (16). Survival seems to improve in patients crossed over from placebo to sorafenib treatment (17).

7.3.2 ***Sunitinib***

Sunitinib is an oxindol tyrosine kinase (TK) inhibitor. It selectively inhibits PDGFR, VEGFR, c-KIT and FLT-3 and has anti-tumour and anti-angiogenic activity. Phase II trials with sunitinib as second-line monotherapy in patients with mRCC demonstrated a partial response rate in 34-40% of patients and stable disease > 3 months in 27-29% of patients (18).

In a recent phase III trial of first-line monotherapy comparing treatment with sunitinib versus IFN-alpha, sunitinib achieved a longer progression-free survival than IFN-alpha (11 versus 5 months, $p < 0.000001$). Results suggested monotherapy with IFN-alpha was inferior compared to sunitinib in low- and intermediate-risk patients with mRCC (19). Overall survival was 26.4 and 21.8 months in the sunitinib and IFN-alpha arms, respectively ($p = 0.05$) (19). In patients crossed over from IFN-alpha to sunitinib ($n = 25$), median survival times were 26.4 versus 20.0 months for sunitinib and IFN-alpha, respectively ($p = 0.03$). In patients who did not receive any post-study treatment, the median overall survival reached 28.1 months in the sunitinib group versus 14.1 months in the IFN-alpha group ($p = 0.003$).

7.3.3 ***Bevacizumab monotherapy and combined with interferon-alpha***

Bevacizumab is a humanised monoclonal antibody that binds isoforms of VEGF-A. Bevacizumab, 10 mg/kg every 2 weeks, in patients refractory to immunotherapy showed an increase in overall response (10%) and in progression-free survival versus placebo (20). A recent double-blind phase III trial ($n = 649$) in mRCC compared bevacizumab + IFN-alpha to IFN-alpha monotherapy (6). The median overall response was 31% in the bevacizumab + IFN-alpha group versus 13% in the IFN-alpha-only group ($p < 0.0001$). Median progression-free survival increased significantly from 5.4 months with IFN-alpha to 10.2 months for bevacizumab + IFN-alpha ($p < 0.0001$), but only in low-risk and intermediate-risk patients. No benefit was seen in high-risk patients. No mature data are yet available on overall survival.

7.3.4 ***Pazopanib***

Pazopanib is an oral angiogenesis inhibitor targeting VEGFR, PDGFR, and c-KIT. In a prospective randomised trial of pazopanib versus placebo in treatment-naïve mRCC patients and cytokine-treated patients, there was a significant improvement in progression-free survival and tumour response (9.2 vs 4.2 months) (20).

7.3.5 ***Mammalian target of rapamycin (mTOR) inhibitors***

7.3.5.1 Temsirolimus

Temsirolimus is a specific inhibitor of mammalian target of rapamycin (mTOR) (21). Patients with high-risk mRCC were randomised to receive first-line treatment with temsirolimus or IFN-alpha monotherapy or in combination. In the temsirolimus group, overall survival was 10.9 months versus 7.3 months in the IFN-alpha group ($p < 0.0069$). However, overall survival in the temsirolimus + IFN-alpha group was not significantly improved (8).

7.3.5.2 Everolimus

Everolimus is an oral mTOR inhibitor. A recent phase III study compared everolimus plus best supportive care (BSC) versus placebo plus BSC in patients who had failed previous anti-VEGFR treatment. Median progression-free survival was 4 months with everolimus versus 1.9 months with placebo ($p < 0.001$) (13,22).

Table 10: 2010 EAU evidence-based recommendations for first- and second-line systemic therapy in mRCC

Treatment	Risk or prior treatment	Recommended agent
1st-line therapy	Low- or intermediate-risk	Sunitinib
		Bevacizumab + IFN-alpha
		Pazopanib
	High risk	Temsirolimus
2nd-line therapy	Prior cytokine	Sorafenib
		Pazopanib
	Prior VEGFR	Everolimus
	Prior mTOR(-)	Clinical trials

7.3.6 Conclusions

	LE
Tyrosine kinase inhibitors (TKIs) increase progression-free survival and or overall survival as both first- and second-line treatment of mRCC.	1b
Sorafenib has proven efficacy as second-line treatment after failure of cytokine therapy or in patients unfit for cytokines.	1b
Sunitinib is more effective than IFN-alpha in treatment-naïve, low- and intermediate-risk tumours.	1b
The association between bevacizumab and IFN-alpha is more effective than IFN-alpha in treatment-naïve, low- and intermediate-risk tumours.	1b
Pazopanib is superior to placebo in both naïve mRCC patients as post-cytokine patients.	1b
Temsirolimus monotherapy in poor-risk mRCC patients is more effective than IFN-alpha or temsirolimus + IFN-alpha.	1b
Everolimus prolongs progression-free survival in patients who have failed treatment with TKIs.	
The role of the new drugs is still under development and combination studies are ongoing. To date, no data are available indicating the new agents have a curative effect. These agents appear to promise to stabilise mRCC for a prolonged period of time. However, their promise has to be balanced against their toxicity profile and the patient's quality of life.	4

7.3.7 Recommendations for systemic therapy for mRCC

Recommendations	GR
Sunitinib is recommended as first-line therapy in low- and intermediate-risk patients.	A
Bevacizumab + IFN-alpha is recommended as first-line therapy in low- and intermediate-risk patients.	A
Sorafenib is recommended as a second-line treatment for mRCC after cytokine failure.	A
Pazopanib is recommended as first-line and after cytokine failure.	A
Temsirolimus is recommended as first-line treatment in high-risk patients.	A
Everolimus is recommended as second-line treatment after failure of tyrosine kinase inhibitors.	A

8. SURVEILLANCE FOLLOWING RADICAL OR PARTIAL NEPHRECTOMY OR ABLATIVE THERAPIES FOR RCC

8.1 Introduction

Surveillance after treatment for RCC allows the urologist to monitor or identify:

- post-operative complications;
- renal function;
- local recurrence after partial nephrectomy or ablative treatment;
- recurrence in the contralateral kidney;
- development of metastases.

The method and timing of investigation has been the subject of many publications. There is no consensus on surveillance after treatment for RCC and in fact no evidence that early versus later diagnosis of recurrence improves survival. However, follow-up is important to increase our knowledge of RCC and should be performed by the urologist, who should record the time elapsed to recurrence or development of metastasis.

Post-operative complications and renal function are readily assessed by history, physical examination and measurement of serum creatinine and estimated glomerular filtration rate (eGFR). Repeated long-term monitoring of eGFR is indicated if there is impaired renal function before surgery or a post-operative deterioration. Renal function (1,2) and non-cancer survival (3-5) can be optimised by performing nephron-sparing surgery whenever possible for T1 and T2 tumours (6) (LE: 3). Tumour-bed recurrence is rare (2.9%), but early diagnosis is useful because the most effective treatment is cytoreductive surgery (7,8). Recurrence in the contralateral kidney is also rare (1.2%) and is related to positive margins, multifocality and grade (9) (LE: 3).

The reason for surveillance is to identify local recurrence or metastases early. This is particularly important with ablative therapies, such as cryotherapy and RFA. Even though the local recurrence rate is higher than conventional surgery, the patient may still be cured by repeat ablative therapy or radical nephrectomy (10) (LE: 3). In metastatic disease, more extended tumour growth can reduce the possibility of surgical resection, which is considered the standard therapy in cases of resectable and preferably solitary lesions. In addition, within clinical trials, an early diagnosis of tumour recurrence may enhance the efficacy of a systemic treatment if the tumour burden is low.

8.2 Which investigations for which patients, and when?

Intensive radiological surveillance for all patients is unnecessary. For example, the outcome after surgery for T1a, low-grade, tumours is almost always excellent. It is therefore reasonable to stratify follow-up, taking into account the risk of a recurrence or metastases developing. Although no randomised evidence exists, there are large studies examining prognostic factors with long follow-up from which some conclusions can be drawn (11-13) (LE: 4).

- When the likelihood of relapse is low, chest x-ray and ultrasound may be appropriate. However, the sensitivity of chest x-ray for small metastases is poor and ultrasound has limitations.
- When the risk of relapse is intermediate or high, CT of the chest and abdomen is the investigation of choice, though the significant morbidity of radiation dose with repeated CT scans should be taken into account (14).

Depending on the availability of new effective treatments, more strict follow-up schedules may be required, particularly as there is a higher local recurrence rate after cryotherapy and RFA. There is controversy over the optimal duration of follow-up. Some argue that follow-up by imaging is not cost-effective after 5 years; however, late metastases are more likely to be solitary and justify more aggressive therapy with curative intent. In addition, patients with tumours that develop in the contralateral kidney can be treated with nephron-sparing surgery if detected when small. Furthermore, for tumours < 4 cm, there is no difference between partial or radical nephrectomy in recurrence during follow-up (15) (LE: 3).

Several authors, notably Kattan, Liebovich, UCLA, and Karakiewicz (16-19), have designed scoring systems and nomograms to quantify the likelihood of patients developing tumour recurrence, metastases, and subsequent death. These systems have been compared and validated (20) (LE: 2). Using prognostic variables, several stage-based surveillance regimes have been proposed (21,22), but these do not include ablative therapies. A post-operative nomogram is available to give the likelihood of freedom from recurrence at 5 years (23). Most recently, a pre-operative prognostic model based on age, symptoms, and TNM staging has been published and validated (24) (LE: 3). There is therefore a need for a surveillance algorithm to monitor patients

after treatment for RCC, recognising not only the patient risk profile, but also the efficacy of the treatment given (Table 11).

Table 11: Proposed algorithm for surveillance following treatment for RCC taking into account patient risk profile and treatment efficacy

Risk profile	Treatment	Surveillance						
		6 months	1 year	2 years	3 years	4 years	5 year	After 5 years
Low	RN/PN only	CXR and US	CXR and US	CXR and US	CXR and US	CXR and US	CXR and US	Discharge
Intermediate	RN/PN/cryo/ RFA	CT	CXR and US	CT	CXR and US	CXR and US	CT	Yearly CXR and US
High	RN/PN/cryo/ RFA	CT	CT	CT	CT	CT	CT	CXR/CT alternate years

RN = radical nephrectomy; PN = partial nephrectomy; CXR = chest x-ray; US = ultrasound of kidneys and renal bed; CT = computed tomography of chest and abdomen; cyro = cryotherapy; RFA = radiofrequency ablation.

8.3 Conclusions

Surveillance after treatment for RCC should be based on a patient's risk factors and the type of treatment delivered. The aim of surveillance is to detect either local recurrence or metastatic disease while the patient is still surgically curable.

- For low-risk disease, the use of CT can be infrequent (LE: 4).
- In the intermediate-risk group, an intensified follow-up that includes CT scans at regular time intervals should be performed according to a risk-stratified nomogram (LE: 4).
- In high-risk patients, the follow-up examinations should include routine CT scans (LE: 4).

8.4 Recommendation

	GR
The intensity of the follow-up programme for an individual patient should be adapted according to the risk of tumour recurrence and the type of treatment.	C

9. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

ACKD	acquired cystic kidney disease
AML	Angiomyolipoma
5FU	5-fluorouracil
BSC	best supportive care
CaIX	carbonic anhydrase IX
cRCC	clear cell renal carcinoma
chRCC	chromophobe renal cell carcinoma
CT	computed tomography
eGFR	estimated glomerular filtration rate
ESKD	end-stage kidney disease
FLT-3	FMS-like tyrosine kinase 3
GR	grade of recommendation
HIF	hypoxia inducible factor
HIFU	high-intensity focused ultrasound
HU	Hounsfield unit
IFN-alpha	interferon-alpha
IL-2	interleukin-2
LDH	lactate dehydrogenase
LE	level of evidence
MESTK	mixed epithelial and stromal tumour of the kidney
mRCC	metastatic renal cell carcinoma
MRI	magnetic resonance imaging
mTOR	mammalian target of rapamycin
NSS	nephron-sparing surgery
PA	predictive accuracy
pRCC	papillary renal cell carcinoma
RCC	renal cell carcinoma
PDGF	platelet-derived growth factor
PDGFR	platelet-derived growth factor receptor
PET	positron emission tomography
PTEN	phosphatase and tensin homolog
REST	Renal epithelial and stromal tumours
RFA	radiofrequency ablation
SAE	selective arterial embolisation
TFE3	transcription factor E3
TK	tyrosine kinase
TKI	Tyrosine kinase inhibitors
TNM	Tumour Node Metastasis
US	abdominal ultrasound
VEGF	vascular endothelial growth factor
VEGFR	vascular endothelial growth factor receptor
VHL	von Hippel-Lindau
WHO	World Health Organization

Conflict of interest

All members of the Renal Cell Carcinoma Guidelines working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on Testicular Cancer

Association
of Urology

TABLE OF CONTENTS PAGE

1. BACKGROUND

Testicular cancer represents between 1% and 1.5% of male neoplasms and 5% of urological tumours in general, with 3-10 new cases occurring per 100,000 males/per year in Western society (1-3). An increase in the incidence of testicular cancer was detected during the 1970s and 1980s, particularly in Northern European countries, and there is a clear trend towards an increased testicular cancer incidence in the last 30 years in the majority of the industrialised countries in North America, Europe and Oceania, although surprising differences in incidence rates are seen between neighbouring countries (4,5). Data from the Surveillance Epidemiology and End Results Program during the years 1973 to 1998 show a continuing increased risk among Caucasian men in the USA only for seminoma (6).

Only 1-2% of cases are bilateral at diagnosis. The histological type varies, although there is a clear predominance (90-95%) of germ cell tumours (1). Peak incidence is in the third decade of life for nonseminoma, and in the fourth decade for pure seminoma. Familial clustering has been observed, particularly among siblings (7).

Genetic changes have been described in patients with testicular cancer. A specific genetic marker (an isochromosome of the short arm of chromosome 12 – i(12p) – has been described in all histological types of germ cell tumours (7). Intratubular germ cell neoplasia (testicular intraepithelial neoplasia, Tin) shows the same chromosomal changes, and alterations in the p53 locus have been found in 66% of cases of testicular Tin (8).

A deregulation in the pluripotent programme of fetal germ cells (identified by specific markers such as M2A, C-KIT and OCT4/NANOG) is probably responsible for the development of Tin and germ cell neoplasia. There is overlap in the development to seminoma and embryonal carcinoma as shown by genome-wide expression analysis and detection of alpha-fetoprotein (AFP) mRNA in some atypical seminoma (9,10). Continued genome wide screening studies and gene expression analysis data suggest testis cancer specific gene mutations on chromosomes 4, 5, 6 and 12 (namely expressing SPRY4, kit-Ligand and Synaptopodin) (11-13).

Epidemiological risk factors for the development of testicular tumours are: a history of cryptorchidism or undescended testis (testicular dysgenesis syndrome), Klinefelter's syndrome, familial history of testicular tumours among first-grade relatives (father/brothers), the presence of a contralateral tumour or Tin, and infertility (14-20). Tallness was associated with a risk of germ cell cancer, although further confirmation is needed (21,22).

Testicular tumours show excellent cure rates. The main factors contributing to this are: careful staging at the time of diagnosis; adequate early treatment based on chemotherapeutic combinations, with or without radiotherapy and surgery; and very strict follow-up and salvage therapies. In the past decades, a decrease in the mean time delay to diagnosis and treatment has been observed (23). In the treatment of testicular cancer, the choice of centre where this treatment is going to be administered is of utmost importance. Although early stages can be successfully treated in a non-reference centre, the relapse rate is higher (24). In poor prognosis non-seminomatous germ cell tumours, it has been shown that overall survival within a clinical trial depended on the number of patients treated at the participating centre (worse < 5 patients enrolled) (25). In the same context, the frequency of post-chemotherapy residual tumour resection is associated with perioperative mortality and overall survival (26,27).

1.1 Methodology

A multidisciplinary team of urologists, medical oncologists, radiotherapists and a pathologist were involved in producing this text, which is based on a structured review of the literature from January 2008 until December 2010 for both the germ cell tumour and non-germ cell sections. Also, data from meta-analysis studies, Cochrane evidence, and the recommendations of the European Germ Cell Cancer Collaborative Group Meeting in Amsterdam in November 2006 have been included (28-31). A validation scoping search with a focus on the available level 1 (systematic reviews and meta-analyses of randomised controlled trials [RCTs]) data was carried out in Medline and Embase on the Dialog-Datastar platform, covering a time frame of 2009 through September 2010. The searches used the controlled terminology of the respective databases. Both MesH and EMTREE were analysed for relevant terms.

References used in the text have been assessed according to their level of scientific evidence (LE) (Table 1), and guideline recommendations have been graded (GR) (Table 2) according to the Oxford Centre for Evidence-based Medicine Levels of Evidence (32). The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

* *Modified from Sackett et al. (32).*

It should be noted that when recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of RCTs may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Alternatively, absence of high level evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful for the reader. The quality of the underlying scientific evidence – although a very important factor – has to be balanced against benefits and burdens, values and preferences and cost when a grade is assigned (33-35).

The EAU Guidelines Office do not perform cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever this data is available, the expert panels will include the information.

Table 2: Grade of recommendation*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett et al. (32).*

Publication history

The content of these guidelines has not changed respect to the previous version, but for assessing the currency of the references used; replacing old references by more recent publications. This resulted in the inclusion of 5 new references. No changes in the recommendations were made. The European Association of Urology (EAU) published a first guideline on Testicular Cancer in 2001 with limited updates achieved in 2002, 2004, a major update in 2005, followed by limited updates in 2008, 2009 and 2010. Review papers have been published in the society scientific journal European Urology, the latest version dating to 2011 (36). Since 2008, the edition contains a separate chapter on testicular stromal tumours.

A quick reference document presenting the main findings of the Testicular Cancer guidelines is also available, following the large text updates. All texts can be viewed and downloaded for personal use at the EAU website: http://www.uroweb.org/guidelines/online-guidelines/.

For 2013, a revised version is scheduled which will address the findings of the Third European Consensus Conference on the Diagnosis and treatment of Germ Cell Cancer.

2. PATHOLOGICAL CLASSIFICATION

The recommended pathological classification (modified from the 2004 version of the World Health Organization [WHO] guidance) is shown below (37).

1. Germ cell tumours
- Intratubular germ cell neoplasia, unclassified type (IGCNU)
- Seminoma (including cases with syncytiotrophoblastic cells)
- Spermatocytic seminoma (mention if there is sarcomatous component)
- Embryonal carcinoma
- Yolk sac tumour
- Choriocarcinoma
- Teratoma (mature, immature, with malignant component)
- Tumours with more than one histological type (specify percentage of individual components).

2. Sex cord/gonadal stromal tumours
- Leydig cell tumour
- Malignant Leydig cell tumour
- Sertoli cell tumour
  - lipid-rich variant
  - sclerosing
  - large cell calcifying
- Malignant Sertoli cell tumour
- Granulosa cell tumour
  - adult type
  - juvenile type
- Thecoma/fibroma group of tumours
- Other sex cord/gonadal stromal tumours
  - incompletely differentiated
  - mixed
- Tumours containing germ cell and sex cord/gonadal stromal (gonadoblastoma).

3. Miscellaneous non-specific stromal tumours
- Ovarian epithelial tumours
- Tumours of the collecting ducts and rete testis
- Tumours (benign and malignant) of non-specific stroma.

3. DIAGNOSIS

3.1 Clinical examination

Testicular cancer generally affects young men in the third or fourth decade of life. It normally appears as a painless, unilateral mass in the scrotum or the casual finding of an intrascrotal mass (38). In approximately 20% of cases, the first symptom is scrotal pain, and up to 27% of patients with testicular cancer may have local pain (1).

Occasionally, trauma to the scrotum may reveal the presence of a testicular mass. Gynaecomastia appears in 7% of cases and is more common in non-seminomatous tumours. Back and flank pain are present in about 11% of cases (1).

In about 10% of cases, a testicular tumour can mimic an orchioepididymitis, with consequent delay of the correct diagnosis (1,2). Ultrasound must be performed in any doubtful case. Physical examination reveals the features of the mass and must always be carried out in conjunction with a general examination in order to find possible (supraclavicular) distant metastases, a palpable abdominal mass or gynaecomastia. A correct diagnosis must be established in all patients with an intrascrotal mass (39).

3.2 Imaging of the testis

Currently, diagnostic ultrasound serves to confirm the presence of a testicular mass and to explore the contralateral testis. Its sensitivity in detecting a testicular tumour is almost 100%, and it has an important role in determining whether a mass is intra- or extratesticular (40). Ultrasound is an inexpensive test and should be

performed even in the presence of a testicular tumour that is clinically evident (41).

Ultrasound of the testis has to be performed in young men without a palpable testicular mass who have retroperitoneal or visceral masses or elevated serum chorionic gonadotrophin (hCG) or AFP or in men consulting for fertility problems (42-44).

Ultrasound may be recommended in the follow up of patients at risk (45), when other risk factors than microlithiasis are present (e.g. size < 12 ml or athrophy, inhomogeneous parenchyma). The solely presence of microlithiasis is not an indication for a regular scrotal ultrasound (46).

In the absence of other risk factors (< 12 ml (atrophy), maldescent testis), testicular microlithiasis is not an indication for biopsy or further (ultrasound) screening (45,47).

Magnetic resonance imaging (MRI) offers higher sensitivity and specificity than ultrasound for diagnosing tumours (40,48). MRI of the scrotum offers a sensitivity of 100% and a specificity of 95-100% (49), but its high cost does not justify its use for diagnosis.

3.3 Serum tumour markers at diagnosis

Serum tumour markers are prognostic factors and contribute to diagnosis and staging (50). The following markers should be determined:

- AFP (produced by yolk sac cells);
- hCG (expression of trophoblasts);
- LDH (lactate dehydrogenase).

In all tumours, there is an increase in these markers in 51% of cases of testicular cancer (23,38). Alphafetoprotein increases in 50-70% of patients with non-seminomatous germ cell tumour (NSGCT), and a rise in hCG is seen in 40-60% of patients with NSGCT. About 90% of non-seminomatous tumours present with a rise in one or two of the markers. Up to 30% of seminomas can present or develop an elevated hCG level during the course of the disease (51,52).

Lactate dehydrogenase is a less specific marker, and its concentration is proportional to tumour volume. Its level may be elevated in 80% of patients with advanced testicular cancer (51). It should be noted that negative marker levels do not exclude the diagnosis of a germ cell tumour. Other markers studied include placental alkaline phosphatase (PLAP), which may be of value in monitoring patients with pure seminoma. Cytogenetic and molecular markers are available in specific centres, but at present only contribute to research studies. Measurement of serum AFP, hCG and LDH is mandatory, while that of PLAP is optional.

3.4 Inguinal exploration and orchidectomy

Every patient with a suspected testicular mass must undergo inguinal exploration with exteriorisation of the testis within its tunics. Orchidectomy with division of the spermatic cord at the internal inguinal ring must be performed if a malignant tumour is found. If the diagnosis is not clear, a testicular biopsy (an enucleation of the intraparenchymal tumour) is taken for frozen (fresh tissue) section histological examination.

In cases of disseminated disease and life-threatening metastases, it is current practice to start with up-front chemotherapy, and orchidectomy may be delayed until clinical stabilisation has occurred.

3.5 Organ-sparing surgery

Although organ-sparing surgery is not indicated in the presence of non-tumoural contralateral testis, it can be attempted in special cases with all the necessary precautions.

In synchronous bilateral testicular tumours, metachronous contralateral tumours, or in a tumour in a solitary testis with normal pre-operative testosterone levels, organ preserving surgery can be performed when the tumour volume is less than 30% of the testicular volume and surgical rules are respected. In those cases, the rate of associated TIN is high (at least up to 82%), and all patients must be treated with adjuvant radiotherapy (16-20 Gy) at some point (53).

Infertility will result after radiotherapy and the risk of long-term Leydig cell insufficiency after radiotherapy of a solitary testis is increased (54). Radiation treatment may be delayed in fertile patients who wish to father children. The option must be carefully discussed with the patient and surgery performed in a centre with experience (55,56).

3.6 Pathological examination of the testis

Mandatory pathological requirements:

- Macroscopic features: side, testis size, maximum tumour size, and macroscopic features of epididymis, spermatic cord, and tunica vaginalis.
- Sampling: a 1 cm^2 section for every centimetre of maximum tumour diameter, including normal macroscopic parenchyma (if present), albuginea and epididymis, with selection of suspected areas. At least one proximal and one distal section of spermatic cord plus any suspected area.
- Microscopic features and diagnosis: histological type (specify individual components and estimate amount as percentage) according to WHO 2004 (37):
  - presence or absence of peri-tumoural venous and/or lymphatic invasion;
  - presence or absence of albuginea, tunica vaginalis, rete testis, epididymis or spermatic cord invasion;
  - presence or absence of intratubular germ cell neoplasia (TIN) in non-tumour parenchyma intratubular germ cell neoplasia.
- pT category according to Tumour Node Metastasis (TNM) 2009 (57).
- Immunohistochemical studies: in seminoma and mixed germ cell tumour, AFP and hCG.

Advisable immunohistochemical markers, in cases of doubt, are:

- in seminoma: cytokeratins (CAM 5.2), PLAP, c-kit;
- in intratubular germ cell neoplasia: PLAP, c-kit;
- other advisable markers: chromogranine A (Cg A), Ki-1 (MIB-1).

3.7 Diagnosis and treatment of testicular intraepithelial neoplasia (TIN)

Contralateral biopsy has been advocated to rule out the presence of TIN (58). Although this is routine policy in some countries, the low incidence of TIN and contralateral metachronous testicular tumours (up to 9% and approximately 2.5%, respectively) (59,60), the morbidity of TIN treatment, and the fact that most of these metachronous tumours are at a low stage at presentation make it controversial to recommend a systematic contralateral biopsy in all patients (61-63). It is still difficult to reach a consensus on whether the existence of contralateral TIN must be identified in all cases. However, biopsy of the contralateral testis should be offered to high-risk patients for contralateral TIN with a testicular volume of less than 12 mL, a history of cryptorchidism, or poor spermatogenesis (Johnson Score 1-3). A contralateral biopsy is not necessary for patients older than 40 years (64-69). A double biopsy is preferred to increase sensitivity (66).

Once TIN is diagnosed, local radiotherapy (16-20 Gy in fractions of 2 Gy) is the treatment of choice in solitary testis. Because this may produce infertility, the patient must be carefully counselled before treatment commences (61,70). In addition to infertility, Leydig cell function and testosterone production may be impaired long-term following radiotherapy for TIN (55). Radiation treatment may be delayed in fertile patients who wish to father children (66). Patients have to be informed that a testicular tumour may arise in spite of a negative biopsy (71).

If TIN is diagnosed and the contralateral testis is healthy, the options for management are orchidectomy or close observation (with a risk of 50% in 5 years to develop a testicular cancer) (72).

3.8 Screening

Although there are no surveys proving the advantages of screening programmes, it has been demonstrated that stage and prognosis are directly related to early diagnosis. In the presence of clinical risk factors, selfphysical examination by the affected individual is advisable.

4. STAGING

4.1 Diagnostic tools

To determine the presence of metastatic or occult disease, the half-life kinetics of serum tumour markers must be assessed, the nodal pathway must be screened, and the presence of visceral metastases ruled out. Consequently, it is mandatory to assess:

- the post-orchidectomy half-life kinetics of serum tumour markers;
- the status of retroperitoneal and supraclavicular lymph nodes, and the liver;
- the presence or absence of mediastinal nodal involvement and lung metastases;
- the status of brain and bone, if any suspicious symptoms are present.

The mandatory tests are:

- serial blood sampling;
- abdominopelvic and thoracic computed tomography (CT) scan.

4.2 Serum tumour markers: post-orchidectomy half-life kinetics

The mean serum half-life of AFP and hCG is 5-7 days and 2-3 days, respectively (51). Tumour markers have to be re-evaluated after orchidectomy to determine half-life kinetics. Marker decline in patients with clinical stage I disease should be assessed until normalisation has occurred. Markers before start of chemotherapy are important to classify the patient according to the International Germ Cell Cancer Collaborative Group (IGCCCG) risk classification. The persistence of elevated serum tumour markers after orchidectomy might indicate the presence of metastatic disease (macro- or microscopically), while the normalisation of marker levels after orchidectomy does not rule out the presence of tumour metastases. During chemotherapy, the markers should decline; persistence has an adverse prognostic value.

4.3 Retroperitoneal, mediastinal and supraclavicular lymph nodes and viscera

Retroperitoneal and mediastinal lymph nodes are best assessed by means of a CT scan. The supraclavicular nodes are best assessed by physical examination.

Abdominopelvic CT scanning offers a sensitivity of 70-80% in determining the state of the retroperitoneal nodes. Its accuracy depends on the size of the nodes; sensitivity and the negative predictive value increase using a 3 mm threshold to define metastatic nodes in the landing zones (69). Those figures decrease slightly in stages I and II (70,73), with a rate of understaging of 25-30% (74). New generations of CT scans do not seem to improve the sensitivity.

Magnetic resonance imaging produces similar results to CT scanning in the detection of retroperitoneal nodal enlargement (75,76). Again, the main objections to its routine use are its high cost and limited access to it. Nevertheless, MRI can be helpful when abdominopelvic CT or ultrasound are inconclusive (75), when CT scan is contraindicated because of allergy to contrast media, or when the physician or the patient are concerned about radiation dose. MRI is an optional test, and there are currently no indications for its systematic use in the staging of testicular cancer.

A chest CT scan is the most sensitive way to evaluate the thorax and mediastinal nodes. This exploration has to be recommended in all patients with testicular cancer because up to 10% of cases can present with small subpleural nodes that are not visible radiologically (77). The CT scan has high sensitivity but low specificity (75).

There is no evidence to support the use of the fluorodeoxyglucose-PET (FDG-PET) scan in the staging of testis cancer (78,79). It is recommended in the follow-up of patients with seminoma with any residual mass at least 6 weeks after chemotherapy in order to decide on watchful waiting or active treatment (80-83). fluorodeoxyglucose-PET, however, is not recommended in the re-staging of patients with non-seminomatous tumours after chemotherapy (84,85).

Other examinations, such as brain or spinal CT, bone scan or liver ultrasound, should be performed if there is suspicion of metastases to these organs. A CT or MRI scan of the skull is advisable in patients with NSGCT and multiple lung metastasis and poor prognosis IGCCG risk group. Table 3 shows the recommended test at staging.

Table 3: Recommended tests for staging at diagnosis

Test	Recommendation	GR
Serum tumour markers	Alpha-fetoprotein hCG LDH	A
Abdominopelvic CT scan	All patients	A
Chest CT scan	All patients	A
Testis ultrasound (bilateral)	All patients	A
Bone scan	In case of symptoms	
Brain scan (CT/MRI)	In case of symptoms and patients with metastatic disease with multiple lung metastases and high beta-hCG values	

Further investigations	
Fertility investigations: Total testosterone LH FSH Semen analysis	B
Sperm banking should be offered	A

hCG = human chorionic gonadotrophin; LDH = lactate dehydrogenase; CT = computed tomography; LH = luteinising hormone; FSH = follicle-stimulating hormone.

4.4 Staging and prognostic classifications

The staging system recommended in these guidelines is the 2009 TNM of the International Union Against Cancer (UICC) (Table 4) (57). This includes:

- determination of the anatomical extent of disease;
- assessment of serum tumour markers, including nadir values of hCG, AFP and LDH after orchidectomy (S category);
- clear definition of regional nodes;
- some N-category modifications related to node size.

Table 4: TNM classification for testicular cancer (UICC, 2009, 7th edn [57])

pT	**Primary tumour[1]**	
	pTX	Primary tumour cannot be assessed (see note 1)
	pT0	No evidence of primary tumour (e.g. histological scar in testis)
	pTis	Intratubular germ cell neoplasia (testicular intraepithelial neoplasia)
	pT1	Tumour limited to testis and epididymis without vascular/lymphatic invasion: tumour may invade tunica albuginea but not tunica vaginalis
	pT2	Tumour limited to testis and epididymis with vascular/lymphatic invasion, or tumour extending through tunica albuginea with involvement of tunica vaginalis
	pT3	Tumour invades spermatic cord with or without vascular/lymphatic invasion
	pT4	Tumour invades scrotum with or without vascular/lymphatic invasion
N	**Regional lymph nodes clinical**	
	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Metastasis with a lymph node mass 2 cm or less in greatest dimension or multiple lymph nodes, none more than 2 cm in greatest dimension
	N2	Metastasis with a lymph node mass more than 2 cm but not more than 5 cm in greatest dimension, or multiple lymph nodes, any one mass more than 2 cm but not more than 5 cm in greatest dimension
	N3	Metastasis with a lymph node mass more than 5 cm in greatest dimension
pN	**Pathological**	
	pNX	Regional lymph nodes cannot be assessed
	pN0	No regional lymph node metastasis
	pN1	Metastasis with a lymph node mass 2 cm or less in greatest dimension and 5 or fewer positive nodes, none more than 2 cm in greatest dimension
	pN2	Metastasis with a lymph node mass more than 2 cm but not more than 5 cm in greatest dimension; or more than 5 nodes positive, none more than 5 cm; or evidence or extranodal extension of tumour
	pN3	Metastasis with a lymph node mass more than 5 cm in greatest dimension
M	**Distant metastasis**	
	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis
	M1a	Non-regional lymph node(s) or lung
	M1b	Other sites
S	**Serum tumour markers**	
	Sx	Serum marker studies not available or not performed
	S0	Serum marker study levels within normal limits

	LDH (U/l)	hCG (mIU/ml)	AFP (ng/ml)
S1	< 1.5 x N and	< 5,000 and	< 1,000
S2	1.5-10 x N or	5,000-50,000 or	1,000-10,000
S3	> 10 x N or	> 50,000 or	> 10,000

N indicates the upper limit of normal for the LDH assay.

LDH, lactate dehydrogenase; hCG = human chorionic gonadotrophin; AFP = alpha-fetoprotein.
[1]Except for pTis and pT4, where radical orchidectomy is not always necessary for classification purposes, the extent of the primary tumour is classified after radical orchidectomy; see pT. In other circumstances, TX is used if no radical orchidectomy has been performed.

According to the 2009 TNM classification, stage I testicular cancer includes the following substages:

Stage grouping

Stage 0	pTis	N0	M0	S0,SX
Stage I	pT1-T4	N0	M0	SX
Stage IA	pT1	N0	M0	S0
Stage IB	pT2 - pT4	N0	M0	S0
Stage IS	Any patient/TX	N0	M0	S1-3
Stage II	Any patient/TX	N1-N3	M0	SX
Stage IIA	Any patient/TX	N1	M0	S0
	Any patient/TX	N1	M0	S1
Stage IIB	Any patient/TX	N2	M0	S0
	Any patient/TX	N2	M0	S1
Stage IIC	Any patient/TX	N3	M0	S0
	Any patient/TX	N3	M0	S1
Stage III	Any patient/TX	Any N	M1a	SX
Stage IIIA	Any patient/TX	Any N	M1a	S0
	Any patient/TX	Any N	M1a	S1
Stage IIIB	Any patient/TX	N1-N3	M0	S2
	Any patient/TX	Any N	M1a	S2
Stage IIIC	Any patient/TX	N1-N3	M0	S3
	Any patient/TX	Any N	M1a	S3
	Any patient/TX	Any N	M1b	Any S

Stage IA patients have primary tumours limited to the testis and epididymis, with no evidence of microscopic vascular or lymphatic invasion by tumour cells on microscopy, no sign of metastases on clinical examination or imaging, and post-orchidectomy serum tumour marker levels within normal limits. Marker decline in patients with clinical stage I disease should be assessed until normalisation. Stage IB patients have a more locally invasive primary tumour, but no sign of metastatic disease. Stage IS patients have persistently elevated (and usually increasing) serum tumour marker levels after orchidectomy, which is evidence of subclinical metastatic disease (or possibly a second germ cell tumour in the remaining testis). If serum tumour marker levels are declining according to the expected half-life decay after orchidectomy, the patient is usually followed up until normalisation.

In large population-based patient series, 75-80% of seminoma patients, and about 55% of patients with NSGCT cancer have stage I disease at diagnosis (86,87). True stage IS (persistently elevated or increasing serum marker levels after orchidectomy) is found in about 5% of non-seminoma patients. If a staging retroperitoneal lymph node dissection (RPLND) was to be performed in stage IS patients, nearly all patients would be found to have pathological stage II disease (pN+) (1,7,86,88).

In 1997, the IGCCCG defined a prognostic factor-based staging system for metastatic testis tumour based on identification of some clinical independent adverse factors. This staging system has been incorporated

into the TNM Classification and uses histology, location of the primary tumour, location, of metastases and prechemotherapy marker levels in serum as prognostic factors to categorise patients into 'good', 'intermediate' or 'poor' prognosis (Table 5) (89).

Table 5: Prognostic-based staging system for metastatic germ cell cancer (International Germ Cell Cancer Collaborative Group)*

Good-prognosis group	
Non-seminoma (56% of cases) 5-year PFS 89% 5-year survival 92%	*All of the following criteria:* • Testis/retroperitoneal primary • No non-pulmonary visceral metastases • AFP < 1,000 ng/mL • hCG < 5,000 IU/L (1,000 ng/mL) • LDH < 1.5 x ULN
Seminoma (90% of cases) 5-year PFS 82% 5-year survival 86%	*All of the following criteria:* • Any primary site • No non-pulmonary visceral metastases • Normal AFP • Any hCG • Any LDH
Intermediate prognosis group	
Non-seminoma (28% of cases) 5 years PFS 75% 5-year survival 80%	• Testis/retroperitoneal primary • No non-pulmonary visceral metastases • AFP 1,000 - 10,000 ng/mL or • hCG 5,000 - 50,000 IU/L or • LDH 1.5 - 10 x ULN
Seminoma (10% of cases) 5-year PFS 67% 5-year survival 72%	*Any of the following criteria:* • Any primary site • Non-pulmonary visceral metastases • Normal AFP • Any hCG • Any LDH
Poor prognosis group	
Non-seminoma (16% of cases) 5-year PFS 41% 5-year survival 48%	*Any of the following criteria:* • Mediastinal primary • Non-pulmonary visceral metastases • AFP > 10,000 ng/mL or • hCG > 50,000 IU/L (10,000 ng/mL) or • LDH > 10 x ULN
Seminoma No patients classified as poor prognosis	

**Pre-chemotherapy serum tumour markers should be assessed immediately prior to the administration of chemotherapy (same day).*
PFS = progression-free survival; AFP = alpha-fetoprotein; hCG = human chorionic gonadotrophin; LDH = lactate dehydrogenase.

4.5 Prognostic risk factors

Retrospectively, for seminoma stage I tumour size (> 4 cm) and invasion of the rete testis have been identified as predictors for relapse in a pooled analysis (29). However, these risk factors have not been validated in a prospective setting except that the absence of both factors indicated a low recurrence rate (6%) (90).

For non-seminoma stage I, vascular invasion of the primary tumour in blood or lymphatic vessels is the most important predictor of occult metastatic disease. The proliferation rate, as well as the percentage of embryonal carcinoma, are additional predictors that improve upon the positive and negative predictive value of vascular invasion (91,92).

The significant prognostic pathological risk factors for stage I and clinical risk factors for metastatic disease are listed in Table 6.

Table 6: Prognostic factors for occult metastatic disease in testicular cancer

	For seminoma	For non-seminoma
Pathological (for stage I)		
Histopathological type	• Tumour size (> 4 cm) • Invasion of the rete testis	• Vascular/lymphatic in or peri-tumoural invasion • Proliferation rate > 70% • Percentage of embryonal carcinoma > 50%
Clinical (for metastatic disease)		
• Primary location • Elevation of tumour marker levels • Presence of non-pulmonary visceral metastasis		

4.6 Impact on fertility and fertility- associated issues

Sperm abnormalities are frequently found in patients with testis tumours. Furthermore, chemotherapy and radiation treatment can also impair fertility. In patients in the reproductive age group, pre-treatment fertility assessment (testosterone, luteinising hormone [LH] and FSH levels) should be performed, and semen analysis and cryopreservation should be offered. If cryopreservation is desired, it should be preferably performed before orchidectomy, but in any case prior to chemotherapy treatment (54,93-99).

In cases of bilateral orchidectomy or low testosterone levels after treatment of TIN, life-long testosterone supplementation is necessary (100). Patients with unilateral or bilateral orchidectomy should be offered a testicular prosthesis (101). For more detailed information, the reader is referred to the EAU Male Infertility Guidelines.

5. GUIDELINES FOR THE DIAGNOSIS AND STAGING OF TESTICULAR CANCER

	GR
1. Testicular ultrasound is mandatory assessment	A
2. Orchidectomy and pathological examination of the testis are necessary to confirm the diagnosis and to define the local extension (pT category). In a life-threatening situation due to extensive metastasis, chemotherapy must be started before orchidectomy.	A
3. Serum determination of tumour markers (AFP, hCG, and LDH must be performed before and after orchidectomy for staging and prognostic reasons	A
4. The state of the retroperitoneal, mediastinal and supraclavicular nodes and viscera must be assessed in testicular cancer.	A

AFP = alpha-fetoprotein; hCG = human chorionic gonadotrophin; LDH = lactate dehydrogenase.

6. TREATMENT: STAGE I GERM CELL TUMOURS

6.1 Stage I seminoma

After modern staging procedures, about 15-20% of stage I seminoma patients have subclinical metastatic disease, usually in the retroperitoneum, and will relapse after orchidectomy alone.

*6.1.1 **Surveillance***

Several prospective non-randomised studies of surveillance have been conducted during the past decade, the largest study coming from Canada with > 1,500 patients (102). Previous analysis from four studies showed an actuarial 5 years' relapse-free rate of 82.3%. The Princess Margaret Hospital series (n = 1559) showed an overall relapse rate in unselected patients of 16.8%. The actuarial relapse rate is in the order of 15-20% at 5 years, and most of the relapses are first detected in infra-diaphragmatic lymph nodes (103).

In patients with low risk (tumour size ≤ 4 cm and no rete testis invasion) the recurrence under surveillance is as low as 6% (104).

Chemotherapy according to IGCCCG classification is a possible treatment for seminoma relapse under surveillance. However, 70% of patients with relapse are suitable for treatment with radiotherapy alone because of small volume disease at the time of recurrence. Patients who relapse again can be effectively treated with chemotherapy (105).

The overall cancer-specific survival rate reported with surveillance performed by experienced centres is 97-100% for seminoma stage I (103,105). The main drawback of surveillance is the need for more intensive follow-up, especially with repeated imaging examinations of the retroperitoneal lymph nodes, for at least 5 years after orchidectomy. This compares with the very low risk of subdiaphragmatic relapse after adjuvant radiotherapy.

There is a small but clinically significant risk of relapse more than 5 years after orchidectomy for stage I seminoma which supports the need for long term surveillance.

*6.1.2 **Adjuvant chemotherapy***

A joint trial by the Medical Research Council (MRC) and the European Organisation for Research and Treatment of Cancer (EORTC) (MRC TE 19 trial), which compared one cycle of carboplatin (area under curve [AUC] 7) with adjuvant radiotherapy, did not show a significant difference with regard to recurrence rate, time to recurrence and survival after a median follow-up of 4 years (106-108). Therefore, adjuvant carboplatin therapy using a dosage of one course AUC 7 is an alternative to radiotherapy or surveillance in stage I seminoma (103,106-108). Two courses of adjuvant carboplatin seem to further reduce the relapse rate to the order of 1-3% (109,110), but further experience and long-term observations are needed.

*6.1.3 **Adjuvant radiotherapy***

Seminoma cells are extremely radiosensitive. Adjuvant radiotherapy to a para-aortic (PA) field or to a hockeystick field (para-aortic and ipsilateral iliac nodes), with moderate doses (total 20-24 Gy), will reduce the relapse rate to 1-3% (111-114). After modern radiotherapy, nearly all relapses will first occur outside the irradiated field (supradiaphragmatic lymph nodes or in the lungs) (111-114). Based on the results of a large randomised MRC trial, Fossa et al. (111,112) recommended radiotherapy to a PA field as standard treatment for patients with testicular seminoma stage I, T1-T3 and with undisturbed lymphatic drainage. Acute toxicity was reduced and the sperm count within the first 18 months was significantly higher after PA irradiation than after irradiation of the traditional dog-leg field. On the other hand, the relapse rate in the iliac lymph nodes was about 2% (all of them on the right side) after PA and 0% after dog-leg irradiation. Another possible site of failure is in the left renal hilum. PA irradiation should be tailored according to the site of the primary tumour. Adjuvant irradiation of supradiaphragmatic lymph nodes is not indicated in seminoma stage I.

With regard to the irradiation dose, the MRC recently finished a large randomised trial of 20 Gy versus 30 Gy PA radiation in stage I seminoma that showed equivalence for both doses in terms of recurrence rates (112). The rate of severe radiation-induced long-term toxicity is less than 2%. Moderate chronic gastrointestinal (GI) side-effects are seen in about 5% of patients, and moderate acute GI toxicity in about 60% (111). The main concern surrounding adjuvant radiotherapy is the increased risk of radiation-induced second non-germ cell malignancies (115-119).

A scrotal shield can be of benefit during adjuvant radiotherapy in order to prevent scattered radiation toxicity in the contralateral testis (118).

*6.1.4 **Retroperitoneal lymph node dissection (RPLND)***

In a prospective, non-randomised study comparing radiotherapy and RPLND in stage I seminoma, there was a trend towards a higher incidence of retroperitoneal relapses (9.5%) after RPLND as primary treatment. Therefore this policy should not be recommended in stage I seminoma (120).

*6.1.5 **Risk-adapted treatment***

Using tumour size > 4 cm and rete testis invasion, patients with seminoma stage I may be subdivided into a low-and high-risk group of occult metastatic disease. Patients with and without both risk factors have a risk of occult disease of 32% and 12%, respectively. These risk factors were introduced by an analysis of retrospective trials (29). A prospective trial based on these risk factors (no risk factors: surveillance; both risk factors: two courses of carboplatin AUC 7) showed the feasibility of a risk-adapted approach. Early data with limited follow-up indicate that patients without either risk factor have a 6.0% risk of relapse at 5 years. Patients

in the high risk group treated with carboplatin experienced a 1.4% relapse rate at mean follow up of 34 months (121).

However, given the fact that cure is achieved in ~100% in patients with stage I seminoma whatever therapy used (adjuvant radiotherapy, adjuvant chemotherapy, or surveillance) and that the relapse rate in large surveillance series not using risk factors is about 15-20% indicates a risk of over-treatment.

Therefore, the therapeutic decision should be shared with an informed patient.

6.2 Guidelines for the treatment of seminoma stage I

	GR
1. Surveillance is the recommended management option (if facilities available and patient compliant)	A*
2. Carboplatin-based chemotherapy (one course at AUC 7) can be recommended.	B
3. Adjuvant treatment is not recommended for patients at very low risk.	A
4. Radiotherapy is not recommended as adjuvant treatment.	A

**Upgraded following panel consensus.*

6.3 NSGCT stage I

Up to 30% of NSGCT patients with clinical stage I (CS1) disease have subclinical metastases and will relapse if surveillance alone is applied after orchidectomy.

*6.3.1 **Surveillance***

Improvements in clinical staging and follow-up methods, and the availability of effective salvage treatment with cisplatin-based chemotherapy and post-chemotherapy surgery, have led to studies of only close surveillance after orchidectomy in CS1 NSGCT patients. The largest reports of the surveillance strategy indicate a cumulative relapse rate of about 30%, with 80% of relapses occurring during the first 12 months of follow-up, 12% during the second year and 6% during the third year, decreasing to 1% during the fourth and fifth years, and occasionally even later (122-126). About 35% of relapsing patients have normal levels of serum tumour markers at relapse. About 60% of relapses are in the retroperitoneum. Despite very close follow-up, 11% of relapsing patients presented with large-volume recurrent disease.

The somewhat lower relapse rates reported from surveillance studies compared with some series of patients staged by RPLND (127) can be explained by the fact that some patients (presumably at risk) are excluded once surveillance is advised. Based on the overall cancer-specific survival data, surveillance within an experienced surveillance programme may be offered to patients with non-risk stratified clinical stage I non-seminoma as long as they are compliant and informed about the expected recurrence rate as well as the salvage treatment (128,129).

*6.3.2 **Primary chemotherapy***

Several studies involving two courses of chemotherapy with cisplatin, etoposide and bleomycin (PEB) as primary treatment for high-risk patients (having about 50% risk of relapse) have been reported (130-135). In these series, involving more than 200 patients, some with a median follow-up of nearly 8 years (130), a relapse rate of only 2.7% was reported, with very little long-term toxicity. Two cycles of cisplatin-based adjuvant chemotherapy do not seem to adversely affect fertility or sexual activity (136). However, the very-long term (> 20 years) side effects of adjuvant chemotherapy in this setting are currently unknown, and this should be taken in consideration for decision-making; especially the long-term cardio-vascular effects of chemotherapy in GCT survivors (137).

It is important to be aware of the slow-growing retroperitoneal teratomas after primary chemotherapy (138).

The results of cost analyses comparing surveillance, RPLND and primary chemotherapy show different results among the reported studies, possibly because of differences in intensity and costs related to follow-up procedures (139). With a low frequency of follow-up CTs (such as has been proven effective for the surveillance strategy in non-seminoma CS1), the costs of follow-up can be considerably reduced (140).

*6.3.3 **Risk-adapted treatment***

Risk-adapted treatment is based on the risk factor vascular invasion. Stratifying patients with CS1 NSGCT

according to their presumed risk of relapse is a rational option, as several studies have reported similar survival rates and a final cure rate close to 100% with all available treatment options using the risk-stratifying approach (130-135,141-144). Risk-adapted treatment is therefore an equally effective alternative treatment of choice in CS1 NSGCT.

If the risk-adapted policy is applied, patients with vascular invasion are recommended to undergo adjuvant chemotherapy with two cycles of PEB, and patients without vascular invasion are recommended to undergo surveillance. Only if patients or doctors are not willing to accept the consequent risk-adapted treatment, or if there are circumstances that militate against the risk-adapted treatment option, should the remaining treatments be considered.

Thus, the decision about treatment should be based on a thorough discussion with the patients, taking into account the described advantages and disadvantages, as well as the individual situation of the patient and/or the treatment centre. The Swedish-Norwegian Testicular Cancer Project (SWENOTECA) recently showed that in a large population-based study with a risk-adapted approach within a management programme and a median follow-up of 4.7 years, the relapse rate was 3.2% for patients with vascular invasion treated with only one adjuvant PEB (145). Taken together, about 300 patients with high risk CS I have been adjuvantly treated with 1 x PEB with a follow-up of more than 5 yrs. Still, a randomised trial between 1 and 2 courses of PEB is accruing patients. As long as 1 x PEB has not been proven superior or at least equivalent to 2 courses PEB, this adjuvant treatment cannot be recommended outside of a clinical trial or a prospective registry.

*6.3.4 **Retroperitoneal lymph node dissection***

If RPLND is performed, about 30% of patients are found to have retroperitoneal lymph node metastases, which corresponds to pathological stage II (PS2) disease (146-148). If no retroperitoneal metastases are found at RPLND (PS1), approximately 10% of the PS1 patients relapse at distant sites (92,128,149-151).

The main predictor of relapse in CS1 NSGCT managed by surveillance, for having PS2 disease and for relapse in PS1 after RPLND, is histopathological evidence of vascular invasion by tumour cells in, or near, the primary tumour in the testis (92,123,128,151,152). The presence of vascular invasion seems to be a very robust parameter, and is clinically usable even without centralised review by an expert panel (142,151). Vascular invasion was the most predictive of stage in a multifactorial analysis. The absence of vascular invasion has a negative predictive value of 77%, thus allowing for surveillance in low-risk compliant patients (92).

Patients without vascular invasion constitute about 50-70% of the CS1 population, and these patients have only a 15-20% risk of relapse on surveillance, compared with a 50% relapse rate in patients with vascular invasion. The risk of relapse for PS1 patients is less than 10% for those without vascular invasion and about 30% for those with vascular invasion (142,151,153,154).

If CS1 patients with PS2 are followed up only after RPLND, about 30% relapse, mainly at sites outside the abdomen and pelvis. The risk of relapse depends upon the amount of retroperitoneal disease resected (155-157). If two (or more) courses of cisplatin-based chemotherapy are given adjuvant to RPLND in PS2 cases, the relapse rate is reduced to less than 2%, including teratoma relapse (128,152,158). The risk of retroperitoneal relapse after a properly performed nerve-sparing RPLND is very low (less than 2%), as is the risk of ejaculatory disturbance or other significant side-effects (152,155,156).

The follow-up after RPLND is much simpler and less costly than that carried out during post-orchidectomy surveillance because of the reduced need for abdominal CT scans (152). If there is a rare indication to perform a staging RPLND, a laparoscopic or robot-assisted RPLND is feasible in expert hands. This minimal-invasive approach cannot be recommended as standard approach outside of a specialized laparoscopic centre (159-162). In a randomised comparison of RPLND with one course of PEB chemotherapy, adjuvant chemotherapy significantly increased the 2-year recurrence-free survival to 99.41% (confidence interval [CI] 95.87%, 99.92%) as opposed to surgery, which had a 2-year recurrence-free survival of 92.37% (CI 87.21%, 95.50%). The difference was 7.04%, CI 2.52%, 11.56%. The hazard ratio to experience a tumour recurrence with surgery as opposed to chemotherapy was 7.937, CI 1.808, 34.48. Therefore, one course of adjuvant PEB is superior to RPLND with regard to recurrence rates in patients unstratified for risk factors (163). In the SWENOTECA data mentioned in section 7.3.3 it was also found that one adjuvant PEB reduced the number of recurrences to 3.2% of the high risk and to 1.4% of the low risk patients (145).

6.4 CS1S with (persistently) elevated serum tumour markers

Serum tumour markers should be followed closely until levels fall into the reference values according to the expected half-life values for AFP and hCG. If the marker level increases after orchidectomy, the patient has

residual disease. If RPLND is performed, up to 87% of these patients have pathologically documented nodes in the retroperitoneum (164). An ultrasound examination of the contralateral testicle must be performed, if this was not done initially.

The treatment of true CS1S patients is still controversial. They may be treated with three courses of primary PEB chemotherapy and with follow-up as for CS1B patients (high risk, see below) after primary chemotherapy (165), or by RPLND (140). The presence of vascular invasion may strengthen the indication for primary chemotherapy as most CS1S with vascular invasion will need chemotherapy sooner or later anyway.

6.5 Guidelines for the treatment of NSGCT stage I

CS1 risk-adapted treatments based on vascular invasion or surveillance without using risk factors are recommended treatment options.

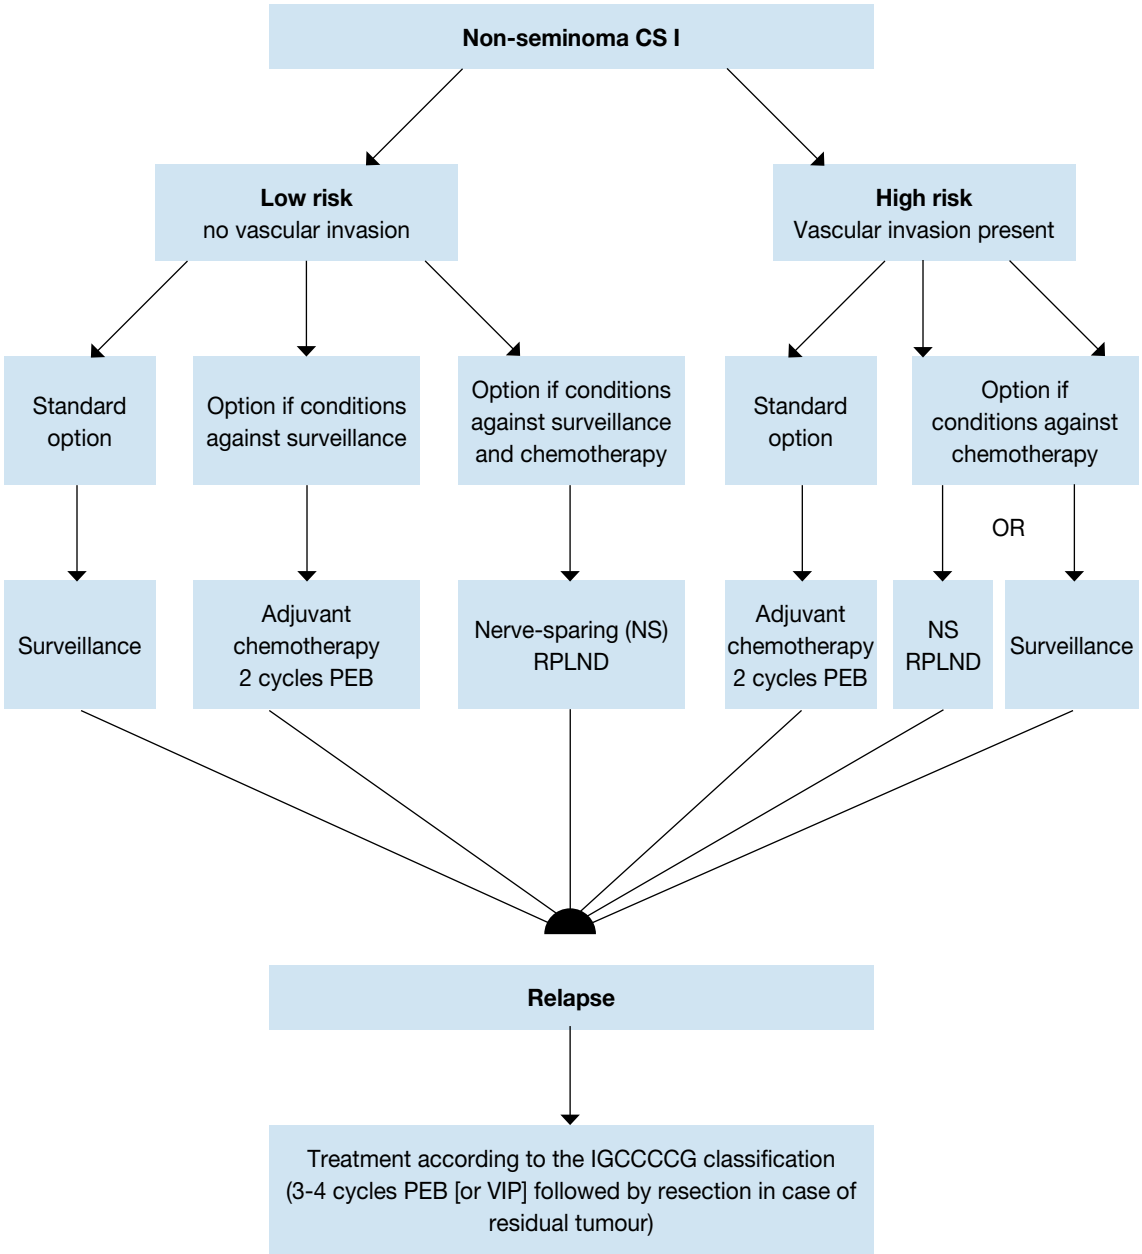
Table 7: Risk-adapted treatments for CS1 based on vascular invasion

	GR
CS1A (pT1, no vascular invasion): low risk	
1. If the patient is willing and able to comply with a surveillance policy, long-term (at least 5 years) close follow-up should be recommended.	A*
2. In low-risk patients not willing (or suitable) to undergo surveillance, adjuvant chemotherapy or nerve-sparing RPLND are treatment options If RPLND reveals PN+ (nodal involvement) disease, chemotherapy with two courses of PEB should be considered.	A
CS1B (pT2-pT4): high risk	
1. Primary chemotherapy with two courses of PEB should be recommended (one course of PEB within a clinical trial or registry).	A*
2. Surveillance or nerve-sparing RPLND in high-risk patients remain options for those not willing to undergo adjuvant chemotherapy. If pathological stage II is revealed at RPLND, further chemotherapy should be considered.	A

**Upgraded following panel consensus.*
PEB = cisplatin, eposide, bleomycin; RPLND = retroperitoneal lymph node dissection.

Figure 1 provides a treatment algorithm for patients with NSGCT stage I.

Figure 1: Treatment algorithm after orchidectomy according to individual risk factors in patients with non-seminoma NSGCT CS1 (31)



PEB = cisplatin, etoposide, bleomycin; CS = clinical stage; IGCCCG = International Germ Cell Cancer Collaborative Group; RLNPD = retroperitoneal lymph node dissection; VIP = etoposide, cisplatin, ifosfamide.

7. TREATMENT: METASTATIC GERM CELL TUMOURS

The treatment of metastatic germ cell tumours depends on:

- the histology of the primary tumour;
- prognostic groups as defined by the IGCCCG based on 5202 non-seminoma and 660 seminoma cases (Table 5) (166).

7.1 Low-volume metastatic disease (stage IIA/B)

*7.1.1 **Stage IIA/B seminoma***

So far, the standard treatment for stage IIA/B seminoma has been radiotherapy. The radiation dose delivered in stage IIA and IIB is **approximately** 30 Gy and 36 Gy, respectively. The standard radiation field compared with stage I will be extended from the PA region to the ipsilateral iliac field (the hockey-stick field). In stage IIB, the lateral borders should include the metastatic lymph nodes with a safety margin of 1.0-1.5 cm. This technique yields a relapse-free survival in stage IIA and IIB of 92% and 90%, respectively. Overall survival is almost 100% (167,168). Conversely, dose reduction to 27Gy has been associated with 11% of relapses (105).

In stage IIB chemotherapy (4 x etoposide and cisplatin [EP] or 3 x PEB in good prognosis) is an alternative to radiotherapy. Although more toxic in the short term, 4 x EP or 3 x PEB achieve a similar level of disease control (169). Single-agent carboplatin is not an alternative to standard EP or PEB chemotherapy (170).

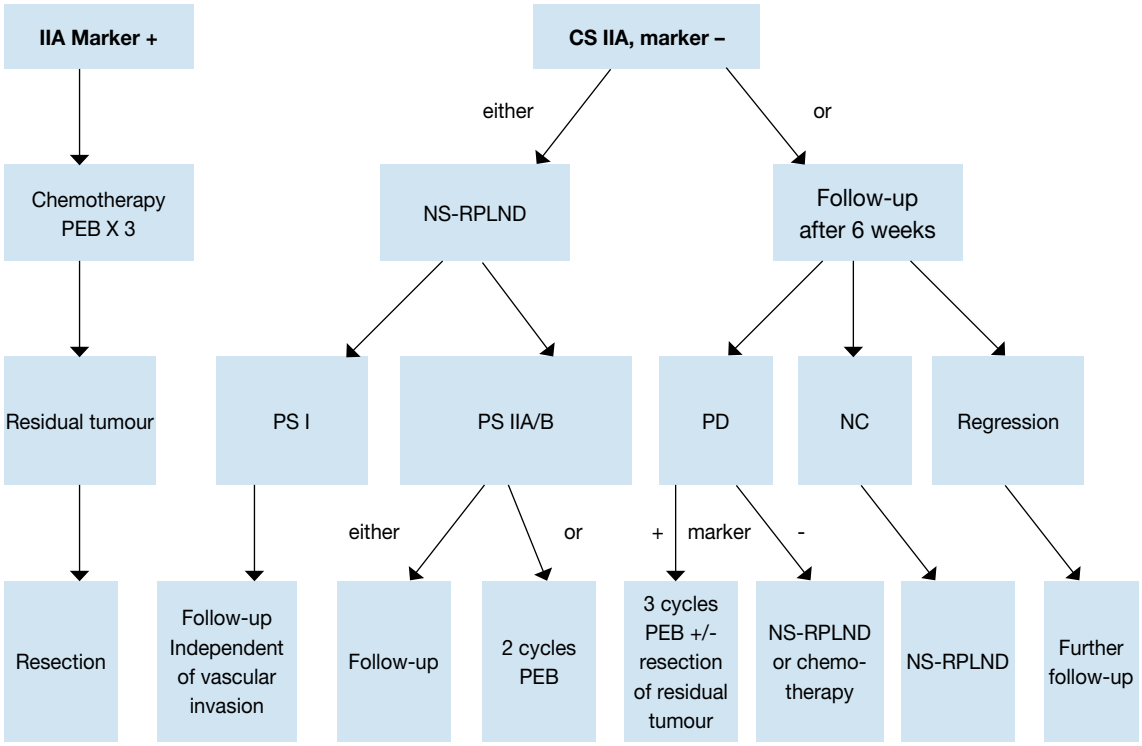
*7.1.2 **Stage IIA/B non-seminoma***

There is a general consensus that treatment should start with initial chemotherapy in all advanced cases of NSGCT except for stage II NSGCT disease without elevated tumour markers, which alternatively can be managed by primary RPLND or surveillance to clarify stage (171,172).

If surveillance is chosen, one follow-up after 6 weeks is indicated to document whether the lesion is growing, remaining stable or shrinking. A shrinking lesion is likely to be of non-malignant origin and should be observed further. A stable or growing lesion indicates either teratoma or an undifferentiated malignant tumour. If the lesion is growing without a corresponding increase in the tumour markers AFP or beta-hCG, RPLND should be performed by an experienced surgeon because of suspected teratoma. Patients with a growing lesion and a concomitant increase in the tumour markers AFP or beta-hCG should not undergo surgery; they require chemotherapy with PEB according to the treatment algorithm for patients with metastatic disease and IGCCCG recommendations (173-175) (Figure 2). An alternative to the surveillance strategy in marker-negative II A/B non-seminoma with suspicion of an undifferentiated malignant tumour is a (computer tomography-guided) biopsy, if technically possible. There is insufficient published data on PET scans in this situation.

Patients not willing to undergo primary chemotherapy have the option of primary nerve-sparing RPLND with adjuvant chemotherapy (two cycles of PEB) in case of metastatic disease (pII A/B). Primary chemotherapy and primary RPLND are comparable options in terms of outcome but side-effects and toxicity are different, allowing for involvement of the patient in selecting the treatment of choice (176). The cure rate with either approach will be close to 98% (158,177-182).

Figure 2: Treatment options in patients with non-seminoma clinical stage IIA (32)



PEB = cisplatin, etoposide, bleomycin; NS = nerve-sparing; RPLND = retroperitoneal lymph node dissection; PS = pathological stage; PD = progressive disease; NC = no change.

7.2 Advanced metastatic disease

*7.2.1 **Primary chemotherapy***

The primary treatment of choice for advanced disease is three or four cycles of PEB combination chemotherapy (Table 8), depending on the IGCCCG risk classification (see Table 3). This regimen has proven superiority to cisplatin, vinblastine and bleomycin (PVB) in patients with advanced disease (183-185). Data support a 3-day regimen of administering combination chemotherapy to be equally effective as a 5-day regimen, but associated with increased toxicity when 4 cycles are used (186).

Table 8: PEB regimen (interval 21 days)

Drug	Dosage	Duration of cycles
Cisplatin	20 mg/m^2	Days 1-5*
Etoposide	100 mg/m^2	Days 1-5
Bleomycin	30 mg	Days 1, 8, 15

*Plus hydration.
PEB = cisplatin, etoposide, bleomycin.

For patients with a 'good prognosis', according to the IGCCCG Classification (166), standard treatment consists of three cycles of PEB, and only in very selected cases where bleomycin is contraindicated, four cycles of EP (166,185-189). A randomised trial from the GETUG suggested that when the PEB regimen is being used in this setting the mortality was half that of EP, although the difference did not reached statistical significance (189,190). Therapy should be given without reduction of the doses at 21-day intervals; delaying the following chemotherapy cycle is justified only in cases of fever with granulocytopenia < 1000/mm^3 or thrombocytopenia < 100,000/IU. There is no indication for prophylactic application of haematopoietic growth factors such as, for example, granulocyte colony-stimulating factor (G-CSF). However, if infectious complications have occurred during chemotherapy, prophylactic administration of G-CSF is recommended for the following cycles (187,191).

The 'intermediate prognosis' group in the IGCCCG has been defined as patients with a 5-year survival rate of about 80%. The available data support four cycles of PEB as standard treatment (166,192).

For patients with a 'poor prognosis', standard treatment consists of four cycles of PEB. Four cycles of cisplatin, etoposide and ifosfamide (PEI) have the same effect, but are more myelotoxic (193,194). The 5-year progression-free survival is between 45% and 50%. Three randomised trials have shown no advantage in high-dose chemotherapy for the overall group of 'poor prognosis' patients (195-197). However, patients with a slow marker decline after the first or second cycle may represent a prognostically inferior subgroup with a potential role for dose-intensified chemotherapy after detection of inadequate marker decline (195). More aggressive chemotherapy may also be investigated in a very poor prognostic group (e. g. primary mediastinal germ cell tumours or synchroneous brain metastasis).

Since a matched-pair analysis resulted in a better survival rate (198-200), poor prognosis patients should still be treated in ongoing prospective trials, investigating the value of dose intensified or high-dose chemotherapy (e. g. the international GETUG 13 trial (EU-20502, NCT00104676).

Patients meeting 'poor-prognosis' criteria should therefore be transferred to a reference centre because a better outcome was reported for intermediate and poor prognosis patients who had been treated within a clinical trial in a high volume centre (25). There are no general recommendations for treatment modifications for patients with a poor general condition (Karnofsky < 50%) or extended liver infiltration (> 50%). Patients with extended pulmonary infiltration are at risk for acute respiratory distress syndrome: adapting the doses of the PEB regimen in the first cycle of chemotherapy (only 3 days of EP without bleomycin) was suggested to reduce the risk of early death in this setting (201).

7.3 Restaging and further treatment

7.3.1 ***Restaging***

Restaging is performed by imaging investigations and re-evaluation of tumour markers. At marker decline and stable or regressive tumour manifestation, chemotherapy will be completed (three or four cycles, depending on the initial stage) (166,202,203). In the case of marker decline but growing metastases, resection of the tumour is obligatory after termination of induction therapy, other than in an emergency, according to local tumour growth (204).

Only with documented marker increase after two courses of chemotherapy is an early crossover of therapy indicated. These patients are usually candidates for new drugs trials (198,205). Patients with a low-level hCG marker plateau post-treatment should be observed to see whether complete normalisation occurs. Patients with a low plateau serum AFP level after chemotherapy, surgery of residual masses should be performed, with post-surgery AFP monitoring. Salvage chemotherapy is indicated for documented marker rise only (206,207).

7.3.2 ***Residual tumour resection***

A residual mass of seminoma should not be primarily resected, irrespective of the size, but controlled by imaging investigations and tumour markers (208-214).

FDG-PET has a high negative predictive value in patients with residual masses after treatment of seminoma but false positive results can be a problem and scans should not be performed less than 2 months after chemotherapy. In patients with residuals of > 3 cm, FDG-PET should be performed in order to gain more information on the viability of these residuals. In patients with residuals of < 3 cm, the use of FDG-PET is optional (215).

On progression, salvage therapy is indicated (chemotherapy, salvage surgery, radiotherapy) (216-220). In patients with concurrent hCG elevation, progressing seminoma after first-line chemotherapy should be treated by salvage chemotherapy (or radiotherapy if only small volume recurrence is present). Progressing patients without hCG progression should undergo histological verification (e. g. by biopsy or open surgery) before salvage chemotherapy is given.

In the case of non-seminoma and complete remission after chemotherapy (no tumour visible), residual tumour resection is not indicated (221-228). The long-term relapse rate in this patient group is 6-9%, however, one third of the late relapsing patients will not survive (228).

In the case of any visible residual mass and marker normalisation, surgical resection is indicated. In patients with lesions < 1 cm, there still is an increased risk of residual cancer or teratoma (229) although the role of surgery in this setting is debated. In persistent larger volume retroperitoneal disease, all areas of primary metastatic sites must be completely resected within 4-6 weeks of completion of chemotherapy. If technically feasible, a nerve-sparing procedure should be performed (221,228-237).

Overall, following PEB induction chemotherapy, only 10% of residual masses contain viable cancer, 50% contain mature teratoma, and 40% contain necrotic-fibrotic tissue. As yet, no imaging investigations, including PET or a prognosis model, are able to predict histological differentiation of the non-seminomatous residual tumour. Thus, residual tumour resection is mandatory in all patients with residual disease > 1 cm (222-224,236-246).

The extent of surgery should be based on the risk of relapse of an individual patient and quality of life issues (231). If possible, all the masses should be resected, because a complete resection, in the setting of viable malignant cells, is more critical than recourse to post-operative chemotherapy (247). There is growing evidence that "template" resections in selected patients yield equivalent long-term results compared to bilateral systematic resections in all patients (248,249). However, the mere resection of the residual tumour (so called "lumpectomy") should not be performed.

The histology may diverge in different organ sites (239). Resection of contralateral pulmonary lesions is not mandatory in case pathologic examination of the lesions from the first lung shows complete necrosis (250).

7.3.3 ***Quality of surgery***

Post-chemotherapy surgery is demanding and frequently needs ad hoc vascular interventions (like vena cava or aortic prosthesis). Therefore, patients should be referred to specialized centres capable of interdisciplinary surgery (hepatic resections, vessel replacement, spinal neurosurgery, thoracic surgery). Patients treated within such centres benefit with a significant reduction in perioperative mortality from 6% to 0.8% (26,251). In addition, specialised urologic surgeons are capable to reduce the local recurrence rate from 16% to 3% (252) with a higher rate of complete resections.

7.3.4 ***Consolidation chemotherapy after secondary surgery***

After resection of necrosis or mature/immature teratoma, no further treatment is required. In the case of incomplete resection of other germ cell tumour pathologies, two adjuvant cycles of conventionally dosed cisplatin-based chemotherapy may be given in certain subgroups (e.g. 'poor prognosis' patients) (247,253) (caution: cumulative doses of bleomycin). After complete resection of 'vital' tumour < 10% of the total volume, especially in patients with an initially good prognosis group according to IGCCCG, the relapse rate is vey low and adjuvant chemotherapy is not beneficial for preventing further relapse. The prognosis will definitely deteriorate if vital malignant neoplasm is found in resection specimens after second- and third-line chemotherapy. In this latter situation, post-operative chemotherapy is not indicated and is unable to improve the prognosis (235,240).

7.4 Systemic salvage treatment for relapse or refractory disease

Cisplatin-based combination salvage chemotherapy will result in long-term remissions for about 50% of the patients who relapse after first-line chemotherapy (254). The regimens of choice are four cycles of PEI/VIP (etoposide, ifosfamide, cisplatin), four cycles of TIP (paclitaxel, ifosfamide, cisplatin) or four cycles of VeIP (vinblastine, ifosfamide, cisplatin) (Table 9).

A randomised trial showed no benefit in progression-free survival nor overall survival in patients treated with 3 cycles of VeIP plus 1 cycle of high-dose chemotherapy, compared with 4 cycles of VeIP (255). At present, it is impossible to determine whether conventionally dosed cisplatin-based combination chemotherapy is sufficient as first-salvage treatment or whether early intensification of first-salvage treatment with high-dose chemotherapy should be attempted. However, there is evidence from large retrospective analyses that there are different prognostic groups in case of relapse after first line chemotherapy (256-258). An international randomised trial of high-dose versus conventional dose chemotherapy in patients with first-line relapse is planned. It is therefore of the utmost importance that these rare patients are treated within clinical trials and at experienced centres.

Table 9: Standard PEI/VIP, TIP and VeIP chemotherapy (interval 21 days)

Chemotherapy agents	Dosage	Duration of cycles
PEI/VIP	20 mg/m^2	Days 1-5
Cisplatin*	75-100 mg/m^2	Days 1-5
Etoposide	1.2 g/m^2	Days 1-5
Ifosfamide†		
TIP		
Paclitaxel	250 mg/m^2 [xx]	24 hour continuous infusion day 1
Ifosfamide†	1.5 g/ m^2	Days 2-5
Cisplatin*	25 mg/m^2	Days 2-5
VeIP		
Vinblastin	0.11 mg/kg	Days 1 + 2
Ifosfamide†	1.2 g/m^2	Days 1-5
Cisplatin*	20 mg/m^2	Days 1-5

PEI/VIP = cisplatin, etoposide, ifosfamide; TIP = paclitaxel, ifosfamide, cisplatin; VeIP = vinblastine, ifosfamide, cisplatin.
**Plus hydration.*
†Plus mesna protection.
[xx] An MRC schedule uses paclitaxel at 175mg/m2 in a 3 hour infusion (259).

Conventionally dosed salvage chemotherapy may achieve long-term remissions in 15-40% of patients, depending on individual risk factors (207,260-262).

The IGCCCG-2 prognostic score comprised of 7 important factors as listed in Table 10 (seminoma vs. non-seminoma histology, primary tumour site, response to initial chemotherapy, duration of progression-free interval, AFP marker level at salvage, HCG marker level at salvage, and the presence of liver, bone, or brain metastases at salvage). Using these factors, 5 risk groups (very low risk = -1 points; low risk = 0 points; intermediate-risk = 1-2 points, high risk = 3-4 points; and very high risk ≥5 points) were identified with significant differences in PFS and OS. Table 9 illustrates the 5 risk groups and the corresponding 2-year PFS and 3-year OS rates (263).

Table 10: IGCCCG-2 (Lorch-Beyer) Score Construction (257)

Points Variable	-1	0	1	2	3
Histology	Seminoma	Non-seminoma			
Primary site		Gonadal	Retroperitoneal		Mediastinal
Response		CR/PRm-	PRm+/SD	PD	
PFI		> 3 months	3 months		
AFP salvage		Normal	< 1000	1000	
HCG salvage		< 1000	1000		
LBB		No	Yes		

AFP = alpha-fetoprotein; hCG = human chorionic gonadotropin; IGCCCG = International Germ Cell Cancer Collaborative Group; LBB = alkaline extract of L. barbarum; PFI = platinum-free interval.

Table 11: PFS and OS estimates for all patients according to IGCCCG-2 prognostic score (257)

	N	%	HR	2-years PFS	3-years OS
Score (N=1435)					
Very Low	76	5.30	1	75.1	77.0
Low	257	17.9	2.07	52.6	69.0
Intermediate	646	45.0	2.88	42.8	57.3
High	351	24.5	4.81	26.4	31.7
Very High	105	7.3	8.95	11.5	14.7
Missing	159				

IGCCCG = International Germ Cell Cancer Collaborative Group; OS = overall survival; PSF = progression-free survival.

Salvage therapy with VeIP is probably not superior to other conventionally dosed cisplatin-based combination regimens (250,253,254). Recently, paclitaxel and gemcitabine have proved to be active in the treatment of refractory germ cell tumours; both drugs are synergistic with cisplatin (264-266).

Depending on the presence of adverse prognostic factors, the results of salvage therapy after first-line cisplatin-based treatment are unsatisfactory (207,267). Although some phase II trials indicate a 10% improvement in survival with early intensification of first-salvage treatment using high-dose chemotherapy, others fail to demonstrate such improvement (259,268-271).

High dose chemotherapy offered no advantage as first salvage treatment according to the results of the randomised IT 94 trial in good prognosis patients (255). Patients with good prognostic features should therefore be offered conventional-dose first salvage treatment. However, several phase II trials, as well as one retrospectively matched pair-analysis, have shown an improvement in survival in poor-prognosis patients with early intensification of first-salvage treatment using high-dose chemotherapy (256,261,272,273). All of these patients should, if possible, be entered into ongoing studies to define the optimal approach to salvage treatment, and should be referred to centres experienced in caring for relapse and/or refractory patients (274,275).

*7.4.3 **Late relapse (≥ 2 years after end of first-line treatment)***

Late relapse is defined as any patient relapsing more than 2 years following chemotherapy for metastatic nonseminoma. If technically feasible, all nonseminoma patients with late relapse should undergo immediate radical surgery of all lesions, irrespective of the level of their tumour markers to resect completely all undifferentiated germ-cell tumour, mature teratoma or secondary non-germ cell cancer (139,276). Patients with rapidly rising HCG may present an exception for immediate surgery and may benefit from induction salvage chemotherapy before complete resection. If the lesions are not completely resectable, biopsies should be obtained for histological assessment, and salvage chemotherapy should be initiated according to the histological results. In these cases consultation of an experimented pathologist is required to avoid misinterpretation of the therapeutic morphological changes in the germ cell neoplasms (277). If the patient responds to salvage chemotherapy, secondary surgery should be conducted whenever possible. In the case of unresectable, but localised, refractory disease, radiotherapy can be considered. To avoid excess mortality, late relapses should be treated only at centres experienced in managing such patients (278).

7.5 Salvage surgery

Residual tumours after salvage chemotherapy should be resected if possible. In the case of marker progression after salvage treatment and a lack of other chemotherapeutic options, resection of residual tumours ('desperation surgery') should be considered if complete resection of all tumour seems feasible (about 25% long-term survival may be achieved) (206,232,240,243,279-288).

7.6 Treatment of brain metastases

Brain metastases occur in the frame of a systemic relapse and rarely as an isolated relapse. The long-term survival of patients presenting with brain metastases at initial diagnosis is poor (30-40%), but even poorer is the development of a brain metastasis as a recurrent disease (the 5-year survival-rate is 2-5%) (289,290). Chemotherapy is the initial treatment in this case, and some data support the use of consolidation radiotherapy, even in the case of a total response after chemotherapy (291). Surgery can be considered in the case of a persistent solitary metastasis, depending on the systemic state, the histology of the primary tumour and the location of the metastasis.

7.7 Guidelines for the treatment of metastatic germ cell tumours

	GR
1. Low volume NSGCT stage IIA/B with elevated markers should be treated like 'good or intermediate prognosis' advanced NSGCT, with three or four cycles of PEB.	A
2. In stage IIA/B witout marker elevation, histology can be gained by RPLND or biopsy. A repeat staging can be performed after six weeks of surveillance before final decision on further treatment.	B
3. In metastatic NSGCT (> stage IIC) with a good prognosis, three courses of PEB is the primary treatment of choice.	A
4. In metastatic NSGCT with an intermediate or poor prognosis, the primary treatment of choice is four courses of standard PEB and inclusion in clinical trials is strongly recommended.	A
5. Surgical resection of residual masses after chemotherapy in NSGCT is indicated in the case of visible residual masses and when serum levels of tumour markers are normal or normalising.	A
6, Seminoma CSII A/B can initially be treated with radiotherapy. When necessary, chemotherapy can be used as a salvage treatment with the same schedule as for the corresponding prognostic groups of NSGCT.	A
7. In seminoma stage CS IIB, chemotherapy (4 x EP or 3 x PEB, in good prognosis) is an alternative to radiotherapy. It appears that 4 x EP or 3 x PEB achieve a similar level of disease control.	B
8. Seminoma stage IIC and higher should be treated with primary chemotherapy according to the same principles used for NSGCT.	A

EP = eposide, cisplatin; GR = grade of recommendation; NSGCT = non-seminomatous germ cell tumour; PEB = cisplatin, eposide, bleomycin; RPLND = retroperitoneal lymph node dissection.

8. FOLLOW-UP AFTER CURATIVE THERAPY

8.1 General considerations

The selection of the test to be performed in follow-up should adhere to the following principles (292).

- The interval between examination and duration of testing should be consistent with the time of maximal risk of recurrence and the natural history of the tumour.
- The tests should be directed at the most likely sites of recurrence and should have a high predictive value, both positive and negative.
- Therapy should be available that will result in cure of the recurrence, significant prolongation of life or palliation of symptoms. The initiation of earlier therapy should improve the outcome compared with therapy given when the patient becomes symptomatic from the tumour recurrence.
- The increased risk of second malignancy, both in the primary site and in other tissues that may have been exposed to the same carcinogens, or in which there is epidemiological evidence of increased risk, should also guide the ordering tests. Malignant and non-malignant complications of therapy must also be considered. Such testing should also be performed with a frequency and duration consistent with the nature of the risk, and include only tests with high positive- and negative-predictive values.

The following considerations apply in a general manner for the selection of an appropriate schedule and testing in the follow-up of all stages of testis tumour.

- Most recurrences after curative therapy will occur in the first 2 years; surveillance should therefore be most frequent and intensive during this time.
- Late relapses can occur beyond 5 years, and therefore yearly follow-up for life may be advocated.
- After RPLND, relapse in the retroperitoneum is rare, the most likely site of recurrence being the chest.
- The value of chest X-ray has been recently questioned in the follow-up of patients with disseminated disease after complete remission (293,294).
- CT of the chest has a higher predictive value than chest X-ray (294).
- The results of therapy are dependent on the bulk of disease; thus an intensive strategy to detect asymptomatic disease may be justifiable.
- After chemotherapy or radiotherapy, there is a long-term risk of the development of secondary malignancies.
- Exposure to diagnostic X-rays causes second malignancies (295). Thus, the frequency of CT-scans

should generally be reduced and any exposure to X-rays should be well justified in a patient cohort with a very long life-expectancy after successful treatment.

- In specialised centres, CT can be substituted by MRT. However, MRT is a protocol-dependent method and, thus, should be performed in the same institution with a standardized protocol.
- With special expertise, ultrasound may be used as a method to screen the retroperitoneum during follow-up. However, the method is very much dependent on the investigator and cannot be recommended as general method during follow-up.
- Longer follow-up in patients after radiotherapy and chemotherapy is justified to detect late toxicities (e.g. cardio-vascular, endocrine).

A number of interdisciplinary organisations have presented recommendations for follow-up of testicular cancer patients (296-298). The follow-up tables presented below (tables 12 through 15) present the minimum follow-up criteria and should therefore be considered as a GR A.

8.2 Follow-up: stage I non-seminoma

Approximately 5% of patients with CS1 NSGCT present with elevated levels of tumour markers after orchidectomy, and up to 25-30% relapse during the first 2 years (5,131,151,154,177,299-302).
The follow-up schedule will differ depending on which of the three possible treatment strategies was chosen:

- surveillance;
- nerve-sparing RPLND;
- adjuvant chemotherapy.

*8.2.1 **Follow-up investigations during surveillance***

The results of a surveillance policy depend upon a careful pre-operative staging procedure and follow-up management. In a 'wait and see' policy, relapses will occur in 30% of cases. Of these relapses, 80% will occur in the first 12 months after orchidectomy, and approximately 12% during the second year. The median time to relapse is 6 months (range 1-62 months), but relapses after 3-5 years, and even later, can still occur, with an annual rate of 4% (112,113). Relapse occurs mainly in the retroperitoneum: approximately 70% of patients have evident metastases in the retroperitoneum, and 10% in the mediastinum and lungs (303). Sometimes the only indication is an elevated level of tumour markers.

A randomised trial of two versus five CT scans has been published by the MRC recommending the reduction of imaging during surveillance in this stage to one CT scan at 3 months after orchidectomy, and another at 12 months. The trial, with a cohort of 414 patients, was powered to exclude a 3% probability of detecting a patient during surveillance only, with a relapse presenting already-metastatic disease with 'intermediate' or 'poor' prognosis features. Relapses were detected in 15% with two CTs, and 20% with five CTs; 1.6% of these patients had 'intermediate' or 'poor' prognosis features. Only 10% of patients had high-risk features (vascular invasion). In summary, this first randomised trial yielded level 1 evidence for a minimum follow-up in patients with CS1 non-seminoma (141). The recommended follow-up schedule (Table 12) includes the minimum requirements for imaging, and adds recommendations for other surveillance tests.

Table 12: Recommended follow-up schedule in a surveillance policy: stage I non-seminoma

Procedure	**Year**			
	1	**2**	**3-5**	**6-10**
Physical examination	4 times	4 times	Once/year	Once/year
Tumour markers	4 times	4 times	Once/year	Once/year
Chest X-ray	Twice	Twice		
Abdominopelvic CT scan	Twice (at 3 and 12 months)			

CT= computed tomography scan.

During the initial post-treatment phase, follow-up consists of regular clinical examinations, the monitoring of serum tumour markers, and imaging investigations. The frequency and type of the examinations depend on the estimated risk of relapse, the chosen treatment strategy, and the time that has elapsed since completion of therapy, and should be modified according to these risks. However, only limited information about the optimal follow-up strategy exists, and currently recommendations can only be given for seminoma (304).

For low-risk stage I non-seminoma, two abdominopelvic CT scans during the first year seem sufficient

to detect relapses at an early stage (141). The significance of additional CT scans remains uncertain. No studies are available that address the optimal monitoring of such patients by serum tumour markers (AFP, beta-hCG).

*8.2.2 **Follow-up after nerve-sparing RPLND***

Retroperitoneal relapse after a properly performed nerve-sparing RPLND is rare. RPLND should eliminate the retroperitoneal nodes as a site of relapse and thus the need for repeated abdominal CT scans. The US Testicular Cancer Intergroup study data show retroperitoneal relapse in 7/264 patients with pathological stage I disease (and 20 pulmonary relapses); four of these seven had no marker elevation (305). In the Indiana series, only one relapse in 559 cases was reported (306). If a relapse occurs, it is generally in the chest, neck or at the margins of the surgical field.

Pulmonary relapses occur in 10-12% of patients, and more than 90% of those relapses occur within 2 years of RPLND (87,307). However, the low rate of retroperitoneal relapse after RPLND can only be achieved by surgery in specialised centres, as shown by the high in-field relapse rate (7/13 relapses) in the German randomised trial of RPLND versus one course of PEB (163). The recommended minimum follow-up schedule is shown in Table 13.

Table 13: Recommended follow-up schedule after retroperitoneal lymphadenectomy or adjuvant chemotherapy: stage I non-seminoma

Procedure	Year			
	1	**2**	**3-5**	**6-10**
Physical examination	4 times	4 times	Once/year	Once/year
Tumour markers	4 times	4 times	Once/year	Once/year
Chest X-ray	Twice	Twice		
Abdominopelvic CT scan	Once	Once		

CT = computed tomography scan.

*8.2.3 **Follow-up after adjuvant chemotherapy***

Prospective reports with long-term follow-up after adjuvant chemotherapy have shown a low relapse rate (131,132,299,300) of about 3%. In a randomised trial with one course of PEB versus RPLND, the relapse rate with adjuvant chemotherapy was 1% (2/174 patients, one with marker relapse, one with mature teratoma in the retroperitoneum) (163). The need for repeated and long-term assessment of the retroperitoneum is still not clear. Owing to the risk of developing a late, slow-growing teratoma in the retroperitoneum after adjuvant chemotherapy, an abdominal CT should still be performed (see Table 13).

8.3 Follow-up: stage I seminoma

The majority of patients with seminoma (70-80%) present with clinical stage I disease at diagnosis. In 15-20% of cases, there is nodal radiological involvement at the level of the retroperitoneum, and only 5% of patients present with distant metastasis.

The relapse rate varies between 1% and 20%, depending on the post-orchidectomy therapy chosen. Only up to 30% of seminomas present with elevation of hCG at diagnosis or in the course of the disease. Consequently, in most cases, measurement of blood markers will not be a reliable test for follow-up (308). The treatment options post-orchidectomy in stage I seminoma are retroperitoneal radiotherapy, surveillance and adjuvant chemotherapy. Due to extreme radio- and chemosensitivity, high cure rates of almost 100% are reached with each of the approaches, even in cases of relapse. The costs of the different therapies vary, as do the expected side-effects (309-311).

*8.3.1 **Follow-up after radiotherapy***

Low doses of radiotherapy (20-24 Gy) limited to the retroperitoneal or the hockey-stick field achieve an overall survival rate of approximately 99% at 5-10 years (112-114,312,314). The rate of relapse is 1-2% and the most common time of presentation is within 18 months of treatment (112,115,311,314,315), although late relapses have also been described (316). The site of relapse is mainly at the supradiaphragmatic lymph nodes, mediastinum, lungs or bones. In a small proportion of cases, the tumour will relapse in the inguinal or external iliac nodes. After para-aortic field RT there is also a pelvic node relapse pattern.

The side-effects of radiotherapy include temporary impaired spermatogenesis, GI symptoms (peptic ulceration), and induction of second malignancies (311,317,318). Up to 50% of patients can develop moderate toxicity grade I-II (308). The schedule of follow-up is described in Table 14.

Table 14: Recommended follow-up schedule for post-orchidectomy surveillance, radiotherapy or chemotherapy: stage I seminoma

Procedure	Year			
	1	2	3-4	5-10
Physical examination	3 times	3 times	Once/year	Once/year
Tumour markers	3 times	3 times	Once/year	Once/year
Chest X-ray	Twice	Twice		
Abdominopelvic CT scan	Twice	Twice		

CT = computed tomography scan.

*8.3.2 **Follow-up during surveillance***

The actuarial risk of relapse at 5 years ranges between 6% (low risk) and 20% (118,329-323). There is no increased risk of death. The median time to relapse ranges from 12-18 months, but up to 29% of relapses can develop later than this (102,324). The sites of relapse are the PA lymph nodes in up to 82% of cases; the pelvic lymph nodes, inguinal nodes and lungs can also be affected (102,137,325-328). Due to the high and often late rate of relapse, close and active follow-up is mandatory for at least 5 years (329) (see Table 14).

*8.3.3 **Follow-up after adjuvant chemotherapy***

One or two courses of carboplatin-based chemotherapy is an effective alternative treatment in stage I seminoma. The relapse rate is 1.9-4.5%. In general, this treatment is well tolerated, with only mild, acute and intermediate-term toxicity (329,330). Long-term data on late relapses and survival are missing (see Table 14).

8.4 Follow-up: stage II and advanced (metastatic) disease

The more advanced the nodal stage of the disease, the higher the likelihood of recurrence (158). In general, the primary tumour bulk governs the outcome for patients with NSGCT (331). In stage II NSGCT, regardless of the treatment policy adopted, excellent survival rates of 97% are reached provided that relapse is identified as soon as possible (171,172,178).

In advanced metastatic germ cell tumours, the extent of the disease is correlated with the response to therapy and with survival. The combination of cisplatin-based chemotherapy and surgery (aggressive multimodality) achieves cure rates of between 65% and 85%, depending on the initial extent of disease (332,333). Complete response rates to chemotherapy are in the order of 50-60% (332); another 20-30% of patients could be rendered disease-free with post-chemotherapy surgery (334).
The main reasons for failure of therapy in advanced NSGCT are (331,335,336):

- the presence of bulky disease not responding completely to chemotherapy;
- unresectable residual teratoma after chemotherapy;
- the presence or development of chemoresistant non-germ elements, which account for 8.2% of cases.

Table 15 presents the recommended minimum follow-up schedule in advanced NSGCT and seminoma.

Table 15: Recommended minimum follow-up schedule in advanced NSGCT and seminoma

Procedure	Year			
	1	2	3-5	Thereafter
Physical examination	4 times	4 times	Twice/year	Once/year
Tumour markers	4 times	4 times	Twice/year	Once/year
Chest X-ray	4 times	4 times	Twice/year	Once/year
Abdominopelvic CT scan*†	Twice	Twice	as indicated	as indicated
Chest CT scan†‡	As indicated	As indicated	As indicated	As indicated

Brain CT scan§	As indicated	As indicated	As indicated	As indicated

CT = computed tomography scan.

**Abdominal CT scanning must be performed at least annually if teratoma is found in the retroperitoneum.*
†If the post-chemotherapy evaluation in a seminoma patient shows any mass > 3 cm, the appropriate CT scan should be repeated 2 and 4 months later to ensure that the mass is continuing to regress. If available, FDG-PET scanning can be performed.
‡A chest CT scan is indicated if abnormality is detected on chest X-ray and after pulmonary resection.
§In patients with headaches, focal neurological findings, or any central nervous system symptoms.

9. TESTICULAR STROMAL TUMOURS

9.1 Background

Testicular stromal tumours are rare and account for only 2-4% of adult testicular tumours. However, only Leydig cell and Sertoli cell tumours are of clinical relevance. As no general recommendations have been published to date, the Testicular Cancer Working Group of the European Association of Urology (EAU) has decided to include these tumours in the EAU Germ Cell Tumour Guidelines. Recommendations for diagnosis and treatment are given only for Leydig and Sertoli cell tumours.

9.2 Methods

A Medline search for Leydig cell tumours (synonym: interstitial cell tumour) and Sertoli cell tumours (synonym: androblastoma) was performed. Approximately 850 papers were found. After excluding pure laboratory work without clinical data, female and paediatric tumours and animal cases, 371 papers and abstracts were reviewed. Double publications and papers with unclear histology or missing data on clinical course were excluded. The majority of the remaining 285 publications are case reports, with only a few papers reporting series of more than 10 cases, most of them published in the pathology literature. The true incidence of stromal tumours therefore remains uncertain, and the proportion of metastatic tumours can only be given approximately.

Nevertheless, the symptoms for pre-operative suspicion of testicular stromal tumours and the characteristics of tumours at high risk for metastases are sufficiently well established (LE: 2a/2b) to enable recommendations to be made regarding diagnosis and surgical approach. However, no recommendations for appropriate follow-up can be given due to the absence of follow-up data in most reported cases, and the fatal outcome of metastatic tumours, irrespective of the therapy chosen.

The individual publications have been rated according to level of evidence (see above).

The literature research for clinical data on Leydig cell tumours resulted in 193 publications dealing with more than 480 tumours in adults, including three publications (1-3) reporting larger series on a total of 90 patients. Follow-up data of more than 2 years are available for about 80 patients.

The literature research for clinical data on Sertoli cell tumours resulted in 93 publications dealing with more than 260 tumours in adults, including three publications (from the same group) (4-6) reporting on a total of 80 patients. Follow-up data of more than 2 years are available in fewer than 40 patients.

9.3 Classification

The non-germ cell tumours of the testicle include the sex cord/gonadal stromal tumours and the miscellaneous non-specific stromal tumours. The different histological subtypes of testicular tumours are defined according to the WHO classification 2004 (adapted) (7).

9.4 Leydig cell tumours

*9.4.1 **Epidemiology***

Leydig cell tumours constitute about 1-3% of adult testicular tumours (2,8) and 3% of testicular tumours in infants and children (8). The tumour is most common in the third to sixth decade in adults, with a similar incidence observed in every decade. Another peak incidence is seen in children aged between 3 and 9 years.

Only 3% of Leydig cell tumours are bilateral (2). Occasionally, they occur in patients with Klinefelter's syndrome (8).

9.4.2 ***Pathology of Leydig cell tumours***

Leydig cell tumours are the most common type of sex cord/gonadal stromal tumours. Histopathologically, they are well outlined and usually up to 5 cm in diameter. They are also solid, coloured yellow to tan, with haemorrhage and/or necrosis present in 30% of cases. Microscopically, the cells are polygonal, with eosinophilic cytoplasm with occasional Reinke crystals, regular nucleus, solid arrangement and capillary stroma. The cells express vimentin, inhibin, protein S-100, steroid hormones, calretinin and cytokeratin (focally) (7).

About 10% of Leydig cell tumours are malignant tumours, which present with the following parameters:

- large size (> 5 cm);
- cytological atypia;
- increased mitotic activity (> 3 per 10 high-power field [HPF]);
- increased MIB-1 expression (18.6% vs 1.2% in benign);
- necrosis;
- vascular invasion (9);
- infiltrative margins;
- extension beyond the testicular parenchyma;
- DNA aneuploidy (1,10).

9.4.3 ***Diagnosis***

Patients either present with a painless enlarged testis or the tumour is an incidental ultrasound finding. In up to 80% of cases, hormonal disorders with high oestrogen and oestradiol levels and low testosterone, increased levels of LH and FSH are reported (11,12), while negative results are always obtained for the testicular germ cell tumour-markers AFP, hCG, LDH and PLAP. Approximately 30% of patients present with gynaecomastia (13,14). Only 3% of tumours are bilateral (2). Leydig cell tumours must be distinguished from the multinodular tumour-like and often bilaterally occurring lesions of the androgenital syndrome (15).

Diagnostic work-up must include markers, hormones (at least testosterone, LH and FSH; if not conclusive, additionally oestrogen, oestradiol, progesterone and cortisol), ultrasound of both testes, and CT scan of chest and abdomen. On ultrasound, it may be possible to observe well-defined, small, hypoechoic lesions with hypervascularisation, but the appearance is variable and is indistinguishable from germ cell tumours (16,17). The proportion of metastatic tumours in all published case reports is only 10%. Within three larger series with longer follow-up, 18 metastatic tumours were found in a total of 83 cases (21.7%) (1-3). Histopathological signs of malignancy have been depicted above (see 4.2) (1,10). In addition, patients of older age have a greater risk of harbouring a tumour of malignant potential.

9.4.4 ***Treatment***

Asymptomatic testicular tumours of small volume are often misinterpreted as germ cell tumours, and inguinal orchidectomy is performed. It is highly recommended to perform an organ-sparing procedure in every small intraparenchymal lesion in order to obtain the histological diagnosis. Especially in patients with symptoms of gynaecomastia or hormonal disorders, a non germ-cell tumour should be considered and immediate orchidectomy avoided (18). In cases of germ cell tumour in either frozen (fresh tissue) section or paraffin histology, orchidectomy is recommended as long as a contralateral normal testicle is present.

In stromal tumours with histological signs of malignancy, especially in patients of older age, orchidectomy and retroperitoneal lymphadenectomy is recommended to prevent metastases (19). Without histological signs of malignancy, an individualised surveillance strategy after orchidectomy is recommended (CT follow-up may be most appropriate since specific tumour markers are not available).

Tumours that have metastasised to lymph nodes, lung, liver or bone respond poorly to chemotherapy or radiation and survival is poor (19).

9.4.5 ***Follow-up***

Recommendations for appropriate follow-up cannot be given because of the lack of follow-up data in most reported cases and the lethal outcome of metastatic tumours, irrespective of the therapy chosen.

9.5 Sertoli cell tumour

9.5.1 ***Epidemiology***

Sertoli cell tumours account for fewer than 1% of testicular tumours, and the mean age at diagnosis is around 45 years, with rare cases under 20 years of age (4,20). On rare occasions, these tumours may develop in patients with androgen insensitivity syndrome and Peutz-Jeghers syndrome.

*9.5.2 **Pathology of Sertoli cell tumours***

The tumour is well circumscribed, yellow, tan or white, with an average diameter of 3.5 cm (4). Microscopically, the cells are eosinophilic to pale with vacuolated cytoplasm. The nuclei are regular with grooves and there may be inclusions. The arrangement of the cells is tubular or solid; a cord-like or retiform pattern is possible. The stroma is fine and capillary, but in some cases a sclerosing aspect predominates. The cells express vimentin, cytokeratins, inhibin (40%) and protein S-100 (30%) (4).

The rate of malignant tumours ranges between 10% and 22%, and fewer than 50 cases have been reported (21-23). Signs of a malignant Sertoli tumour are:

- large size (> 5 cm);
- pleomorphic nuclei with nucleoli;
- increased mitotic activity (> 5 per 10 HPF);
- necrosis;
- vascular invasion.

9.5.2.1 Classification

Three subtypes have been described (20):

- the classic Sertoli cell tumour (4);
- the large cell calcifying form with characteristic calcifications (5,24);
- the rare sclerosing form (6,25).

*9.5.3 **Diagnosis***

Patients present either with an enlarged testis or the tumour is an incidental ultrasound finding (26). Most classic Sertoli tumours are unilateral and unifocal. Hormonal disorders are infrequent, although gynaecomastia is sometimes seen (4). The testicular tumour-markers AFP, hCG, LDH and PLAP are always negative.

Diagnostic work-up must include tumour markers, hormones (at least testosterone, LH and FSH; if not conclusive, additionally oestrogen, oestradiol, progesterone and cortisol), ultrasound of both testes and CT scan of chest and abdomen.

Sertoli cell tumours are generally hypoechoic on ultrasound, but they can be of variant appearance and therefore cannot be safely distinguished from germ cell tumours (20). Only the large cell calcifying form has a characteristic image with brightly echogenic foci due to calcification (27,28).

The large cell calcifying form is diagnosed in younger men and is associated with genetic syndromes (Carney's complex [29] and Peutz-Jeghers syndrome [30]) or, in about 40% of cases, endocrine disorders. A total of 44% of cases are bilateral, either synchronous or metachronous, and 28% show multifocality (24).

The characteristics of metastatic tumours have been depicted above (24,25). However, among patients whose tumours have been histopathologically classified as 'malignant' using these or similar characteristics (i.e. 18.8% of tumours in all reported cases), only 7% showed metastatic disease during follow-up.

In the largest series with the longest follow-up, 7.5% of patients had been classified as 'malignant' at primary diagnosis and 11.7% showed metastatic disease long-term (4). In general, affected patients are of higher age, tumours are nearly always palpable, and show more than one sign of malignancy (4).

Up to 20% of the large cell sclerosing form are malignant. There are some hints that discrimination between an early and late onset type may define a different risk for metastatic disease (5.5% compared with 23%) (20). Metastases in the infrequent sclerosing subtype are rare.

*9.5.4 **Treatment***

Testicular tumours of small volume, otherwise asymptomatic, are often misinterpreted as germ cell tumours and inguinal orchidectomy is performed. It is highly recommended to proceed with an organ-sparing approach in small intraparenchymal testicular lesions until final histology is available. Especially in patients with symptoms of gynaecomastia or hormonal disorders or typical imaging on ultrasound (calcifications, small circumscribed tumours), organ-sparing surgery should be considered. Secondary orchidectomy can be performed if final pathology reveals a non-stromal (e.g. germ cell) tumour. Organ-sparing surgical approaches are justified as long as the remaining testicular parenchyma is sufficient for endocrine (and in stromal tumours also exocrine) function.

In tumours with histological signs of malignancy, especially in patients of older age, orchidectomy and

retroperitoneal lymphadenectomy are recommended to prevent metastases (19). Without signs of malignancy, an individualised surveillance strategy after orchidectomy is recommended (CT scans may be most appropriate since specific tumour-markers are not available). Tumours metastasising to lymph nodes, lung or bone respond poorly to chemotherapy or radiation, and survival is poor.

9.5.5 ***Follow-up***

Recommendations for appropriate follow-up cannot be given because of the lack of follow-up data in most reported cases and the lethal outcome of metastatic tumours, irrespective of the therapy chosen.

9.6 Granulosa cell tumour

This is a rare tumour, with two variants: juvenile and adult.

- The juvenile type is benign. It is the most frequent congenital testicle tumour and represents 6.6% of all prepubertal testicular neoplasms. The cystic appearance is characteristic of this tumour type (31).
- With the adult type, the average age at presentation is 44 years. The typical morphology is of a homogeneous, yellow-grey tumour, with elongated cells with grooves in microfollicular and Call-Exner body arrangements.

Malignant tumours represent around 20% of cases. They are usually > 7 cm diameter. Vascular invasion and necrosis are features suggestive of malignant biology (32).

9.7 Thecoma/fibroma group of tumours

These tumours are very rare and benign (7).

9.8 Other sex cord/gonadal stromal tumours

Sex cord/gonadal stromal tumours may be incompletely differentiated or mixed forms.
There is limited experience with incompletely differentiated sex cord/gonadal stromal tumours and no cases of reported metastasis (7). In mixed tumour forms, all the histological components should be reported. However, the clinical behaviour is most likely to reflect the predominant pattern or the most aggressive component of the tumour (33).

9.9 Tumours containing germ cell and sex cord/gonadal stromal (gonadoblastoma)

If the arrangement of the germ cells are in a nested pattern and the rest of the tumour is composed of sex cord/gonadal stroma, the term gonadoblastoma is used. It is most frequent in gonadal dysgenesis with ambiguous genitalia. Bilateral tumours are present in 40% of cases. The prognosis is correlated with the invasive growth of the germinal component (34).

In the case of a diffuse arrangement of the different components, there are some doubts about the neoplastic nature of the germinal cells and some authors consider them to be entrapped rather than neoplastic (35).

9.10 Miscellaneous tumours of the testis

9.10.1 ***Tumours of ovarian epithelial types***

These tumours resemble the epithelial tumours of the ovary. A cystic appearance with occasional mucinous material can be observed. Microscopically, the aspect is identical to their ovarian counterparts, and their evolution is similar to that of the different epithelial ovarian subtypes. Some Brenner types can be malignant (7).

9.10.2 ***Tumours of the collecting ducts and rete testis***

These tumours are very rare. Benign (adenoma) and malignant (adenocarcinoma) have been reported, with malignant tumours showing local growth with a mortality rate of 56% (18).

9.10.3 ***Tumours (benign and malignant) of non-specific stroma***

These are very uncommon and have a similar criteria, prognosis and treatment as do the soft tissue sarcomas.

11. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive to the most common abbreviations.

AFP	alpha-fetoprotein
AUC	area under curve
Cg A	chromogranine A
CI	confidence interval
CS	clinical stage
CT	computed tomography
EAU	European Association of Urology
EBM	evidence-based medicine
EP	etoposide, cisplatin
EORTC	European Organisation for Research and Treatment of Cancer
FDG-PET	fluorodeoxyglucose-positron emission tomography
FSH	follicle-stimulating hormone
GI	gastrointestinal
G-CSF	granulocyte colony-stimulating factor
GR	grade of recommendation
hCG	human chorionic gonadotrophin
HPF	high-power field
IGCCCG	International Germ Cell Cancer Collaborative Group
LE	level of evidence
LH	luteinising hormone
LDH	lactate dehydrogenase
MRC	Medical Research Council
MRI	magnetic resonance imaging
NSGCT	non-seminomatous germ cell tumour
PA	para-aortic
PEB	cisplatin, etoposide, bleomycin
PEI	cisplatin, etoposide, ifosfamide
PET	positron emission tomography
PFS	progression-free survival
PS	pathological stage
PLAP	placental alkaline phosphatase
PVB	cisplatin, vinblastine, bleomycin
RPLND	retroperitoneal lymph node dissection
SWENOTECA	Swedish-Norwegian Testicular Cancer Project
Tin	testicular intraepithelial neoplasia
	pathological definition: undifferentiated intratubular germ cell carcinoma
TIP	paclitaxel, ifosfamide, cisplatin
TNM	Tumour Node Metastasis
UICC	International Union Against Cancer
ULN	upper limit of normal
VelP	vinblastine, ifosfamide, cisplatin
WHO	World Health Organization
VIP	(VP-16) etoposide, ifosfamide, cisplatin

Conflict of interest

All members of the Testicular Cancer Guidelines working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided

TABLE OF CONTENTS PAGE

1. INTRODUCTION

The European Association of Urology (EAU) Guidelines Group on Penile Cancer has prepared this guidelines document to assist medical professionals in the management of penile cancer. The guidelines aim to provide detailed, up-to-date information, based on recent developments in our understanding and management of penile squamous cell carcinoma (SCC). However, it must be emphasised that these guidelines provide an updated, but not yet standardised general approach to treatment and that they provide guidance and recommendations without legal implications.

Publication history information: The Penile Cancer Guidelines were first published in 2001 and updated in 2004 and 2009. The literature search for the 2009 update covered the period from October 2004 to December 2008. The reason to present such an early update can also be attributed to the recent publication of the 2009 Tumour Node Metastasis (TNM) classification which, for penile cancer, had remained unchanged since 1987. Additionally, this update allowed inclusion of relevant new references.

2. METHODOLOGY

A systematic literature search on penile cancer was performed by all members of the EAU Penile Cancer Working Group which covered the period between October 2004 and December 2008. At the onset of the project, each member was assigned one or two topics in accordance with their particular expertise. Each panel member was teamed up with another panel member who acted as a reviewer of a section. The panel decided to avoid rare diseases and to restrict the guidelines to SCC only. Since new publications became available in the first 3 years, the initial literature acquisition resulted in a first draft for discussion in 2008. This document was reviewed and updated by the panel and published in the 2009 edition of the EAU guidelines book and as an ultra-short (pocket) edition at the EAU Annual Congress in Stockholm, Sweden. For this 2010 print, the results of the updated search performed by the panel for their scientific publication (1) covering the period between December 2008 and December 2009 was supplemented by a second search with a cut-off date of March 2010.

To date the physician data query on 'Penile Cancer Treatment' (Health Professional Version) published by the National Cancer Institute, National Institutes of Health in Bethesda, MD, USA (2), remains the only evidence-based, peer-reviewed document available. No randomised controlled trials or Cochrane reviews have been published.

References used in the text have been assessed according to their level of scientific evidence (Table 1), and guideline recommendations have been graded (Table 2) according to the Oxford Centre for Evidence-based Medicine Levels of Evidence (3). The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given. As a result of the lack of randomised studies, the levels of evidence (LE) and grades of recommendation (GR) provided in the document are low.

Additionally, a quick reference guide is available. All texts can be viewed and downloaded for personal use at the society website: http://www.uroweb.org/guidelines/online-guidelines/.

Table 1: Level of evidence*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

**Modified from Sackett et al. (3).*

Table 2: Grade of recommendation*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett et al. (3).*

3. DEFINITION OF PENILE CANCER

Penile cancer is a relatively rare SCC. It usually originates in the epithelium of the inner prepuce and glans. It shares similar pathology and natural history with SCC of the oropharynx, female genitalia (cervix, vagina and vulva), and anus. Phimosis, poor hygiene, and smoking are the major risk factors for penile cancer. Typing has been done of the human papillomaviruses (HPVs) that are responsible for the sexual transmission of genital warts, condyloma acuminata, and SCC.

An improved understanding of the natural history of the disease, earlier diagnosis, better technology, research group collaboration, and centralisation of patients in centres of excellence has improved the cure rate for penile cancer from 50% in the 1990s to 80% in recent years.

4. EPIDEMIOLOGY

In Western countries, primary malignant penile cancer is uncommon, with an incidence of less than 1.00 per 100,000 males in Europe and the United States (1,2). However, there are significant geographical variations, within Europe (Figure 1) reporting an incidence greater than 1.00 per 100,000 men (3). Incidence is also affected by race and ethnicity in North America (1), with the highest incidence of penile cancer found in white Hispanics (1.01 per 100,000), followed by Alaskan, Native/American Indians (0.77 per 100,000), Blacks (0.62 per 100,000) and white non-Hispanics (0.51 per 100,000).

In contrast, in the non-Western world, the incidence of penile cancer is much higher and can represent 10-20% of malignant diseases in men ranging from an age-adjusted incidence of 0.7-3 per 100,000 people in India to 8.3 per 100,000 men in Brazil, and even higher in Uganda, where it is the most commonly diagnosed cancer.

Important risk factors include social and cultural habits, and hygienic and religious practices (4). Penile carcinoma is rare in communities that practise circumcision in newborns or before puberty (Jews, Muslims, and the Ibos of Nigeria). Early circumcision reduces the risk of penile cancer by 3-5 times. Adult circumcision does not protect against penile cancer.

In the USA, the overall age-adjusted incidence rate decreased considerably between 1973 and 2002 from 0.84 per 100,000 in 1973-1982 to 0.69 per 100,000 in 1983-1992, and further to 0.58 per 100,000 in 1993-2002 (1). In European countries, the incidence during the 1980s and 1990s was stable or increased only slightly (2). Incidence increases with age (2); however, the disease has been reported in younger men and even in children in non-western countries (3).

Figure 1: Annual incidence rate (world standardised) by European region/country*

5. RISK FACTORS AND PREVENTION

Risk factors for penile cancer were identified by the Karolinska Institute based on a Medline search of published literature from 1966 to 2000 (1). Strong risk factors (OR > 10) identified by case-control studies included (LE: 2a):

- Phimosis;
- Chronic inflammatory conditions, e.g. balanoposthitis, lichen sclerosus, and atrophicus (balanitis xerotica obliterans);
- Treatment with sporalene and ultraviolet A photochemotherapy.

Sexual history (multiple partners, early age of first intercourse) and a self-reported history of condylomata are associated with a 3-5-fold increased risk of penile cancer. Smoking is also a risk factor. Cervical cancer in female sexual partners is not consistently associated with penile cancer in their male partners.

In many case series, HPV DNA has been identified in 70-100% of intraepithelial neoplasia and in 40-50% of cases with invasive penile cancer. These results have been confirmed by a population-based case-control study (2). Among men not circumcised in childhood, phimosis was strongly associated with the development of invasive penile cancer (OR: 11.4; 95% CI: 5.0-25.9) and cigarette smoking was associated with a 4.5-fold increased risk (95% CI: 2.0-10.1). Human papillomavirus DNA was detected in 80% of tumour specimens and 69% were positive for HPV-16 (LE: 2a).

Smegma as a carcinogen has been clearly excluded (3). The risk of cancer of the vulva, vagina, penis, and anus is increased in patients with condyloma acuminata (4) (LE: 2b).

Human papillomavirus-16 and 18 have a causal role in 70% of cancers of the cervix, vagina, and anus and 40-50% of cancers of the vulva, penis, and oropharynx. Other cofactors are very likely to be necessary for progression from HPV infection to cancer (5). Verrucous carcinoma is not related to HPV infection (6).

In June 2006, the US Food and Drug Administration (FDA) licensed the first vaccine to prevent cervical cancer and other HPV-associated diseases in women (7). The vaccine protects against infection with HPV-6, 11, 16 and 18, which together are responsible for 70% of cervical cancers and 90% of genital warts.

Human papillomavirus is highly transmissible, with a peak incidence soon after the onset of sexual activity. The recommended age for vaccination in girls is 11-12 years (8), with catch-up vaccination recommended in females aged 13-26 years.

However, vaccination is not a substitute for routine cervical cancer screening and vaccinated women should continue to have cervical cancer screening. Vaccination against HPV has also been recommended in men (9). Although one study has found that mid-adult women (≥ 25 years) have a high level of acceptance of HPV vaccination (10), only 33% of men wanted the HPV vaccine, 27% did not, and 40% were undecided (11). It has been decided that vaccination in men must wait for results of female HPV vaccination (12).

Interestingly, the presence of high-risk HPV DNA in penile cancer does not compromise prognosis.

An early study has found no difference between HPV DNA-negative and -positive patients for lymph node metastases and 10-year survival rate (13). In a more recent study (14), disease-specific 5-year survival in the high-risk HPV-negative group was 78% versus 93% in the high-risk HPV-positive group (log rank test P = 0.03). This suggests the presence of high-risk HPV confers a survival advantage in patients with penile cancer. The virus plays an important role in oncogenesis through interaction with oncogenes and tumour suppressor genes (P53 and Rb genes) (15).

6. TNM CLASSIFICATION AND PATHOLOGY

6.1 TNM classification

The new 2009 TNM classification for penile cancer (1) includes a change for the T1 category (Table 3). This classification needs a further update for the definition of the T2 category*. Two recent publications have shown that the prognosis for corpus spongiosum invasion is much better than for corpora cavernosa invasion (2,3).

Table 3: 2009 TNM clinical and pathological classification of penile cancer

Clinical classification	
T - Primary tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis	Carcinoma *in situ*
Ta	Non-invasive verrucous carcinoma, not associated with destructive invasion
T1	Tumour invades subepithelial connective tissue
T1a	Tumour invades subepithelial connective tissue without lymphovascular invasion and is not poorly differentiated or undifferentiated (T1G1-2)
T1b	Tumour invades subepithelial connective tissue without with lymphovascular invasion or is poorly differentiated or undifferentiated (T1G3-4)
T2 *	Tumour invades corpus spongiosum/corpora cavernosa
T3	Tumour invades urethra
T4	Tumour invades other adjacent structures
N - Regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No palpable or visibly enlarged inguinal lymph node
N1	Palpable mobile unilateral inguinal lymph node
N2	Palpable mobile multiple or bilateral inguinal lymph nodes
N3	Fixed inguinal nodal mass or pelvic lymphadenopathy, unilateral or bilateral
M - Distant metastasis	
M0	No distant metastasis
M1	Distant metastasis
Pathological classification The pT categories correspond to the T categories. The pN categories are based upon biopsy or surgical excision.	
pN - Regional lymph nodes	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Intranodal metastasis in a single inguinal lymph node
pN2	Metastasis in multiple or bilateral inguinal lymph nodes
pN3	Metastasis in pelvic lymph node(s), unilateral or bilateral or extranodal extension of regional lymph node metastasis
pM - Distant metastasis	
pM0	No distant metastasis
pM1	Distant metastasis
G - Histopathological grading	
GX	Grade of differentiation cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3-4	Poorly differentiated/undifferentiated

Rees et al. (2) have investigated 72 patients with T2 tumours. Local recurrence (35% vs. 17%) and mortality (30% vs. 21%) rates were higher in patients with tunica or cavernosal involvement versus glands-only invasion after a mean follow-up of 3 years (LE: 2b). The authors have proposed defining T2a patients by spongiosum-only invasion and T2b patients by involvement of tunica or corpus cavernosum.

A retrospective analysis of the records of 513 patients treated between 1956 and 2006 has confirmed the above-mentioned difference between tumour invasion of the corpus spongiosum only versus corpus cavernosum (3). It also has confirmed that there are no differences in long-term survival between patients with T2 and T3 tumours, and no significant differences between N1 and N2 tumours in the 1987-2002 TNM classification (LE: 2a).

In the new UICC 2009 TNM classification (1), retroperitoneal node metastases are correctly and accurately defined as extraregional nodal and distant metastases. The difference between corpus spongiosum and corpora cavernosa invasion is not considered.

6.2 Pathology

Squamous cell carcinoma accounts for more than 95% of cases of malignant disease of the penis. Malignant melanoma and basal cell carcinoma are much less common. It is not known how often SCC is preceded by premalignant lesions (1-4). Although SCC is the most common penile neoplasia, different types and varying growth patterns have been identified (5-7) (Tables 4 and 5).

Table 4: Premalignant lesions

Lesions sporadically associated with SCC of the penis • Cutaneous horn of the penis • Bowenoid papulosis of the penis • Balanitis xerotica obliterans (lichen sclerosus et atrophicus)
Lesions at high risk of developing SCC of the penis (up to one-third transform to invasive SCC) • Penile intraepithelial neoplasia (carcinoma *in situ*): erythroplasia of Queyrat and Bowen's disease

Table 5: Penile SCC

Types of SCC • Classic • Basaloid • Verrucous and its varieties: - Warty (condylomatous) carcinoma - Verrucous carcinoma - Papillary carcinoma - Hybrid verrucous carcinoma - Mixed carcinomas (warty basaloid and adenobasaloid carcinoma) • Sarcomatoid • Adenosquamous
Growth patterns of SCC • Superficial spread • Nodular or vertical-phase growth • Verrucous

Differentiation grading systems for SCC

- Broders' grading system (8)
- Maiche's system score (9)

*6.2.1 **Penile biopsy***

There is no need for biopsy if:

- there is no doubt about the diagnosis and/or;
- treatment of the lymph nodes is postponed after treatment of the primary tumour and/or after histological examination of the sentinel node(s).

There is a need for histological confirmation if:

- there is doubt about the exact nature of the lesion (e.g. metastasis or melanoma) and/or;
- treatment of the lymph nodes is based on preoperative histological information (risk-adapted strategy).

In these cases an adequate biopsy is advised. When performing a biopsy, it is important to consider the findings from a study of biopsy size. Studies of biopsies with an average size of 0.1 cm found the following difficulties:

- difficulty in evaluating the extent of depth in 91% of biopsies;
- discordance between the grade at biopsy and in the final specimen in 30% of cases;
- failure to detect cancer in 3.5% of cases (1).

Thus, although a punch biopsy may be sufficient for superficial lesions, an excisional biopsy is preferred.

*6.2.2 **Pathological categories***

Traditionally, SCC has been considered as superficial or invasive. However, Cubilla et al. (5) have divided penile carcinoma into four categories:

- superficial spreading;
- vertical growth;
- verrucous;
- multicentric.

Different types of growth pattern have different prognoses (10) and different ways of dissemination. The limits of partial surgical resection must therefore be set according to the growth pattern at the time of evaluation of the frozen sections (11). If the margins are studied following these criteria (including urethral and periurethral tissue), only 3-4 mm of tumour-free tissue is sufficient to consider the surgical margins to be negative (12). Basaloid SSC is a cellular subtype that is better recognised than before, and it is highly aggressive (13).

*6.2.3 **Histology and metastatic risk***

Histological subtypes carry different risks of developing metastatic lymph nodes:

- Condylomatous: 18.2%;
- SCC: 56.7%;
- Sarcomatoid carcinoma: 89%.

Perineural (14) and lymphovascular invasion (14,15) are correlated with lymph node metastases, with 23.1% of positive lymph nodes associated with a nodular pattern, and 64.6% with an infiltrative pattern. Perineural invasion, lymphovascular invasion, and high histological grade appear to be the most important adverse pathological prognostic factors, reaching 80% mortality (15).

7. DIAGNOSIS AND STAGING

The primary tumour and regional lymph nodes must be staged correctly to enable the most appropriate treatment.

7.1 Primary lesion

Physical examination of a patient with penile cancer includes:

- diameter of the penile lesion or suspicious areas;
- location of lesion on the penis;
- number of lesions;
- morphology of lesion: papillary, nodular, ulcerous or flat;
- relationship of lesion to other structures, e.g. submucosa, tunica albuginea, and urethra;
- corpus spongiosum and corpus cavernosum;
- colour and boundaries of lesion;
- penis length.

Accurate histological diagnosis and staging of the primary tumour and regional nodes are necessary for making treatment decisions (1). In a small series, physical examination alone proved more reliable than imaging with ultrasound to judge infiltration into the corpora cavernosa (2). Artificial erection with prostaglandin E1 (alprostadil) in combination with magnetic resonance imaging (MRI) is helpful in excluding tumour invasion into the corpora cavernosa, and deciding whether limited surgery (e.g. glansectomy) can be performed (3,4).

7.2 Regional lymph nodes

*7.2.1 **Lymphatic drainage of the penis***

Primary lymphatic drainage of penile cancer occurs to the inguinal nodes. A recent single photon emission computed tomography (CT) study (5) has shown that all sentinel nodes were located in the superior and central inguinal zones, with most found in the medial superior zone. No lymphatic drainage was observed from the penis to the two inferior regions of the groin, and no direct drainage to the pelvic nodes was visualised. These findings confirm earlier studies (6-8).

*7.2.2 **Non-palpable nodes***

Careful inguinal physical examination is necessary. In the absence of palpable abnormalities, inguinal ultrasound (7.5 MHz) can reveal abnormal nodes and can be used as a guide for fine-needle aspiration biopsy (FNAB) (9,10). A sentinel node biopsy (SNB) (8) was not recommended until 10 years ago because of a high rate of false-negative results (25%, range: 9-50%) (11). However, recent reports have suggested that dynamic sentinel node biopsy (DSNB) using isosulphan blue and/or Tc99m-colloid sulphur improves survival compared to a 'wait-and-see' policy (LE: 3), and reduces side effects compared to those with inguinal lymphadenectomy (LAD) (12,13). Prospective studies on DSNB have obtained 100% specificity and 95% sensitivity (14-18) (LE: 2b). As analysis of dynamic SNB is operator-dependent (19) and relies on experience, the procedure is only available in a few centres. Nevertheless, a two-centre evaluation of DSNB has demonstrated the reproducibility of the technique, with a short learning curve (20).

Iliac lymph node metastases do not occur in the absence of inguinal metastases (19), therefore pelvic CT is not necessary in patients with no inguinal node metastases.

Conventional CT or MRI scans cannot detect micrometatases (21). No further studies have been performed to confirm the promising results reported with nanoparticle-enhanced MRI (22), but positron emission tomography (PET)/CT imaging can detect pelvic and distant metastases (23).

*7.2.3 **Risk factors and metastasis detection***

Patients with T1G1 category tumours do not need further therapy after local treatment, but in 13% up to 29% of cases those with intermediate T1G2 tumours can develop lymph node metastases (23,24). The risk for lymph node involvement can be evaluated by T and G categories and from other tumour characteristics.

Risk factors identified from retrospective studies include several pathological parameters, such as: perineural invasion, lymphovascular invasion, tumour depth or thickness, anatomical site, size and growth pattern, infiltrative front of invasion, positive resection margins, and urethral invasion (25). Several large series have identified lymphovascular invasion alone, lymphovascular invasion with absence of koilocytosis, lymphovascular invasion plus palpable inguinal nodes, and high histological grade plus perineural invasion as the most important risk factors (26-28).

Finally, the most adverse pathological prognostic factors appears to be lymphovascular invasion and high histological grade (28).

Nomograms have been used to evaluate the predictive value of clinical and pathological indicators, but pathological parameters and nomograms (23-30) cannot achieve more than 80% prediction (23-30). Only ^{18}fluorodeoxyglucose (FDG) PET/CT scanning can improve the detection of early regional and distant metastases (31).

*7.2.4 **Palpable nodes***

Palpable nodes should be described as follows:

- node consistency;
- node location;
- diameter of nodes or masses;
- unilateral or bilateral location;
- number of nodes identified in each inguinal area;
- mobile or fixed nodes or masses;
- relationship (e.g. infiltration or perforation) to other structures, such as the skin or cooper ligament;
- oedema of leg and/or scrotum.

Palpable lymph node metastases can be diagnosed using percutaneous FNAB (cytology and/or histology punction). At the time of diagnosis of penile cancer, as many as 50% of palpable inguinal nodes will be reactive for concomitant infection rather than due to lymph node metastasis. In contrast, during follow-up, nearly 100% of enlarged nodes are metastatic (32) (LE: 2b).

Thus, after allowing time for inflammatory reactions to subside, regional nodes should be evaluated within a few weeks after treatment of the primary tumour. Histological diagnosis can be done using fine-needle aspiration, tissue core, or open biopsy, according to the preference of the pathologist (32,33) (LE: 2b). In the case of a negative biopsy and clinically suspicious nodes, a repeat or excisional biopsy should be performed.

*7.2.5 **Conclusion***

Imaging techniques (e.g. CT and MRI) are widely used, but they are only useful for staging patients with centrimetrical, or lymph node metastases ≥ 1 cm. So far, no current imaging modality can identify microscopic invasion. Imaging using ^{18}FDG-PET/CT have some minor limitations (0.5 cm) (31). The use of molecular biological techniques is experimental (37-41).

7.3 Distant metastases

An assessment of distant metastases should be performed in patients with positive inguinal nodes (23-35) (LE: 2b). Positron emission tomography/CT is reliable for identification of pelvic and distant metastases in patients with positive inguinal nodes (31). Routine blood analysis and chest x-rays are usually performed, despite the fact that they have limited use and lung metastases are exceptionally rare. The value of SCC antigen determination as a staging tool is unclear and therefore not recommended for routine use (37). Biological studies are investigational (38-41).

A diagnostic schedule is summarised below.

7.4 Guidelines for the diagnosis and staging of penile cancer

Recommendations	**GR**
Primary tumour	C
Physical examination, recording morphological and physical characteristics of the lesion. Cytological and/or histological diagnosis.	
Inguinal lymph nodes	C
Physical examination of both groins, recording nodal morphological and physical characteristics: - If nodes are non-palpable, DSNB is indicated; if DSNB not available, ultrasound-guided FNAC/risk factors. - If nodes are palpable, FNAC for cytological diagnosis.	
Regional metastases (inguinal and pelvic nodes)	C
A pelvic CT scan/PET-CT scan is indicated in patients with metastatic inguinal nodes.	
Distant metastases (beside inguinal and pelvic nodes)	C
PET/CT scan also allows evidence of distant metastasis. If PET/CT is not available, abdominal CT scan and chest x-ray are advisable, and in symptomatic M1 patients a bone scan is also advisable.	
Biological laboratory	C
Determinations for penile cancer are investigational and not for clinical use.	

CT = computed tomography; DSNB = dynamic sentinel node biopsy; FNAC = fine-needle aspiration cytology; PET = positron emission tomography.

8. TREATMENT

The primary tumour and regional lymph nodes are usually treated separately. Although it is important to avoid overtreatment, which can lead to loss of penile tissue and adverse effects of an unnecessary lymphadenectomy, it is essential to remove all cancerous tissue with healthy margins.

8.1 Primary tumour

Guidelines on treatment strategies for primary tumour in penile cancer are outlined in Table 6. For small lesions, a penis-preserving strategy is recommended (GR: B). There is a variety of treatment modalities, which have not been compared in a scientifically rigorous manner, and providing recommendations based on published data is therefore difficult. However, treatment choice is influenced by tumour size, its position on the glans or in the corpora cavernosa, and experience of the treating urologist. There are no documented differences in the local recurrence rate between surgery, laser therapy, and radiotherapy. Although conservative surgery improves quality of life, the risk of local recurrence is higher than after ablative surgery (27% vs. 5%). The pathological assessment of surgical margins is essential to guarantee tumour-free margins (1). Tumour-positive margins lead inevitably to local recurrence. Total removal of the glans (glansectomy) and prepuce does have the lowest recurrence rate among the treatment modalities for small penile lesions (2%) (2).

*8.1.1 **Categories Tis, Ta, and T1a***

Superficial lesions can be treated with one of the following penis-sparing techniques:	**LE**
Local excision with (or without) circumcision.	3
Laser therapy with CO_2 laser (peniscopically controlled) or neodymium:yttrium-aluminium-garnet (Nd:YAG) laser (3-5). Small recurrences can be retreated in the same way.	2b
Mohs' micrographic surgery (for verrucous carcinoma) (6).	3
Photodynamic and topical therapy with 5-fluorouracil (5-FU) or 5% imiquimod cream and other agents have been reported for superficial lesions with relatively high recurrence rates (7).	4

*8.1.2 **Category T1b tumours of the glans with deeper infiltration (> 1 mm)***

These tumours can be treated with the following techniques:	**LE**
Wide local (laser) excision plus reconstructive surgery or total glans resurfacing with or without skin transplantation (8).	2b
Neoadjuvant chemotherapy [vinblastine, bleomycin, and methotrexate (VBM)] followed by CO_2 laser excision and spontaneous glans re-epithelialisation (3).	2b
Radiotherapy (*see* section 8.1.7).	
Glansectomy (2,8-11).	2b

Conservative treatment may be less suitable in cases of multifocal lesions, which are responsible for 15% of recurrences. Total treatment of the glans surface combined with concomitant circumcision is recommended to avoid multiple recurrences (3) (GR: C).

Negative surgical margins are imperative when using penile-conserving treatments. Pathological assessment of the surgical margins is recommended (GR: C). In general, a margin of 3 mm is considered safe (1).

*8.1.3 **Category T2 (limited to the glans)***

Total glansectomy, with or without resurfacing of the corporeal heads, is recommended (8,10) (LE: 2b; GR: B). Radiotherapy is also an option (*see* section 8.1.7). Partial amputation should be considered in patients who are unfit for more conservative reconstructive surgery (11) (GR: C).

*8.1.4 **Local disease recurrence after conservative surgery***

A second conservative procedure is advised if there is no corpus cavernosum invasion (2-8) (GR: C). If there is a large or deep infiltrating recurrence, partial or total amputation is inevitable (11) (GR: B). For those cases a total phallic reconstruction should be considered (12,13).

*8.1.5 **Category T2 with invasion into the corpus cavernosum***

Partial amputation with a tumour-free margin is considered standard treatment (11) (GR: B). A surgical margin of 5-10 mm is considered safe (1). Reconstruction may alleviate the mutilation (10,12,13).

*8.1.6 **Categories T3 and T4***

These categories of patients are rare (e.g. 5% in Europe and 13% in Brazil) (13). Total penectomy with perineal urethrostomy is standard surgical treatment for T3 tumours (14) (GR: B). Spatulating the urethra is helpful in preventing stenosis. In more advanced disease (T4), neoadjuvant chemotherapy is advised, followed by surgery in responding patients (as for management of patients with fixed or relapsed inguinal nodes (*see* section 8.2.4) (GR: B). Otherwise, adjuvant chemotherapy or consolidating radiation is advised (GR: C; *see* sections 8.2.4 and 8.1.7).

*8.1.7 **Radiotherapy***

Radiotherapy of the primary tumour is an alternative organ-preserving approach with good results in selected patients with T1-2 lesions < 4 cm in diameter (15-18) (LE: 2b). Best results have been obtained with brachytherapy with local control rates ranging from 70-90% (15,17). Patients with lesions > 4 cm are not candidates for brachytherapy.

A minimum dose of 60 Gy is given for external radiotherapy combined with a brachytherapy boost, or brachytherapy alone (15-18). The penile preservation rate after radiotherapy is approximately 80%. Local failure rates after radiotherapy are higher than after partial penectomy, but salvage surgery can restore local control (16). The following complications are the most prevalent: urethral stenosis (20-35%), glans necrosis (10-20%), and late fibrosis of the corpora cavernosa (18) (LE: 3).

No scientifically sound recommendations can be given regarding surgical procedures versus radiotherapy. Institutional experience and available techniques play an important role in decision making.

*8.1.8 **Guidelines for treatment strategies for penile cancer***

Table 6 provides a graded treatment schedule, also including the level of the underlying evidence on which the recommendations are based.

Table 6: Treatment strategies for penile cancer

Primary tumour	**Conservative treatment is to be considered whenever possible**	**LE**	**GR**
Category Tis, Ta, T1a (G1, G2)	CO_2 or Nd:YAG laser surgery, wide local excision, glans resurfacing, or glans resection, depending on size and location of the tumour.	2b	C
	Mohs' micrographic surgery or photodynamic therapy for well differentiated superficial lesions (Tis, G1 Ta).	3	C
Categories: T1b (G3) and T2 (glans only)	Glansectomy, with or without tips amputation or reconstruction.	2b	B
Category T2 (invasion of the corpora)	Partial amputation.	2b	B
Category T3 (invasion of urethra)	Total amputation with perineal urethrostomy.	2b	B

Category T4 (other adj. structures)	Eligible patients: neoadjuvant chemotherapy followed by surgery in responders. Alternative: external radiation.	3	C
Local disease recurrence after conservative therapy	Salvage surgery, consisting of penis-sparing treatment in small recurrences.	2b	B
	Larger recurrence: some form of amputation.	2b	B
Radiotherapy	Organ-preserving treatment in selected patients with T1-T2 of glans or coronal sulcus, lesions < 4 cm.	2b	B
Chemotherapy	Neoadjuvant, before surgery.	3	C
	Palliation in advanced or metastatic disease.	3	C

CO_2 = carbon dioxide; Nd:YAG = neodymium:yttrium-aluminum-garnet.

8.2 Regional lymph nodes

Guidelines on treatment strategies for nodal metastases are presented in section 8.2.7. Lymphadenectomy is the treatment of choice for patients with inguinal lymph node metastases (GR: B). The procedure requires careful skin-flap management, meticulous lymph node dissection, prophylactic antibiotics, compression stockings, and early ambulation. Prolonged lymph leakage, leg and scrotal lymphoedema, skin-flap necrosis, and wound infection can occur in 30-70% of patients (14) (LE: 2b). Recent studies have shown a decrease in complications, which suggests that these procedures should be done by experienced surgeons (19).

*8.2.1 **Surveillance***

Surveillance can be recommended only in patients with Tis, Ta, and T1G1 tumours (14,19,20).

*8.2.2 **Management of patients with non-palpable inguinal nodes***

All non-invasive diagnostic procedures miss approximately 20% of microscopic metastases. Also, the sensitivity of a published nomogram does not exceed 80% (21) (LE: 2b). Various risk factors have been helpful in stratifying node-negative patients for lymph node dissection (14,19-21) (LE: 2b). This approach was the basis for the 2004 guideline recommendations for the management of clinically node-negative patients (22). In centres without sentinel node diagnostics, these recommendations can still be useful. In addition, T1G2 tumours should be considered intermediate risk, based on a recent analysis (23). The experience from Brazil can be used as a gold standard for survival rates that can only be attained by surgery (14,19). Only DSNB has better sensitivity (94%) (24) (LE: 2b).

To identify the sentinel nodes reliably, preoperative mapping is essential. Tc99m nanocolloid is injected the day before surgery, patent blue is injected, and a γ-ray detection probe is used intraoperatively. Complete inguinal LAD is performed only in tumour-positive patients. The current protocol has a sensitivity of 95% (24). The technique is now reproducible with a short learning curve (25) (GR: B).

Considering the rarity of the disease and possible improvements in diagnosis and treatment, centralisation of patients is recommended. Centralisation of patients with penile SCC in 10 centres in the United Kingdom allowed improvement in the cure of the disease within a few years (26).

*8.2.3 **Management of patients with palpable inguinal nodes***

Ultrasound-guided FNAB provides an excellent, rapid, and easy way to detect metastatic nodal involvement (27) (LE: 3). In suspected cases with tumour-negative findings, various strategies can be followed:
(1) antibiotics are given;
(2) FNAB is repeated;
(3) suspected nodes are surgically removed;
(4) inguinal LAD is performed. Dynamic sentinal node biopsy is not reliable in patients with palpable suspected nodes and should not be used (28) (LE: 3); DSNB can be used for the clinically uninvolved side and LAD is performed at the tumour-positive sites. Inguinal LAD has been shown to have significant morbidity and it is to be limited to positive sides.

In advanced cases, reconstructive surgery is often necessary for primary wound closure (29).
Modified inguinal LAD is associated with less morbidity, but reducing the field of dissection increases the possibility of false-negative results. Current knowledge on lymphatic drainage of the penis suggests that modified LAD should dissect at least the central and both superior Daseler's zones (30,31) (LE: 3).

There is no direct lymphatic drainage from penile tumours to the pelvic lymph nodes (30), therefore, pelvic LAD is not needed if there is no involvement of inguinal nodes or there is only one intranodal metastasis (14,19) (LE: 3).

In contrast, pelvic LAD is recommended if the node of Cloquet or two or more inguinal nodes

are involved. The rate of positive pelvic nodes was found to be 23% in cases with more than two positive inguinal nodes, and 56% for those with more than three positive inguinal nodes, or if there was extracapsular involvement in at least one inguinal node (14,19) (LE: 2b). Pelvic LAD can be performed as a secondary procedure.

If bilateral dissection is indicated, it can be performed though a midline suprapubic extraperitoneal incision. It is also important to avoid delay for LAD (31). Laparoscopy is not suitable for radical surgery.

*8.2.4 **Adjuvant chemotherapy***

Adjuvant chemotherapy after resection of nodal metastases has been reported in a few small heterogeneous series. Nevertheless, at the National Cancer Institute in Milan, Italy, a long-term disease-free survival (DFS) rate of 84% was obtained in 25 consecutive node-positive patients treated with 12 adjuvant weekly courses of VBM during the period 1979-1990 (32,33). This compares with a DFS rate of only 39% for 38 consecutive patients who underwent radical LAD, with or without complementary radiotherapy, in the period 1960-1978 (32).

Since 1991, category pN2-3 patients have received three courses of adjuvant cisplatin and 5-FU, with lower toxicity and even better results compared to VBM (33) (LE: 2b). Category pN1 patients do not need adjuvant chemotherapy (33) (LE: 2b).

*8.2.5 **Management of patients with fixed or relapsed inguinal nodes***

Upfront surgery is not recommended (GR: B) because cure is unlikely, survival is short, and the surgery is usually quite destructive. Upfront chemotherapy followed by surgery is promising, and these procedures should be performed by experienced medical oncologists and surgeons (14,32,33).

Multiple regimens have been used in a small number of patients. Cisplatin, methotrexate, and bleomycin (BMP) at Memorial Sloan-Kettering Cancer Center in New York have shown promising results, but a confirmatory study by the Southwest Oncology Group has reported unacceptable toxicity and only modest results (34).

Leijte et al. have reported on 20 patients with five different neoadjuvant chemotherapy regimens in the 1972-2005 period (36). Responders underwent post-chemotherapy surgery and achieved a 37% long-term survival rate. At the MD Anderson Cancer Center, combination therapy with paclitaxel, carboplatin or paclitaxel, cisplatin, and ifosfamide has been used in seven patients, followed by surgery (37). Four patients were long-term survivors (48-84 months) but none of the other three patients treated with BMP achieved significant remission.

A preliminary study on taxol combined with cisplatin and 5-FU has shown significant responses in five of six patients with fixed or relapsed inguinal nodes, but only the three who underwent post-chemotherapy surgery achieved durable complete remission (38).

Conclusion

Adjuvant chemotherapy is recommended in patients with pN2-3 tumours (33) (GR: C), and neoadjuvant chemotherapy followed by radical surgery is advisable in those with non-resectable or recurrent lymph node metastases (36-38) (GR: C).

*8.2.6 **The role of radiotherapy***

Prophylactic radiotherapy in patients with N0 tumours is not recommended (39) (GR: C) because of:

- failure to prevent the development of metastatic lymph nodes;
- complications of radiotherapy;
- more difficult follow-up due to fibrotic changes.

Adjuvant radiotherapy may improve locoregional control in patients with extensive metastases and/or extranodal spread, but control is achieved at the cost of severe side effects including severe oedema and pain (GR: C).

*8.2.7 **Guidelines for treatment strategies for nodal metastases***

Regional lymph nodes	**Management of regional lymph nodes is fundamental in the treatment of penile cancer**	**LE**	**GR**
No palpable inguinal nodes	Tis, Ta G1, T1G1: surveillance.	2a	B
	> T1G2: DSNB. (NB: Inguinal LAD if histology is positive).	2a	B
	If DSNB not available: risk factors / nomogram decision-making.	3	C

Palpable inguinal nodes	Ultrasound-guided FNAB (DSNB is unsuitable for palpable nodes).	2a	B
	Negative biopsy: surveillance (repeat biopsy).		
	Positive biopsy: inguinal LAD on positive side.		
	(NB: Modified LAD must include the central zone and both superior Daseler's zones).		
Pelvic nodes	Pelvic LAD if there is: extranodal metastasis; Cloquet node involved; > 2 inguinal node metastases.	2a	B
	Unilateral pelvic LAD if unilateral lymph node metastases with prolonged inguinal incision.	2b	B
	Bilateral pelvic LAD if bilateral inguinal metastases.	2a	B
Adjuvant chemotherapy	In patients with > 1 intranodal metastasis (pN2 pN3) after radical LAD, survival is improved by adjuvant chemotherapy (3 courses of cisplatin, fluorouracil [PF] chemotherapy).	2b	B
Patients with fixed or relapsed inguinal nodes	Neo-adjuvant chemotherapy is strongly recommended in patients with unresectable or recurrent lymph node metastases.	2a	B
	Taxanes seems to improve the efficacy of standard PF chemotherapy (or carboplatin).		
Radiotherapy	Curative radiotherapy may be used for primary tumours of the glans penis and sulcus < 4 cm or for palliation.	2a	B
	Prophylactic radiotherapy in clinical N0 patients is not indicated.	2a	B

DSNB = dynamic sentinel node biopsy; FNAB = fine-needle aspiration biopsy; LAD = lymphadenectomy.

9. FOLLOW-UP

Follow-up in penile carcinoma is important for several reasons:

- It enables early detection of recurrence, which is important because most local and/or loco-regional recurrences are potentially curable.
- It is the only way to assess treatment and anticipate early and late complications.
- It is important for patient (and physician) education.

A rational follow-up scheme requires an understanding of the patterns of recurrence. Preferably, follow-up should be introduced within the framework of a controlled study. Based on a retrospective study, a follow-up schedule for penile cancer has been published (1).

9.1 How to follow-up

The aim of follow-up is to detect local and/or regional recurrences because they can be cured. In contrast, metastases at distant sites are always fatal (2). Risk stratification for recurrence is also helpful. Traditional follow-up methods are inspection and physical evaluation. Modern ultrasound imaging is a useful adjunct, with promising results from new imaging modalities, such as PET/CT (3).

9.2 When to follow-up

The follow-up interval and strategies for patients with penile cancer are directed by the initial treatment of the primary lesion and regional lymph nodes. In the above-mentioned multicentre study (1), during the first 2 years of follow-up, the following occurred:

- 74.3% of all recurrences;
- 66.4% of local recurrences;
- 86.1% of regional recurrences;
- 100% of distant recurrences.

Of all recurrences, 92.2% occurred within the first 5 years (1). All recurrences after 5 years were

local recurrences or new primary lesions. Thus, an intensive programme of follow-up during the first 2 years is rational, with less intensive follow-up needed thereafter. In well-educated and motivated patients, follow-up can stop after 5 years, although they must continue to carry out regular self-examination.

9.3 Primary tumour

Local recurrence has been reported in up to 30% of patients treated with penis-preserving surgery, during the first 2 years following treatment. Local recurrence is more likely with all types of local therapy, that is, local resection, laser therapy, brachytherapy, Mohs' procedure, and associated therapies (1,4). However, in contrast to regional recurrence, local recurrence does not have an impact on survival (1,4).

Local recurrences are easily detected by the patient, his partner or doctor. Patient education is an important part of follow-up and the patient should be urged to visit a specialist if any changes are seen. Despite the fact that late local recurrences are well documented, it is reasonable to stop follow-up after 5 years, provided the patient will report local changes immediately (5). This is possible because life-threatening regional and distant metastases no longer occur, while recurrences that are local only are not life-threatening. The emphasis should be placed on patient self-examination. In patients who are unlikely to self-examine, long-term follow-up may be necessary.

Following penis-preserving treatment, a follow-up visit every 3 months is advised in the first 2 years. We then advise a follow-up visit every 6 months, provided that the patient and his partner have been well instructed to examine the penis regularly and to return if any abnormality is observed. It is important to stress that the patient must continue to carry out regular self-examination even after 5 years' follow-up. After amputation, a less frequent time interval of every 6 months is advised. The risk of local recurrence is no more than 5% (1,4).

9.4 Regional recurrences

Stringent follow-up is advised for the 2 years following surgery. This is because most regional recurrences occur within that time, whether a 'wait-and-see' policy has been followed or the patient has undergone SNB or inguinal LAD.

Previous follow-up recommendations have relied heavily on physical examination of the inguinal regions. However, experience with 'wait and see' and DSNB have shown that, despite intensive follow-up, regional recurrences have shown up unexpectedly (6). Ultrasound and immediate FNAB have been encouraging in finding occult metastases (6,7), and it seems reasonable to add ultrasound to physical examination.

Patients managed with a 'wait-and-see' policy have a higher risk of recurrence (9%) than patients staged surgically (2.3%), irrespective whether staging has been performed by LAD or DSNB. This finding only applies to patients without histopathological evidence of lymph node metastases.

Patients treated surgically because of lymph node metastases have an increased risk of recurrence (19%) (1). Based on these findings, a change in the follow-up scheme is proposed. For patients in a 'wait-and-see' programme and those treated with LAD for proven lymph node metastases, follow-up should be every 3 months and should include ultrasound investigation of the groin. This intensive follow-up programme should be observed for 2 years, which is the period when recurrence is most likely. Imaging using CT has been replaced by ultrasound scanning with immediate FNAB, and PET/CT is used in patients at risk of regional recurrence and distant metastases. Bone scan and other tests are only recommended in symptomatic patients.

9.5 Guidelines for follow-up in penile cancer

Table 7 provides a follow-up schedule for penile cancer with grades of recommendation.

Table 7: Follow-up schedule for penile cancer

	Interval of follow-up		**Examinations and investigations**	**Maximum duration of follow-up**	**GR**
	Years 1 and 2	Years 3, 4 and 5			
Recommendations for follow-up of the primary tumour					
Penile preserving treatment	3 months	6 months	Regular physician or self-examination	5 years	C
Amputation	6 months	1 year	Regular physician or self-examination	5 years	C
Recommendations for follow-up of the inguinal lymph nodes					
'Wait-and-see'	3 months	6 months	Regular physician or self-examination	5 years	C

pN0	6 months	1 year	Regular physician or self-examination Ultrasound with FNAB	5 years	C
pN+	3 months	6 months	Regular physician or self-examination Ultrasound with FNAB	5 years	C

FNAB = fine-needle aspiration biopsy.

10. QUALITY OF LIFE

10.1 Sexuality and fertility after cancer

As more people achieve long-term survival after cancer, sexual dysfunction and infertility are increasingly recognised as negative consequences that affect quality of life (1).

*10.1.1 **Sexual activity and quality of life after penile cancer laser treatment***

A retrospective, face-to-face, structured interview study was carried out on Swedish patients treated with laser for localised penile carcinoma during 1986 to 2000 (2). Sixty-seven patients were treated, with 58 of them (mean age 63 years) still alive in 2006. Forty-six (79%) agreed to participate in the interview. Nearly all patients could recall their first symptom, with 37% reporting that they delayed seeking treatment for > 6 months. Patients had a greater lifetime number of sexual partners and a greater lifetime prevalence of sexually transmitted infections than the comparable general Swedish population. Following laser treatment, there was a marked decrease in some sexual practices, such as manual stimulation or caressing and fellatio. Patient satisfaction with life overall was similar to that of the general population.

In conclusion, some patients delayed seeking treatment for a considerable period despite awareness of the first local symptoms. Men with laser-treated localised penile carcinoma resumed their sexual activities to a large extent. Except for satisfaction with somatic health, a similar (or higher) proportion of patients were satisfied with life overall and with other domains of life including their sex life.

*10.1.2 **Sexual function after partial penectomy for penile cancer***

To compare sexual function and satisfaction before and after partial penectomy, 18 Brazilian patients were given a personal interview and answered the International Index of Erectile Function questionnaire to determine erectile function, orgasmic function, sexual desire, intercourse satisfaction, and overall satisfaction with sexual activity (3). The median patient age was 52 years. The medium penile length after partial penectomy was

4 cm in the flaccid state, with 55.6% of patients reporting erectile function that allowed sexual intercourse. The main reason given for not resuming sexual intercourse in 50% of sexually abstinent patients was feeling shame because of a small penis and the absence of the glans penis. Surgical complications also compromised resumption of sexual activity after amputation in 33.3% of these patients. However, 66.7% sustained the same frequency and level of sexual desire prior to surgery, and 72.2% continued to have ejaculation and orgasm every time they had sexual stimulation or intercourse. Nevertheless, only 33.3% maintained their preoperative frequency of sexual intercourse and were satisfied with their sexual relationships with their partners and their overall sex life. In conclusion, the preoperative and postoperative scores were statistically worse for all domains of sexual function after partial penectomy.

10.2 Sexual mutilation, relapse, and death

Today, nearly 80% of penile cancer patients can be cured. Experience in management of this rare tumour is helpful (4). Referral to centres with experience is recommended. Psychological support is very important for these patients. Penis-sparing surgery obviously allows a better quality of life than penile amputation and must be considered whenever feasible.

11. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations.

5-FU	5-fluorouracil
BMP	cisplatin, methotrexate and bleomycin
CT	computed tomography
DFS	disease-free survival
DSNB	dynamic sentinel node biopsy
EAU	European Association of Urology
FDA	[US] Food and Drug Administration
FDG	fluorodeoxyglucose
FNAB	fine-needle aspiration biopsy
FNAC	fine-needle aspiration cytology
GR	grade of recommendation
HPV	human papillomavirus
LAD	lymphadenectomy
LE	level of evidence
MRI	magnetic resonance imaging
Nd:YAG	neodynium:yttrium-aluminum-garnet
PET	positron emission tomography
PF	cisplatin and fluorouracil
SCC	squamous cell carcinoma
SNB	sentinel node biopsy
TC99m	technetium 99m
TNM	tumour, node, metastasis
VBM	vinblastine, bleomycin, methotrexate

Conflict of interest

All members of the Penile Cancer Guidelines working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on

Management of Male Lower Urinary Tract Symptoms (LUTS), incl. Benign Prostatic Obstruction (BPO)

TABLE OF CONTENTS PAGE

1. INTRODUCTION

Lower urinary tract symptoms (LUTS) in elderly men were traditionally attributed to the enlarging prostate. The mechanisms invoked were one or all of the following: histological benign prostatic hyperplasia (BPH), benign prostatic enlargement (BPE), or benign prostatic obstruction (BPO). However, during the last decade the causal link between the prostate and the pathogenesis of LUTS has come into question (1). Although the enlarged prostate can contribute to the onset of LUTS in a proportion of men over 40 years of age, other factors are of equal importance. Latest knowledge suggests that LUTS may be linked to the prostate (BPH-LUTS), bladder (detrusor overactivity-overactive bladder syndrome [OAB], detrusor underactivity) or kidney (nocturnal polyuria) (1). Because of the great prevalence of BPH in elderly men, which is as high as 40% in men in their fifth decade and 90% in men in their ninth decade (2), microscopical changes of the prostate seem to co-exist silently with other bladder or kidney malfunctions in some men. The many causes of LUTS are illustrated in Figure 1. In any single person complaining of LUTS it is common for more than one of these factors to be present. This multi-factorial view of the aetiology of LUTS has led most experts to regard the whole urinary tract as a single functional unit. This broader, more complex approach to the pathogenesis of LUTS meant that we modified the title - to reflect the change in perspective - from the former EAU Guideline on LUTS suggestive of BPO (3) to the more contemporary and precise EAU Guideline on Male LUTS, including BPO.

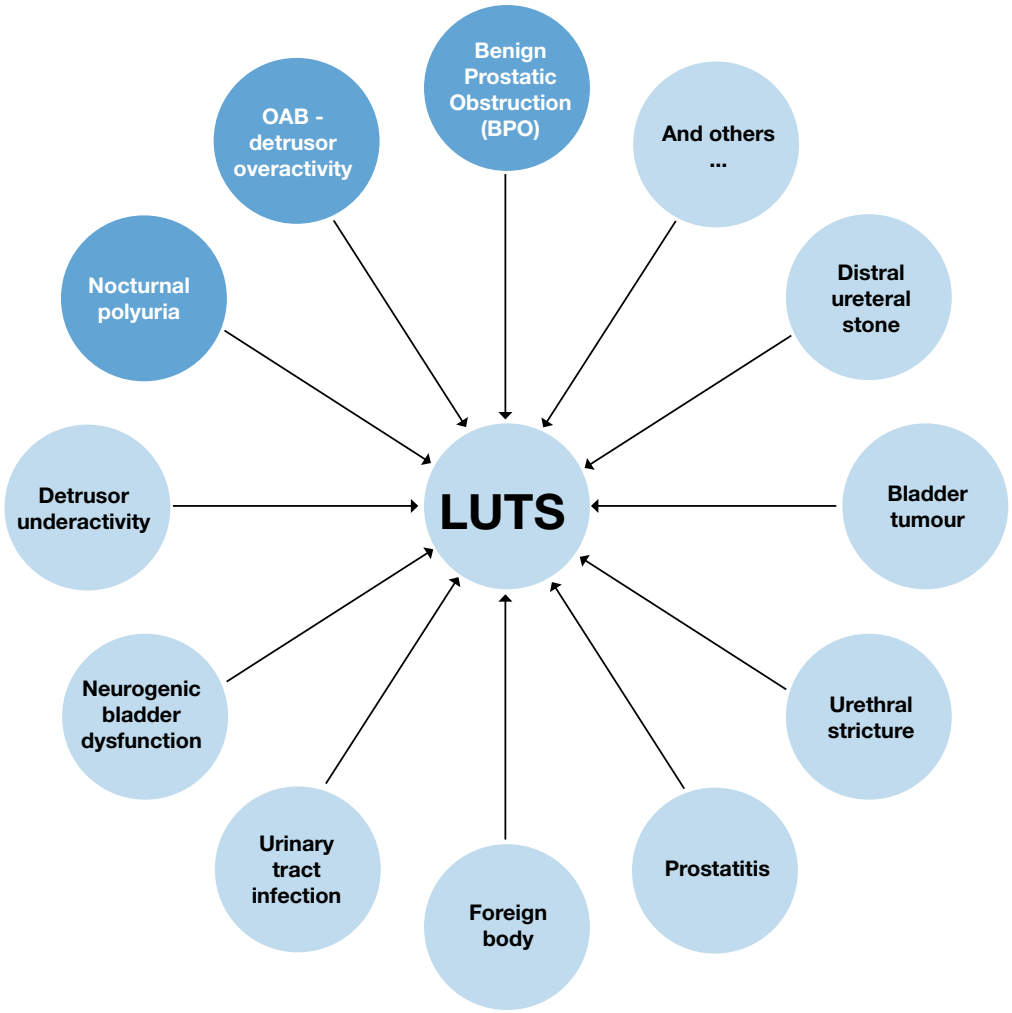

Figure 1: Multifactorial aetiology of lower urinary tract symptoms (LUTS). The EAU Guideline on Male LUTS mainly covers LUTS secondary to benign prostatic enlargement (BPE) or benign prostatic obstruction (BPO), detrusor overactivity or overactive bladder (OAB), and nocturia due to nocturnal polyuria. Other causes of male LUTS are covered by separate EAU Guidelines.

Because patients seek help for LUTS and not an underlying attribute of the prostate such as BPH or BPE, this updated guideline has been written from the perspective of men who complain about a variety of bladder storage, voiding and/or post-micturition symptoms. The recommendations made within the guideline are based on the best available evidence. These recommendations apply to men aged 40 years or older who seek professional help for various forms of non-neurogenic benign forms of LUTS, e.g. LUTS/BPO, detrusor

overactivity-overactive bladder (OAB), or nocturnal polyuria. Assessment and treatment of neurogenic LUTS has been published elsewhere and is valid only for men and women with bladder symptoms due to neurological diseases (4). EAU Guidelines on LUTS due urinary incontinence, urogenital infections, ureteral stones, or malignant diseases of the lower urinary tract have been published elsewhere.

The recommendations of this guideline are based on a structured literature search using articles in English language published in the PubMed/Medline, Web of Science, and Cochrane databases between 1966 and 1st January 2010, including the search terms “lower urinary tract symptoms”, “benign prostatic hyperplasia”, “detrusor overactivity”, “overactive bladder”, “nocturia”, and “nocturnal polyuria” in combination with the various treatment modalities and the search limits “humans”, “adult men”, “review”, “randomised clinical trials”, “clinical trials”, and “meta-analysis”. There have been no new drugs liscensed since the literature search.

Databases: PubMed/Medline (http://www.ncbi.nlm.nih.gov/pubmed/) Web of Science (http://apps.webofknowledge.com) Cochrane (http://www.cochrane.org/)		
Language: English		
Literature Search: conducted 1st February - 1st March 2010		
Search Period: 1966 - 1st January 2010		
Search limits …	for group search terms … **(AND)**	in combination with investigated drugs, operations, or synonyms **(AND)**
humans **AND** adult men **AND** review **OR** randomised clinical trials **OR** clinical trials **OR** meta-analysis	- lower urinary tract symptoms - benign prostatic hyperplasia - detrusor overactivity - overactive bladder - nocturia - nocturnal polyuria	- alpha-adrenoceptor antagonist - adrenergic alpha-1 receptor antagonists - alpha-blocker - alfuzosin - doxazosin - tamsulosin - terazosin - 5α-reductase inhibitor - dutasteride - finasteride

Each extracted article was separately analysed, classified, and labelled with a Level of Evidence (LE), according to a classification system modified from the Oxford Centre for Evidence-based Medicine in 2001 (LE: 1a, highest evidence level) to expert opinion (LE: 4, lowest evidence level) (5). Subsections for the various types of conservative treatments, drugs, and operations are presented in a homogeneous structure listing (1) “mechanism of action”, (2) “available drugs” with a table of key pharmacokinetic profiles or “operative procedure” in case of surgical intervention, (3) “efficacy” with a table of trials with the highest LE, (4) “tolerability and safety”, (5) “practical considerations”, and (6) “recommendations”, which were drawn from the relevant articles using a Grade of Recommendation (GR) according to a classification system modified from the Oxford Centre for Evidence-based Medicine, ranging from a strong (Grade A) to a weak (Grade C) recommendation. (5).

The guideline panel consisted of urologists, a pharmacologist, and an epidemiologist and statistician who have been working on the topic for the last 4 years. The guideline is primarily written for urologists but can also be used by general practitioners, patients, or other stakeholders. The guideline panel intends to update the content and recommendations, according to the given structure and classification systems, every 2 years.

2. ASSESSMENT

Systematic diagnostic work-up should be done by history, validated symptom questionnaires (e.g. IPSS), both ideally proactively, physical examination, uinanlysis, blood analysis, ultrasound of the prostate, bladder and kidneys, uroflowmetry and ultrasound measurement of post-void residual urine, and bladder diary in cases of urinary frequency or nocturia. Only the diagnosis of nocturnal polyuria (> 33% of the 24-hour urine excretion over night) can be made by the bladder diary, whereas the diagnosis of all other forms of non-neurogenic benign forms of LUTS in men aged 40 years or older is mainly made by exclusion. The systematic work-up should exclude relevant diseases or conditions also causing LUTS in adult men. An assessment algorithm is proposed in figure 2.

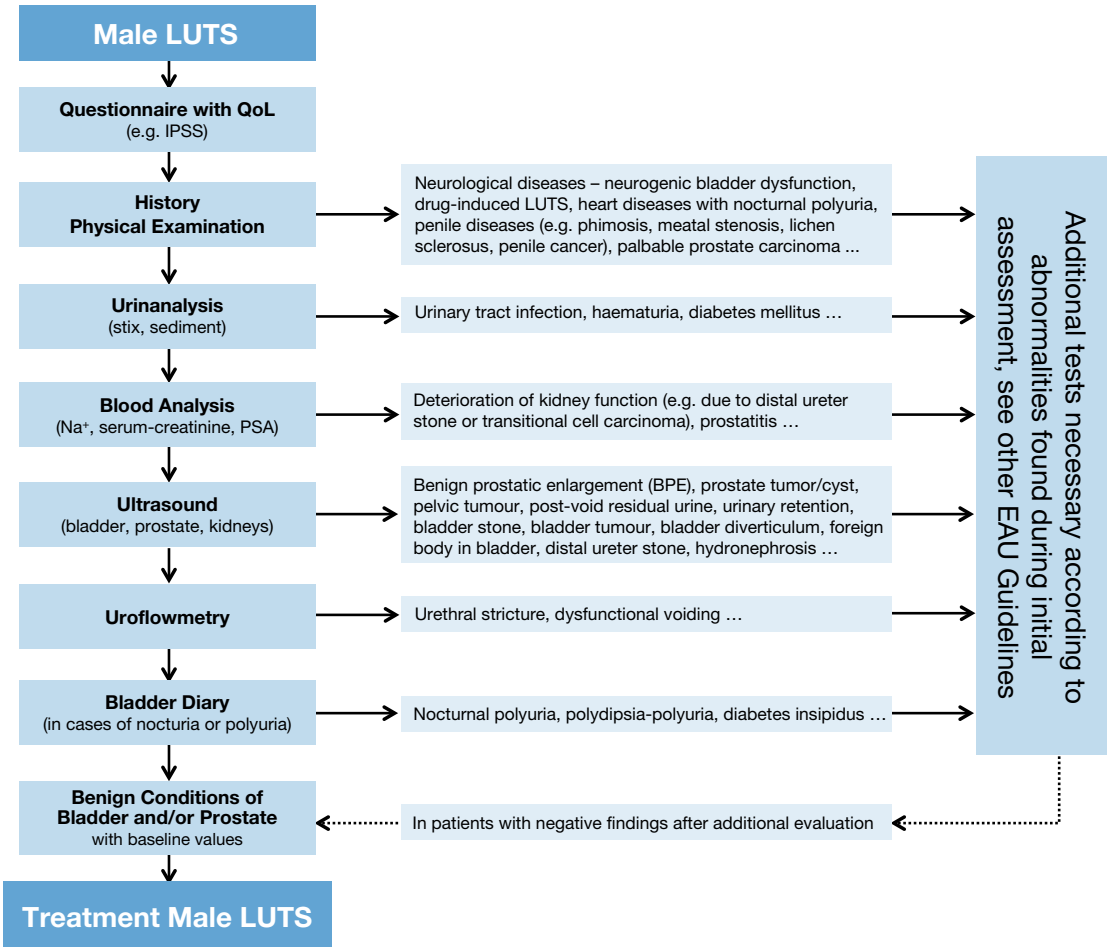

Figure 2: Assessment algorithm of LUTS in men aged 40 years or older. Systematic work-up can exclude other diseases or conditions also associated with LUTS. The assessment may be interrupted or stopped when relevant pathologies have been identified.

Benign prostatic obstruction (BPO) and detrusor overactivity are urodynamic diagnoses. Filling cystometry and pressure-flow measurement are optional tests usually indicated before surgical treatment in men who:

- cannot void ≥ 150 mL;

- have a maximum flow rate ≥ 15 mL/s;
- are < 50 or > 80 years of age;
- can void but have post-void residual urine > 300 mL;
- are suspicious of having neurogenic bladder dysfunction;
- have bilateral hydronephrosis;
- had radical pelvic surgery or;
- had previous unsuccessful (invasive) treatment.

3. CONSERVATIVE TREATMENT

3.1 Watchful waiting - behavioural treatment

Many men with LUTS do not complain of high levels of bother and are therefore suitable for non-medical and non-surgical management - a policy of care known as watchful waiting (WW). It is customary for this type of management to include the following components: education, reassurance, periodic monitoring, and lifestyle advice. In many patients, it is regarded as the first tier in the therapeutic cascade and most men will have been offered WW at some point. WW is a viable option for many men as few, if left untreated, will progress to acute urinary retention and complications such as renal insufficiency and stones (1,2). Similarly, some symptoms may improve spontaneously, while other symptoms remain stable for many years (3).

3.2 Patient selection

All men with LUTS should be formally assessed prior to starting any form of management in order to identify those with complications that may benefit from intervention therapy. Men with mild to moderate uncomplicated LUTS (causing no serious health threat), who are not too bothered by their symptoms, are suitable for a trial of WW. A large study comparing WW and transurethral resection of the prostate (TURP) in men with moderate symptoms showed that those who had undergone surgery had improved bladder function over the WW group (flow rates and post-void residual volumes), with the best results being in those with high levels of bother. Thirty-six per cent of patients crossed over to surgery in 5 years, leaving 64% doing well in the WW group (4). Approximately 85% of men will be stable on WW at 1 year, deteriorating progressively to 65% at 5 years (5, 6). The reason why some men deteriorate with WW and others do not is not well understood; increasing symptom bother and PVR volumes appeared to be the strongest predictors of failure.

3.3 Education, reassurance, and periodic monitoring

There now exists LE 1b that self-management as part of WW reduces both symptoms and progression (7, 8) (Table 1). In this study, men randomised to three self-management sessions in addition to standard care had better symptom improvement and improved quality of life at 3 and 6 months when compared to men treated with standard care only. These differences were maintained at 12 months. Nobody is quite sure which key components of self-management are effective, but most experts believe the key components are:

- education about the patient's condition;
- reassurance that cancer is not a cause of the urinary symptoms;
- framework of periodic monitoring.

Table 1: Self-management as part of watchful waiting reduces symptoms and progression (7)

Trial	Duration (weeks)	Treatment	Patients	IPSS	Q_{max} (mL/s)	PVR (mL)	LE
Brown et al. (2007) (7)	52	Standard care	67	-1.3	-	-	1b
		Standard care plus self-management	73	-5.7 * †	-	-	

IPSS = International Prostate Symptom Score; Q_{max} = maximum urinary flow rate during free uroflowmetry; PVR = post-void residual urine.

** significant compared to standard care ($p < 0.05$); † significant compared to baseline ($p < 0.05$).*

3.4 Lifestyle advice

The precise role of lifestyle advice in conferring benefit seen in the studies reported to date remains uncertain. Minor changes in lifestyle and behaviour can have a beneficial effect on symptoms and may prevent deterioration requiring medical or surgical treatment. Lifestyle advice can be obtained through informal and

formal routes. If it is offered to men, it should probably comprise the following:

- Reduction of fluid intake at specific times aimed at reducing urinary frequency when most inconvenient, e.g. at night or going out in public. The recommended total daily fluid intake of 1500 mL should not be reduced.
- Avoidance or moderation of caffeine and alcohol which may have a diuretic and irritant effect, thereby increasing fluid output and enhancing frequency, urgency and nocturia.
- Use of relaxed and double-voiding techniques.
- Urethral stripping to prevent post-micturition dribble.
- Distraction techniques, such as penile squeeze, breathing exercises, perineal pressure and mental 'tricks' to take the mind off the bladder and toilet, to help control irritative symptoms.
- Bladder re-training, by which men are encouraged to 'hold on' when they have sensory urgency to increase their bladder capacity (to around 400 mL) and the time between voids.
- Reviewing a man's medication and optimising the time of administration or substituting drugs for others that have fewer urinary effects.
- Providing necessary assistance when there is impairment of dexterity, mobility or mental state.
- Treatment of constipation.

3.5 Practical considerations

The components of self-management have not been individually subjected to study. The above components of lifestyle advice have been derived from formal consensus methodology (9). Further research in this area is required.

3.6 Recommendations

	LE	GR
Men with mild symptoms are suitable for watchful waiting.	1b	A
Men with lower urinary tract symptoms should be offered lifestyle advice prior to or concurrent with treatment.	1b	A

4. DRUG TREATMENT

4.1 α_1-adrenoceptor antagonists (α_1-blockers)

4.1.1 Mechanism of action

Historically, it was assumed that α_1-blockers act by inhibiting the effect of endogenously released noradrenaline on prostate smooth muscle cells, thereby reducing prostate tone and bladder outlet obstruction. Contraction of the human prostate is mediated predominantly, if not exclusively, by α_1A-adrenoceptors (1). However, it has been shown that α_1-blockers have little effect on urodynamically determined bladder outlet resistance (2) and treatment-associated improvement of LUTS is correlated only poorly with obstruction (3). Hence, there has been a lot of discussion about the role of α_1-adrenoceptors located outside the prostate (e.g. in the urinary bladder and/or spinal cord) and other α-adrenoceptor subtypes (α_1B- or α_1D-adrenoceptors) as mediators of beneficial effects of α_1-blockers. α_1-adrenoceptors in blood vessels, other non-prostatic smooth muscle cells, and central nervous system are considered to be mediators of side-effects during α-blocker treatment, and all three receptor subtypes seem to be involved. This concept has favoured the use of α_1A-selective adrenoceptor antagonists. However, it remains to be determined whether α_1A-selectivity is the only and main factor determining good tolerability.

4.1.2 Available drugs

Following the early use of phenoxybenzamine and prazosin in BPH-LUTS treatment, four α_1-blockers are currently in mainstream use:

- alfuzosin HCL (alfuzosin);
- doxazosin mesylate (doxazosin);
- tamsulosin HCL (tamsulosin);
- terazosin HCL (terazosin).

Over a period of time, alfuzosin has been clinically available in Europe in three formulations, doxazosin and tamsulosin in two formulations each, and terazosin in one formulation (Table 2). Although different formulations result in different pharmacokinetic behaviours and, perhaps, tolerability profiles, the overall clinical impact of the different formulations is modest. Although some countries also have available indoramin, naftopidil and more recently silodosin, there have been only limited clinical data for these agents at the time of the literature search and, hence, they will not be discussed in these guidelines.

Table 2: Key pharmacokinetic properties and standard doses of α_1-blockers licensed in Europe for treating symptoms of BPH

Drug	t_{max} (hours)	t½ (hours)	Recommended daily dose
Alfuzosin IR	1.5	4-6	3 x 2.5 mg
Alfuzosin SR	3	8	2 x 5 mg
Alfuzosin XL	9	11	1 x 10 mg
Doxazosin IR	2-3	20	1 x 2-8 mg
Doxazosin GITS	8-12	20	1 x 4-8 mg
Silodosin	2.5	11-18	1 x 4-8 mg
Tamsulosin MR	6	10-13	1 x 0.4 mg
Tamsulosin OCAS	4-6	14-15	1 x 0.4 mg
Terazosin	1-2	8-14	1 x 5-10 mg

t_{max} = time to maximum plasma concentration; t½ = elimination half-life; IR = immediate release; SR = sustained release; GITS = Gastrointestinal Therapeutic System; MR = Modified Release; OCAS = Oral Controlled Absorption System.

4.1.3 ***Efficacy***

Indirect comparisons between α_1-blockers, and limited direct comparisons, demonstrate that all α_1-blockers have a similar efficacy in appropriate doses (4). Controlled studies have shown that α_1-blockers typically reduce the International Prostate Symptom Score (IPSS), after a run-in period, by approximately 35-40% and increase the maximum urinary flow rate (Q_{max}) by approximately 20-25% (Table 3). However, considerable improvements also occurred in the corresponding placebo arms (4,5). In open-label studies (without a runin period), an IPSS improvement of up to 50% and Q_{max} increase of up to 40% were documented (4,6).

Although these improvements take a few weeks to develop fully, statistically significant efficacy over placebo was demonstrated within hours to days. α_1-blockers seem to have a similar efficacy, expressed as a percent improvement in IPPS, in patients with mild, moderate and severe symptoms (6). Prostate size does not affect α_1-blocker efficacy in studies with follow-up periods of $\leq$ 1 year but patients with smaller prostates (< 40 mL) seem to have better efficacy compared to those with larger glands in longer-term and is similar across age groups (6). α_1-blockers do not reduce prostate size and do not prevent acute urinary retention in long-term studies (8), so that eventually some patients will have to be surgically treated. Nevertheless, the efficacy of α_1-blockers appears to be maintained over at least 4 years.

Table 3: Randomised, placebo-controlled trials with α_1-blockers in men with LUTS (drugs in chronological order; selection of trials)

*4.1.4 **Tolerability and safety***

Although alfuzosin, doxazosin, and terazosin are similar in terms of molecular structure and lack of α_1-adrenoceptor subtype selectivity, the side-effect profile of alfuzosin is more similar to tamsulosin than to doxazosin and terazosin. The mechanisms underlying such differential tolerability are not fully understood, but may involve better distribution into lower urinary tract tissues by alfuzosin and tamsulosin. Other factors, such as subtype selectivity and the pharmacokinetic profiles of certain formulations, may also contribute to the tolerability profile of specific drugs.

The most frequent side-effects of α_1-blockers are asthenia, dizziness and (orthostatic) hypotension. Although a reduction in blood pressure may benefit hypertensive patients, at least some of the observed asthenia and dizziness can be attributed to a decrease in blood pressure. Vasodilating effects are most pronounced with doxazosin and terazosin, and are much less common for alfuzosin and tamsulosin (odds ratio for vascular-related adverse events 3.3, 3.7, 1.7 and 1.4, respectively; the latter two not reaching statistical significance; [5]). In particular, patients with cardiovascular co-morbidity and/or vasoactive co-medication may be susceptible to α-blocker-induced vasodilatation (9). This includes anti-hypertensive drugs, such as α-adrenoceptor antagonists, diuretics, Ca^{2+}-channel blockers, angiotensin-converting enzyme inhibitors, and angiotensin receptor antagonists, but also phosphodiesterase (PDE) inhibitors prescribed for erectile dysfunction or male LUTS (9).

Despite the long-standing and widespread use of α_1-blockers, an adverse ocular event, termed intraoperative floppy iris syndrome (IFIS), has been discovered only recently in the context of cataract surgery (10). Although IFIS has been observed with all α_1-blockers, most reports have been related to tamsulosin. Whether this reflects a greater risk with tamsulosin than with other α_1-blockers, or rather its more widespread use, is not clear, particularly as the ratio between doses yielding ocular effects and those acting on the lower urinary tract are similar for all α_1-blockers (11). It therefore appears prudent not to initiate α_1-blocker treatment prior to cataract surgery, while existing α_1-blocker treatment should be stopped though it is not clear how long before surgery takes place. It should be noted that the occurrence of IFIS complicates cataract surgery and makes it technically more demanding, however, there are no reports about increased health risks of these patients.

As LUTS and erectile dysfunction often co-exist, medical BPH treatment should not further impair sexual function. A systematic review concluded that α_1-blockers do not adversely affect libido, have a small beneficial effect on erectile function, but sometimes cause abnormal ejaculation (12). Originally, the abnormal ejaculation was thought to be retrograde, but more recent data demonstrate that it is due to (relative) anejaculation, with young age being an apparent risk factor. Although abnormal ejaculation has been observed more frequently with tamsulosin than with other α_1-blockers, this difference did not reach statistical significance in direct comparative studies with alfuzosin and is not associated with an overall reduction of overall sexual function (12). The apparently greater risk for abnormal ejaculation with tamsulosin is intriguing as even more α_1A-selective drugs, such as silodosin, carry a greater risk (13), however, all α_1-blockers are dosed to block α_1A-adrenoceptors effectively. Hence, the mechanism underlying abnormal ejaculation remains to be elucidated.

*4.1.5 **Practical considerations***

α_1-blockers are often considered the first-line drug treatment of moderate-to-severe male LUTS. All α_1-blockers are available in formulations, which are suitable for once-daily administration. To minimise adverse events, it is recommended that dose titration is used to initiate treatment with doxazosin and terazosin; however, this is not necessary with alfuzosin and tamsulosin. Because of their rapid onset of action, α_1-blockers can be considered for intermittent use in patients with fluctuating intensity of symptoms not needing long-term treatment.

*4.1.6 **Recommendations***

	LE	GR
α_1-blockers should be offered to men with moderate-to-severe lower urinary tract symptoms	1a	A

4.2 5α-reductase inhibitors

4.2.1 ***Mechanism of action***

Androgen effects on the prostate are mediated by dihydrotestosterone (DHT), which is converted primarily in the prostatic stroma cells from its precursor testosterone by the enzyme 5α-reductase, a nuclear-bound steroid enzyme (1). Two isoforms of this enzyme exist:

- 5α-reductase type 1, with minor expression and activity in the prostate but predominant activity in extraprostatic tissues, such as skin and liver.
- 5α-reductase type 2, with predominant expression and activity in the prostate.

Finasteride inhibits only 5α-reductase type 2, whereas dutasteride inhibits 5α-reductase types 1 and 2 with similar potency (dual 5α-reductase inhibitor). However, the clinical role of dual inhibition remains unclear. 5α-reductase inhibitors act by inducing apoptosis of prostate epithelial cells (2) leading to prostate size reduction of about 18-28% and circulating PSA levels of about 50% after 6-12 months of treatment (3). Mean prostate volume reduction may be even more pronounced after long-term treatment.

4.2.2 ***Available drugs***

Two 5α-reductase inhibitors are available for clinical use: dutasteride and finasteride (Table 4). The elimination half-time is longer for dutasteride (3-5 weeks). Both 5α-reductase inhibitors are metabolised by the liver and excreted in the faeces. Continuous treatment reduces the serum DHT concentration by approximately 70% with finasteride and 95% with dutasteride. However, prostate DHT concentration is reduced to a similar level (85-90%) by both 5α-reductase inhibitors.

Table 4: 5α-reductase inhibitors licensed in Europe for treating benign prostatic enlargement (BPE) due to benign prostatic hyperplasia (BPH); key pharmacokinetic properties and standard doses

Drug	t_{max} (hours)	t ½	Recommended daily dose
Dutasteride	1-3	3-5 weeks	1 x 0.5 mg
Finasteride	2	6-8 hours	1 x 5 mg

t_{max} = time to maximum plasma concentration; t½ = elimination half-life.

*4.2.3 **Efficacy***

Clinical effects relative to placebo are seen after minimum treatment duration of at least 6 to 12 months. After 2 to 4 years of treatment, 5α-reductase inhibitors reduce LUTS (IPSS) by approximately 15-30%, decrease prostate volume by approximately 18-28% and increase Q_{max} of free uroflowmetry by approximately 1.5-2.0 mL/s in patients with LUTS due to prostate enlargement (Table 5) (4-13).

Symptom reduction by finasteride depends on initial prostate size and may not be more efficacious than placebo in patients with prostates smaller than 40 mL (14). However, dutasteride seems to reduce IPSS, prostate volume, and the risk of acute urinary retention. It also increases Q_{max} even in patients with prostate volumes between 30 and 40 mL at baseline (15,16). Indirect comparison between individual studies and one unpublished direct comparative trial indicate that dutasteride and finasteride are equally effective in the treatment of LUTS (3). Comparative studies with α_1-blockers have demonstrated that 5α-reductase inhibitors reduce symptoms more slowly and, for finasteride, less effectively (5,10,17,18). A long-term trial with dutasteride in symptomatic men with a prostate volume greater than 30 mL (average prostate volume in the CombAT trial was approximately 55 mL) showed that the 5α-reductase inhibitor reduced LUTS in these patients at least as much or even more effectively than tamsulosin (11,12). The greater the baseline prostate volume (serum PSA concentration), the faster and more pronounced the symptomatic benefit of dutasteride (19). IPSS reduction was significantly greater in men with prostate volumes of 58 mL or more (PSA > 4.4) at treatment month 15 or later compared to men with lower baseline prostate volumes (PSA concentrations).

5α-reductase inhibitors, but not α_1-blockers, reduce the long-term (> 1 year) risk of acute urinary retention or need for surgery (8,10,19,20). Prevention of disease progression by 5α-reductase inhibitors is already detectable with prostate sizes considerably smaller than 40 mL (12,13,20). The precise mechanism of action of 5α-reductase inhibitors in reducing disease progression remains to be determined, but it is most likely attributable to reduction of bladder outlet resistance. Open-label trials demonstrated relevant reductions of voiding parameters after computer-urodynamic re-evaluation in men who were treated at least 3 years with finasteride (21,22).

Table 5: Randomised trials with 5α-reductase inhibitors in men with LUTS and benign prostatic enlargement due to BPH

Q_{max} = maximum urinary flow rate (free uroflowmetry); IPSS = International Prostate Symptom Score; † Boyarski Score; a = significant compared to baseline (indexed wherever evaluated); b = significant compared to placebo/ active control.

4.2.4 ***Tolerability and safety***

The most relevant adverse effects of 5α-reductase inhibitors are related to sexual function and include reduced libido, erectile dysfunction and, less frequently, ejaculation disorders, such as retrograde ejaculation, ejaculation failure, or decreased semen volume (3,10,13). The incidence of sexual dysfunction and other adverse events is low and even decreased with trial duration. Gynaecomastia (breast enlargement with breast or nipple tenderness) develops in approximately 1-2% of patients.

4.2.5 ***Practical considerations***

Treatment with 5α-reductase inhibitors should only be considered in men with moderate-to-severe LUTS and enlarged prostates (> 40 mL) or elevated PSA concentrations (> 1.4 – 1.6 µg/L). Due to the slow onset of action, 5α-reductase inhibitors are only suitable for long-term treatment (many years). Their effect on the serum PSA concentration needs to be considered for prostate cancer screening. Of interest, 5α-reductase inhibitors (finasteride) might reduce blood loss during transurethral prostate surgery, probably due to their effects on prostatic vascularisation (23).

4.2.6 ***Recommendations***

	LE	**GR**
5α-reductase inhibitors should be offered to men who have moderate-to-severe lower urinary tract symptoms and enlarged prostates (> 40 mL) or elevated prostate specific antigen concentrations (> 1.4 – 1.6 µg/L). 5α-reductase inhibitors can prevent disease progression with regard to acute urinary retention and need for surgery.	1b	A

4.3 Muscarinic receptor antagonists

*4.3.1 **Mechanism of action***

The predominant neurotransmitter of the urinary bladder is acetylcholine that is able to stimulate muscarinic receptors (m-cholinoreceptors) on the surface of detrusor smooth muscle cells. However, muscarinic receptors are not only densely expressed on smooth muscle cells but also on other cell types, such as epithelial cells of the salivary glands, urothelial cells of the urinary bladder, or nerve cells of the peripheral or central nervous system. Five muscarinic receptor subtypes (M^1-M^5) have been described in humans, of which the M^2 and M^3 subtypes are predominantly expressed in the detrusor. Although approximately 80% of these muscarinic receptors are M^2 and 20% M^3 subtypes, only M^3 seems to be involved in bladder contractions in healthy humans (1,2). The role of M^2 subtypes remains unclear. However, in men with neurogenic bladder dysfunction and in experimental animals with neurogenic bladders or bladder outlet obstruction M^2 receptors seem to be involved in smooth muscle contractions as well (3).

The detrusor is innervated by parasympathic nerves which have their origin in the lateral columns of sacral spinal cord on the level S2-S4 which itself is modulated by supraspinal micturition centres. The sacral micturition centre is connected with the urinary bladder by the pelvic nerves which release acetylcholine after depolarisation. Acetylcholine stimulates postsynaptic muscarinic receptors leading to G-protein mediated calcium release in the sarcoplasmatic reticulum and opening of calcium channels of the cell membrane and, finally, smooth muscle contraction. Inhibition of muscarinic receptors by muscarinic receptor antagonists inhibit/decrease muscarinic receptor stimulation and, hence, reduce smooth muscle cell contractions of the bladder. Antimuscarinic effects might also be induced or modulated by the urothelium of the bladder and/or by the central nervous system (4,5).

*4.3.2 **Available drugs***

The following muscarinic receptor antagonists are licensed for treating overactive bladder/storage symptoms in men and women (Table 6):

- darifencacin hydrobromide (darifenacin);
- fesoterodine fumarate (fesoterodine);
- oxybutynin HCL (oxybutynin);
- propiverine HCL (propiverine);
- solifenacin succinate (solifenacin);
- tolterodine tartrate (tolterodine);
- trospium chloride.

This drug class is still officially contraindicated in men with BPH/BOO due to the possibility of incomplete bladder emptying or development of urinary retention.

Table 6: Antimuscarinic drugs licensed in Europe for treating overactive bladder/storage symptoms; key pharmacokinetic properties and standard doses

Drug	t_{max} [h]	t ½ [h]	Recommended daily dose
Darifencacin	7	13 - 19	1 x 7.5-15 mg
Fesoterodine	5	7	1 x 4-8 mg
Oxybutynin IR	0.5 - 1	2 - 4	3-4 x 2.5-5 mg
Oxybutynin ER	5	16	2-3 x 5 mg
Propiverine	2.5	13 - 20	2-3 x 15 mg
Propiverine ER	7	20	1 x 30 mg
Solifenacin	4 - 6	45 - 68	1 x 5-10 mg
Tolterodine IR	1 - 3	2-10	2 x 1-2 mg
Tolterodine ER	4	6 - 10	1 x 4 mg
Trospium chloride	4 - 6	5 - 15	3 x 10-15 mg 2 x 10-20 mg

IR = immediate release; ER = extended release; t_{max} = time to maximum plasma concentration; t½ = elimination half-life;
** oral bioavailability increased by about 50% for the parent compound, whereas that of the active metabolite is decreased by about 30%; † absolute bioavailability dependent on genotype for CPY 2D6 ranging from 17% in extensive metabolisers to 65% in poor metabolisers.*

*4.3.3 **Efficacy***

Muscarinic receptor antagonists have been predominantly tested in females in the past because it was believed that LUTS in women are caused by the bladder and, therefore, have to be treated with bladder-specific drugs. In contrast, it was believed that LUTS in men are caused by the prostate and need to be treated with prostate specific drugs. However, there is no scientific data for that assumption (6). A sub-analysis of an open-label trial of 2,250 male or female patients with overactive bladder symptoms treated with tolterodine showed that age but not gender has a significant impact on urgency, frequency, or urgency incontinence (7).

The efficacy of the anticholinergic drug tolterodine, and lately also fesoterodine, was tested as a single agent in adult men with bladder storage symptoms (OAB symptoms) but without bladder outlet obstruction (Table 7). Maximum trial duration was 25 weeks, but most of the trials lasted for only 12 weeks. In open-label trials with tolterodine, daytime frequency, nocturia, urgency incontinence, and IPSS were all significantly reduced compared to baseline values after 12-25 weeks (8, 9). In an open-label study with α_1-blocker nonresponders, each answer of the IPSS questionnaire was improved during tolterodine treatment irrespective of storage or voiding symptoms (8). Randomised, placebo-controlled trials demonstrated that tolterodine can significantly reduce urgency incontinence and daytime or 24-hour frequency compared to placebo. It was also demonstrated that urgency related voiding is significantly reduced by tolterodine (10-12). Although nocturia, urgency, or IPSS were reduced in the majority of patients, these parameters did not reach statistical significance in most of the trials. However, if treatment outcome was stratified by PSA-concentration (prostate volume) tolterodine significantly reduced daytime frequency, 24h voiding frequency and IPSS storage symptoms in those men with PSA concentrations below 1.3 ng/mL, which was not the case in men with PSA concentrations of 1.3 ng/mL or more indicating that men with smaller prostates might profit more from antimuscarinic drugs (13).

Table 7: Trials with antimuscarinic drugs only in elderly men with LUTS, predominantly with overactive bladder symptoms (trials in chronological order)

Trials	Duration (weeks)	Treatment	Patients	Voiding frequency [%]	Nocturia [%]	Urgency incontinence [%]	IPSS [%]	LE
Kaplan et al. (2005) [8]	25	Tolterodine 1 x 4 mg/d (after α-blocker failure)	43	-35.7[a]	-29.3[a]	-	-35.3[a]	2b

		Fesoterodine 1 x 8 mg/d	109	-15.6[b]	-	-100[b,c]	-	

IPSS = International Prostate Symptom Score; [a] = significant compared to baseline ($p < 0.01$; indexed wherever evaluated); [b] = significant compared to placebo ($p < 0.05$); c = significant compared to fesoterodine 4 mg ($p < 0.05$)

*4.3.4 **Tolerability and safety***

Muscarinic receptor antagonists are generally well tolerated and associated with approx. 3-10% study withdrawals which were not significantly different compared to placebo in most of the studies. Compared to placebo, drug-related adverse events appear with higher frequencies for dry mouth (up to 16%), constipation (up to 4%), micturition difficulties (up to 2%) nasopharyngitis (up to 3%), and dizziness (up to 5%).

Increase of post-void residual urine in men without bladder outlet obstruction is minimal and not significantly different compared to placebo (0 to 5 mL vs. -3.6 to 0 mL). Nevertheless, fesoterodine 8 mg showed higher post-void residuals (+20.2 mL) compared to placebo (-0.6 mL) or fesoterodine 4 mg (+9.6 mL) (14). The incidence of urinary retention in men without bladder outlet obstruction was comparable with placebo in trials with tolterodine (0 to 1.3 vs. 0 to 1.4%). In men under fesoterodine 8 mg treatment, 5.3% had symptoms suggestive of urinary retention that was higher compared to placebo or fesoterodine 4 mg (0.8% each). These symptoms appeared during the first 2 weeks of treatment and affected men aged 66 years or older.

In men with bladder outlet obstruction, antimuscarinic drugs are not recommended due to the theoretical decrease of bladder strength which might be associated with post-void residual urine or urinary retention. A 12-week placebo-controlled safety study dealing with men who had mild to moderate bladder outlet obstruction (median bladder outlet obstruction index, BOOI, in the placebo or tolterodine group 43 and 49 cm H_2O, respectively) demonstrated that tolterodine significantly increased the amount of post-void residual urine (49 vs. 16 mL) but was not associated with increased events of acute urinary retention (3% in both study arms) (15). Urodynamic effects of tolterodine included significant larger bladder volumes to first detrusor contraction, higher maximum cystometric bladder capacity, and decreased bladder contractility index. Maximum urinary flow remained unchanged in both the tolterodine and placebo groups. This single trial indicated that the short-term treatment with antimuscarinic drugs in men with bladder outlet obstruction is safe.

4.3.5 *Practical considerations*

Although studies in elderly men with LUTS and overactive bladder symptoms were exclusively carried out with tolterodine or fesoterodine it is likely that similar efficacy and adverse events will also appear with other antimuscarinic agents. Long-term studies on the efficacy of muscarinic receptor antagonists in men with LUTS are still missing, therefore, these drugs should be prescribed with caution, and regular re-evaluation of IPSS and post-void residual urine is advised.

4.3.6 *Recommendations*

	LE	GR
Muscarinic receptor antagonists might be considered in men with moderate to severe lower urinary tract symptoms who have predominantly bladder storage symptoms.	1b	B
Caution is advised in men with bladder outlet obstruction.	4	C

4.4 Plant extracts - Phytotherapy

4.4.1 ***Mechanism of action***

Phytotherapy comprises the medical use of various extracts of different plants. It remains controversial which components of the extracts are responsible for symptom relief in male LUTS. The most important compounds are believed to be phytosterols, ß-sitosterol, fatty acids, and lectins (1). In vitro studies have shown that plant extracts:

- have anti-inflammatory, antiandrogenic, or oestrogenic effects;
- decrease sexual hormone binding globulin (SHBG);
- inhibit aromatase, lipoxygenase, growth-factor stimulated proliferation of prostatic cells, α-adrenoceptors, 5α-reductase, muscarinic cholinoceptors, dihydropyridine receptors, or vanilloid receptors;
- improve detrusor function;
- neutralise free radicals (1-3).

However, most in vitro effects have not been confirmed in vivo and the precise mechanisms of action of plant extracts remain unclear.

4.4.2 ***Available drugs***

Herbal drug preparations are made of roots, seeds, pollen, bark, or fruits of a single plant (monopreparations); others combine the extracts of two or more plants to one pill (combination preparations). A large number of different plants are used for the preparation of extracts. The most widely used plants are:

- *Cucurbita pepo* (pumpkin seeds)
- *Hypoxis rooperi* (South African star grass)
- *Pygeum africanum* (bark of the African plum tree)
- *Secale cereale* (rye pollen)
- *Serenoa repens* (syn. *Sabal serrulata*; berries of the American dwarf palm, saw palmetto)
- *Urtica dioica* (roots of the stinging nettle).

Different producers use different extraction techniques, distribute active ingredients with different qualitative and quantitative properties, or combine two or more herbal compounds in one pill. The extracts of the same plant produced by different companies do not necessarily have the same biological or clinical effects so that the effects of one brand cannot be extrapolated to others (4). To complicate matters, even two different batches of the same producer might contain different concentrations of active ingredients and cause different biological effects (5). Thus, the pharmacokinetic properties can differ significantly between different plant extracts.

4.4.3 ***Efficacy***

Each class of plant extract is discussed separately because of the above-mentioned reasons (Table 8). Whenever possible, the brand name is mentioned to demonstrate possible differences between products. In general, no phytotherapeutic agent has been shown to significantly reduce prostate size and no trial has proven reduction of bladder outlet obstruction or decreased disease progression.

- ***Cucurbita pepo***: Only one trial has evaluated the efficacy of pumpkin seeds extracts (Prosta Fink™ forte) in patients with BPH-LUTS (6). A total of 476 patients were randomly assigned to placebo or Prostat Fink™ forte. After a follow-up of 12 months, IPSS and daytime voiding frequency were significantly reduced in the pumpkin seed group. However, uroflowmetry parameters (Q_{max}), post-void residual urine, prostate volume, PSA concentration, nocturia, or quality of life (QoL) Score were not statistically different between the groups.

- ***Hypoxis rooperi***: These phytopharmacological extracts contain a mixture of phytosterols bonded with glycosides of which ß-sitosterol is the most important compound (Harzol™, Azuprostat™). Four randomised, placebo-controlled trials with durations between 4 and 26 weeks were published and summarised in a Cochrane report (7). Daily doses of plant extracts ranged from 60 to 195 mg. Two trials evaluated symptoms (8,9) and all four trials investigated Q_{max} and post-void residual urine. A meta-analysis calculated weighted mean differences of -4.9 IPSS points, +3.9 mL/s in terms of Q_{max} and -28.6 mL in terms of post-void residual urine in favour of ß-sitosterol. Prostate size remained unchanged in all trials. No further trials have been carried out since the Cochrane report was published in 2000.
- ***Pygeum africanum***: A Cochrane report dealing with the clinical results of *Pygeum africanum* extracts (mono- or combination preparations) summarised the results of 18 randomised, placebo-controlled trials (10). Most trials used the *Pygeum africanum* extract Tadenan™. The meta-analysis comprised 1,562 men, but individual trials were small in size and lasted only between 30 and 122 days. Most trials were performed in the 1970s and 1980s and did not use validated questionnaires such as the IPSS. Men treated with *Pygeum africanum* were twice as likely to report symptom improvement (relative risk [RR] 2.07) compared to men treated with placebo. The mean weighted difference of Q_{max} was +2.5 mL/s and of post-void residual volume -13.2 mL in favour of *Pygeum africanum*. No further trials have been published since the Cochrane report in 2002.
- ***Secale cereale***: A Cochrane report dealt with the clinical results of the main *Secale cereale* product Cernilton™ and comprised 444 men who were enrolled in two placebo-controlled and two comparative trials (Tadenan™, Paraprost™) lasting between 12 and 24 weeks (11). Men treated with Cernilton™ reported that they were twice as likely to benefit from therapy compared to placebo (RR 2.4). However, there were no significant differences between Cernilton™ and placebo with regard to Q_{max}, post-void residual urine, or prostate volume. No additional placebo-controlled trial with the mono preparation of *Secale cereale* has been published since the Cochrane report in 2000.
- ***Sabal serrulata/Serenoa repens***: A recently updated Cochrane report summarised the clinical results of 30 randomised trials comprising 5,222 men (12). *Serenoa repens* (mainly Permixon™ or Prostaserene™) was compared as mono or combination preparations either with placebo, other plant extracts (*Pygeum africanum*, *Utica dioica*), the 5-reductase inhibitor finasteride, or the α_1-blocker tamuslosin. Mean follow-up of these trials varied between 4 and 60 weeks. The Cochrane report concluded that *Serenoa repens* was not superior to placebo, finasteride, or tamsulosin with regard to IPSS improvement, Q_{max}, or prostate size reduction. Similar levels of IPSS or Q_{max} improvements in trials with finasteride or tamsulosin might be interpreted as treatment equivalence (13). For nocturia, *Serenoa repens* was significantly better than placebo (mean weighted difference -0.78).
- ***Urtica diocia***: Two trials investigated the efficacy of stinging nettle mono preparations compared to placebo (14,15). One trial investigated 246 men with BPH-LUTS over a period of 52 weeks (14); only IPSS decreased significantly in the phytotherapy group (Bazoton™ uno), whereas Q_{max} and post-void residual urine were not statistically different between the groups at the end of the trial. The second trial investigated 620 patients with BPH-LUTS over a period of 26 weeks (15); IPSS, Q_{max}, and post-void residual urine significantly improved compared to placebo.
- ***Combination preparations***: Trials have been carried out, especially with the extract combination of *Sabal serrulata* and *Utica dioica* (PRO 160/120, Prostatgutt™ forte). A 24-weeks placebo-controlled trial demonstrated a significant improvement in IPSS in the phytotherapy arm (-2 IPSS points difference) (16); Q_{max} reduction was similar in both groups. A 24-week open label extension trial of the same patients, in which all patients were treated with PRO 160/120, showed similar improvements of IPSS at week 48 in both groups (-7 IPSS points). A second trial, in which PRO 160/120 was randomised against finasteride, showed similar results for IPSS and Q_{max} in both groups (17).

Table 8: Trials with plant extracts in patients with BPH-LUTS (selection; in alphabetical order)

IPSS = International Prostate Symptom Score; Q_{max} = maximal urinary flow rate (free uroflowmetry); PVR = post-void residual urine; n.s. = not significant; RR = relative risk
† absolute values; a = significant reduction compared to placebo/comparison treatment arm ($p<0.05$); b = in favour of plant extract.

*4.4.4 **Tolerability and safety***

Side-effects during phytotherapy are generally mild and comparable to placebo with regard to severity and frequency. Serious adverse events were not related to study medication. Gastrointestinal complaints were the

most commonly reported side-effects. In formulations with *Hypoxis rooperi*, erectile dysfunction appeared in 0.5% of patients. Trial withdrawals were almost equal in both placebo and phytotherapy groups.

4.4.5 ***Practical considerations***

Phytotherapeutic agents are a heterogeneous group of plant extracts used to improve BPH-LUTS. Phytotherapy remains problematic to use because of different concentrations of the active ingredient(s) in different brands of the same phytotherapeutic agent. Hence, meta-analyses of extracts of the same plant do not seem to be justified and results of these analyses have to be interpreted with caution.

4.4.6 ***Recommendations***

The guidelines committee is unable to make specific recommendations about phytotherapy of male lower urinary tract symptoms because of the heterogeneity of the products and the methodological problems associated with meta-analyses.

4.5 Vasopressin analogue - desmopressin

*4.5.1 **Mechanism of action***

The antidiuretic hormone arginine vasopressin (AVP) plays a key role in body water homeostasis and the control of urine production by binding to the V2 receptor in the renal collecting ducts. AVP increases water re-absorption as well as urinary osmolality and decreases water excretion as well as total urine volume. AVP might be therapeutically used to manipulate the amount of urine excretion but, however, AVP also has V1 receptor mediated vasoconstrictive / hypertensive effects and a very short serum half-life, which makes the hormone unsuitable for the treatment of nocturia / nocturnal polyuria.

*4.5.2 **Available drugs***

Desmopressin acetate (desmopressin) is a synthetic analogue of AVP with high V2 receptor affinity and antidiuretic properties. It is the only registered drug for antidiuretic treatment (Table 9). In contrast to AVP, desmopressin has no relevant V1 receptor affinity and hypertensive effects. Desmopressin may be used by intravenous infusion, nasal spray, tablet, or MELT formulation. Nasally or orally administered desmopressin is rapidly absorbed and, later, excreted 55% unchanged by the kidneys (1). Desmopressin has been used for over 30 years in the treatment of diabetes insipidus or primary nocturnal enuresis and has recently been approved in most European countries for the treatment of nocturia polyuria for adult male and female patients. After intake before sleeping, urine excretion during the night decreases and, therefore, the urge to void is postponed and the number of voids at night is reduced (2,3). The clinical effects - in terms of urine volume decrease and an increase in urine osmolality - last for approximately 8-12 hours (2).

Table 9: Antidiuretics licensed in Europe for treating nocturia due to nocturnal polyuria; key pharmacokinetic properties and standard doses

Drug	t_{max} (hours)	t ½ (hours)	Recommended daily dose
Desmopressin	1-2	3	1 x 0.1-0.4 mg orally before sleeping

t_{max} = time to maximum plasma concentration; t½ = elimination half-life.

4.5.3 *Efficacy*

The majority of clinical trials have used desmopressin in an oral formulation. A dose-finding study showed that the nocturnal urine volume/nocturnal diuresis was more reduced by oral desmopressin 0.2 mg than 0.1 mg; however, this study also showed that a 0.4 mg dose taken once before sleeping had no additional effects on the nocturnal diuresis compared to a 0.2 mg dose (4). In the pivotal clinical trials, the drug was titrated from 0.1 to 0.4 mg according to the individual clinical response. Desmopressin significantly reduced nocturnal diuresis by approximately 0.6-0.8 mL/min (-40%), decreased the number of nocturnal voids by approximately 0.8-1.3 (-40%) (-2 in the long-term open-label trial), and extended the time until the first nocturnal void by approximately 1.6 hours (-2.3 in the long-term open-label trial) (Table 10). Furthermore, desmopressin significantly reduced night-time urine volume as well as the percentage of urine volume excreted at night (5,8).

The clinical effects of desmopressin were more pronounced in patients with more severe nocturnal polyuria and bladder capacity within the normal range at baseline. The 24-hour diuresis remained unchanged during desmopressin treatment (6). The clinical effects were stable over a follow-up period of 10-12 months and returned to baseline values after trial discontinuation (12). A significantly higher proportion of patients felt fresh in the morning-time after desmopressin use (odds ratio 2.71) (11).

**Majority of study participants were men; ‡ only male data; a = significant compared to placebo.*

4.5.4 *Tolerability*

The absolute number of adverse events associated with desmopressin treatment were higher compared to placebo but usually mild in nature. The most frequent adverse events in short-term (up to 3 weeks) and long-term studies (12 months) were headache, nausea, diarrhoea, abdominal pain, dizziness, dry mouth, and hyponatraemia. These events were comparable with the established safety profile of desmopressin in the treatment of polyuria due to other conditions. Peripheral oedema (2%) and hypertension (5%) were reported in the long-term treatment trial (12).

Hyponatraemia (serum sodium concentration < 130 mmol/L) was observed mainly in patients aged

65 years or older and seemed to occur less frequently in men compared to women of the same age (3). Hyponatraemia of all degrees, not necessarily associated with symptoms, occurs in approximately 5% (13) to 7.6% of patients (14) early after treatment initiation. The risk of developing hyponatraemia significantly increases with age (odds ratio 1.16 per year of age), lower serum sodium concentration at baseline (odds ratio 0.76), and higher basal 24-hour urine volume per bodyweight (odds ratio 1.09) (13). The chance of developing hyponatraemia in patients younger than 65 years is less than 1%, whereas the risk for older patients increases to 8% with normal sodium concentration and up to 75% in patients with low sodium concentration at baseline (13).

Therefore, the treatment of men aged 65 years or older should not be initiated without monitoring the serum sodium concentration. At the time of treatment initiation or dose change, older men with normal values of serum sodium should be monitored by Na^+ measurement at day 3 and day 7 of treatment as well as at 1 month later. If serum sodium concentration has remained normal and no dose adjustment is intended, Na^+ should be monitored every 3-6 months thereafter (15). Furthermore, patients should be informed about the prodromal symptoms of hyponatraemia, such as headache, nausea, or insomnia.

*4.5.5 **Practical considerations***

Desmopressin should be taken once daily before sleeping. As the optimal dose differs between patients, desmopressin treatment should be initiated at a low dose (0.1 mg/day) and may be gradually increased every week until maximum efficacy is reached. The maximal daily dose recommended is 0.4 mg/day. Patients should avoid drinking fluids at least 1 hour before using desmopressin until 8 hours thereafter. In men aged 65 years or older, desmopressin should not be used if the serum sodium concentration is below the normal value. In all other men aged 65 years or older, serum sodium concentration should be measured at day 3 and 7 as well as after 1 month and, if serum sodium concentration has remained normal, every 3-6 months subsequently.

4.6 Combination therapies

4.6.1 α_1-blockers + 5α-reductase inhibitors

4.6.1.1 Mechanism of action

Combination therapy of α_1-blockers and 5α-reductase inhibitors aims to combine the differential effects of both drug classes to create synergistic efficacy in symptom improvement and prevention of disease progression.

4.6.1.2 Available drugs

Combination therapy consists of an α_1-blocker (alfuzosin, doxazosin, tamsulosin, or terazosin; pharmacokinetic properties see Section 3.1.2) together with a 5α-reductase inhibitor (dutasteride or finasteride; pharmacokinetic properties see Section 3.2.2). The α_1-blocker exhibits clinical effects within hours or days, whereas the 5α-reductase inhibitor needs several months to develop significant clinical efficacy. Of all drug combinations possible, so far finasteride together with alfuzosin, doxazosin, or terazosin, and dutasteride together with tamsulosin, have been tested in clinical trials. Both compounds show class effects with regard to efficacy and adverse events. No differences in pharmacokinetic or pharmacodynamic properties of the combined use of both drugs have been reported compared to single drug.

4.6.1.3 Efficacy

Several studies have investigated the efficacy of combination therapy against the efficacy of an α_1-blocker, 5α-reductase inhibitor, or placebo alone (Table 11). Initial studies with follow-up periods between 6 and 12 months used symptom (IPSS) change as their primary endpoint (1-3). These trials consistently demonstrated that the α_1-blocker was superior to finasteride in symptom reduction, whereas the combination treatment was not superior to the α_1-blocker alone. In studies which included a placebo arm, the α_1-blocker was consistently more effective than placebo, whereas finasteride was consistently not more effective than placebo. Data from the 1-year time point of the MTOPS (Medical Therapy of Prostatic Symptoms) study, which have been published but not specifically analysed for this time point, showed similar results (4).

More recently, 4-year data analysis from MTOPS as well as the 2- and 4-year results from the CombAT (Combination of Avodart® and Tamsulosin) trials, have been reported (4-6). The latter trial included older men with larger prostates and higher serum PSA concentrations and therefore appears to represent men at greater risk of disease progression. In contrast to earlier studies with only 6 to 12 months follow-up, long-term data have demonstrated that combination treatment is superior to either monotherapy with regard to symptom reduction and Q_{max} improvement and superior to α_1-blocker in reducing the risk of acute urinary retention and the need for surgery (4-6). The CombAT study demonstrated that combination treatment is superior to either monotherapy with regard to symptom improvement and Q_{max} starting from month 9 and superior to α_1-blocker with regard to the reduction in the risk of acute urinary retention and the need for surgery after month 8 (6). The different results between the CombAT and MTOPS trials appear to arise from different inclusion and exclusion criteria rather than the types of α_1-blockers or 5α-reductase inhibitors. Dutasteride or finasteride alone reduced prostate volume as effectively as combination treatment (-20 to -27%).

Three studies addressed the issue of discontinuation of the α_1-blocker (7-9). One trial evaluated the combination of tamsulosin with dutasteride and the impact of tamsulosin discontinuation after 6 months (7). After cessation of the α_1-blocker, almost three-quarters of patients reported no worsening of symptoms. However, patients with severe symptoms (IPSS > 20) at baseline may benefit from longer combination therapy. A more recently published trial evaluated the symptomatic outcome of finasteride monotherapy at 3 and 9 months after discontinuation of 9-month combination therapy (finasteride plus α_1-blocker) (8). LUTS improvement after combination therapy was sustained at 3 months (IPSS difference 1.24) and 9 months (IPSS difference -0.44).

In a retrospective study, the likelihood of α_1-blocker discontinuation, which was based on the individual decision of the patient, was evaluated over a 12-month period in men aged > 65 years receiving α_1-blockers in combination with either dutasteride or finasteride (9). Dutasteride patients discontinued α_1-blocker therapy 64% faster than finasteride patients at any time point. At 12 months, 62% of patients were treated with dutasteride alone compared to 43.7% of men treated with finasteride alone.

Combination therapy was shown to be superior to monotherapy in both the MTOPS and CombAT trials in preventing overall clinical progression, as defined by an IPSS increase of at least 4 points, acute urinary retention, urinary tract infection, incontinence, or an increase in serum creatinine > 50% compared to baseline values). For combination therapy in the MTOPS trial versus the CombAT trial, the following reductions were observed:

- overall risk of disease progression was 66% versus 44%;
- symptomatic progression, 64% vs. 41%;
- acute urinary retention, 81% vs. 68%;
- urinary incontinence, 65% vs. 26%;
- BPH-related surgery, 67% vs. 71%.

Monotherapy with 5α-reductase inhibitor appeared to reduce the risks of acute urinary retention and prostaterelated surgery as effectively as combination treatment (differences not significant), although the preventive effects were more pronounced with combination therapy (4,6). The MTOPS trial results suggested that the α_1-blocker alone might also reduce the risk of symptom progression.

Table 11: Randomised trials using α_1-blocker, 5α-reductase inhibitor, and the combination of both drugs in men with LUTS and benign prostatic enlargement due to benign prostatic hyperplasia (Of note: references 5 and 6 reflect different time points of the same study.)

Q_{max} = maximum urinary flow rate (free uroflowmetry); IPSS = International Prostate Symptom Score; a = significant compared to baseline (indexed wherever evaluated); b = significant compared to placebo; c = significant compared to α_1-blocker monotherapy; d = significant compared to 5α-reductase inhibitor monotherapy.

4.6.1.4 Tolerability and safety

In both the CombAT and MTOPS trials, overall drug-related adverse events were significantly more frequent during combination treatment than during either monotherapy. The adverse events observed during combination treatment were typical of an α_1-blocker and 5α-reductase inhibitor. The frequencies of adverse events were significantly higher for combination therapy for most adverse events (4).

4.6.1.5 Practical considerations

Compared to α_1-blockers or 5α-reductase inhibitor monotherapy, combination therapy results in a greater improvement in LUTS and increase in Q_{max}, and is superior prevention of disease progression. However, combination therapy is also associated with more adverse events. Combination therapy should therefore be used primarily in men who have moderate to severe LUTS and are at risk of disease progression (higher prostate volume, higher PSA concentration, advanced age, etc). Combination therapy should only be used when long-term treatment (more than 12 months) is intended; this issue should be discussed with the patient before treatment. Discontinuation of the α_1-blocker after 6 months might be considered in men with moderate LUTS.

4.6.1.6 Recommendations

	LE	GR
Combination treatment with α_1-blocker together with 5α-reductase inhibitor should be offered to men with moderate-to-severe lower urinary tract symptoms, enlarged prostates (> 40 mL), and reduced Q_{max} (men likely to develop disease progression). Combination treatment is not recommended for short-term therapy (< 1 year).	1b	A

4.6.2 α_1-blockers + muscarinic receptor antagonists

4.6.2.1 Mechanism of action

Combination therapy of an α_1-blocker together with a muscarinic receptor antagonist aims to antagonise both α_1-adrenoceptor and muscarinic cholinoreceptors (M^2 and M^3) in the lower urinary tract, hereby using the efficacy of both drug classes to achieve synergistic effects.

4.6.2.2 Available drugs

Combination treatment consists of an α_1-blocker (alfuzosin, doxazosin, tamsulosin, or terazosin; pharmacokinetic properties chapter 3.1.2) together with a muscarinic receptor antagonist (darifencacin, fesoterodine, oxybutynin, propiverine, solifenacin, tolterodine, or trospium chloride; pharmacokinetic properties chapter 3.3.2). However, only the combinations of the α_1-blocker doxazosin, tamsulosin, or terazosin and the muscarinic receptor antagonist oxybutynin, propiverine, solifenacin, or tolterodine have been tested in clinical trials so far. Until now, both drug classes have to be taken as separate pills as no combination pill is yet available. No differences in terms of pharmacokinetic or pharmacodynamic properties of the combined use of both drugs have been described compared to the use of the single drugs.

4.6.2.3 Efficacy

At least nine trials have been published investigating the efficacy of the combination treatment with α_1-blockers and muscarinic receptor antagonists in adult male patients with LUTS (1-8). Additionally, one trial was published using the α_1-blocker naftopidil (not registered in most European countries) with and without anticholinergic agents (9). Only one of those trials had a placebo arm (LE: 1b) and also tested the drug combination against the α_1-blocker as well as against the muscarinic receptor antagonist (4); all other trials compared the efficacy of the combination therapy with the efficacy of an α_1-blocker alone (Table 12) (LE: 2b). Maximum trial duration was 25 weeks but the majority of trials lasted 4-12 weeks only.

The combination of drugs was in general more efficacious in reducing voiding frequency, nocturia, or IPSS compared to α_1-blockers or placebo alone. Furthermore, the combination treatment significantly reduced urgency urinary incontinence episodes as well as urgency and significantly increased QoL (4).

Overall symptom improvement in the combination therapy arm was significantly higher compared to placebo regardless of PSA serum concentration, whereas tolterodine alone significantly improved symptoms predominantly in men with a serum PSA concentration less than 1.3 ng/mL (10). Three trials investigated the efficacy of combination treatment in patients with persistent LUTS during α_1-blocker treatment by adding a muscarinic receptor antagonist to the existing α_1-blocker therapy (add-on approach) (6-8). These trials demonstrated that persistent LUTS can be significantly reduced by the additional use of a muscarinic receptor antagonist (tolterodine) especially if detrusor overactivity had been demonstrated (Table 12). Patient reported QoL, treatment benefit, symptom bother, or patient perception of bladder condition was significantly improved in the combination treatment arm.

Table 12: Efficacy of muscarinic receptor antagonists together with α_1-blockers

Trials	Duration (weeks)	Treatment	Patients	Voiding frequency [%]	Nocturia [%]	IPSS [%]	LE

a = significant compared to baseline ($p \leq 0.05$, indexed wherever evaluated)
b = significant reduction compared to placebo ($p < 0.05$)

4.6.2.4 Tolerability and safety

Adverse events of both drug classes appear during combination treatment of α_1-blockers and muscarinic receptor antagonists. The most frequently reported side effect in all trials was xerostomia. Some side effects (e.g. xerostomia or ejaculation failure) appear with increased frequency and cannot simply be explained by adding the frequencies of adverse events of either drug. Post-void residual urine increased in most trials. Although the mean increase of post-void residual urine was low (+6 to +24 mL) some men developed higher post-void residuals or even urinary retention (0.9 to 3.3%). It remains unknown which men are at risk of developing post-void residual urine or urinary retention during the combination treatment.

4.6.2.5 Practical considerations

Class effects are likely to be responsible for increased efficacy and QoL in patients treated with α_1-blocker and muscarinic receptor antagonist. Measuring of post-void residual urine is recommended during combination treatment to assess increase or urinary retention.

4.6.2.6 Recommendations

	LE	GR
Combination treatment with α_1-blocker and muscarinic receptor antagonist might be considered in patients with moderate to severe lower urinary tract symptoms if symptom relief has been insufficient with the monotherapy of either drug.	1b	B
Combination treatment should cautiously be prescribed in men who are suspicious of having bladder outlet obstruction.	2b	B

4.7 Emerging drugs

4.7.1 Phosphodiesterase (PDE) 5 Inhibitors (with or without α_1-blockers)

4.7.2 ***Mechanism of action***

Nitric oxide (NO) represents an important non-adrenergic, non-cholinergic neurotransmitter in the human body and is involved in signal transmission in the human urinary tract. NO is synthesised from the amino acid L-arginine by NO synthases (NOS), which are classified based on their original tissues of detection as neuronal (nNOS), endothelial (eNOS), and immune cells (inducible NOS, iNOS). After being synthesised, NO diffuses

into cells and stimulates the synthesis of cyclic guanosine monophosphate (cGMP) mediated by the enzyme guanylyl-cyclase. cGMP can activate protein kinases, ion channels, and cGMP-binding phosphodiesterases (PDEs) leading to smooth muscle cell relaxation via depletion of intracellular Ca^{2+} and desensitisation of contractile proteins (1). The effects of cGMP are terminated by PDE isoenzymes catalysing the hydrolysis of cGMP to an inactive form. PDE inhibitors increase the concentration and prolong the activity of intracellular cGMP, hereby reducing smooth muscle tone of the detrusor, prostate, and urethra. Until now, 11 different PDEs have been identified of which the PDEs 4 and 5 are the predominant ones in the transition zone of the human prostate, bladder, and urethra (2,3). NO might also be involved in the micturition cycle by inhibiting reflex pathways in the spinal cord and neurotransmission in the urethra, prostate, or bladder (4).

*4.7.3 **Available drugs***

Three selective oral PDE5 inhibitors (sildenafil citrate [sildenafil], tadalafil, and vardenafil hcl [vardenafil]) have been licensed in Europe for the treatment of erectile dysfunction or pulmonary arterial hypertension (sildenafil and tadalafil), but these drugs have not yet been officially registered for the treatment of male LUTS (Table 13). The available PDE5 inhibitors differ primarily in their pharmacokinetic profiles (5). All PDE5 inhibitors are rapidly resorbed from the gastrointestinal tract, have a high protein binding in plasma, and are metabolised primarily by the liver and eliminated predominantly by the faeces. However, their half-lives differ markedly. PDE5 inhibitors are taken on-demand by patients with erectile dysfunction but tadalafil is also registered for daily use in lower dose (5 mg) than for on-demand use.

Table 13: PDE5 inhibitors licensed in Europe for treating erectile dysfunction; key pharmacokinetic properties and doses used in clinical trials

Drugs	t_{max} (hours)	t ½ (hours)	Daily doses in clinical trials of patients with male LUTS
Sildenafil	1 * (0.5-2)	3-5	1 x 25-100 mg
Tadalafil	2 (0.5-12)	17.5	1 x 2.5-20 mg
Vardenafil	1 * (0.5-2)	4-5	2 x 10 mg

*t_{max} = time to maximum plasma concentration; t½ = elimination half-life; * dependent on food intake (i.e. slower resorption of the drug and an increase in tmax by approximately 1 hour after a fatty meal).*

*4.7.4 **Efficacy***

A post-hoc analysis of patients with erectile dysfunction treated with sildenafil initially showed that the PDE5 inhibitor was capable of significantly reducing concomitant LUTS and increasing bladder symptoms-related QoL, as measured by the IPSS questionnaire (6,7). LUTS improvement was found to be independent of improvement of erectile function. Randomised, placebo-controlled trials on the efficacy of all three available oral PDE5 inhibitors have been published during the last years and have investigated changes in symptoms (IPSS), uroflowmetry parameters (Q_{max}), and post-void residual urine (6-16). The maximum trial duration was 12 weeks. These trials demonstrated that all PDE5 inhibitors significantly and consistently reduced IPSS by approximately 17-35% (Table 14). Both bladder storage and voiding symptoms decreased equally during treatment with PDE5 inhibitors. Post-void residual urine remained unchanged in most of the trials. Q_{max} of free uroflowmetry increased in a dose-dependent fashion (tadalafil [16]), but was not significantly different to placebo (sildenafil, tadalafil, and vardenafil). In contrast to the EBM level 1b-trials listed in Table 14, two singlecentre uroflowmetry studies documented improvements of Q_{max} and Q_{ave} following oral administration of 50 or 100 mg sildenafil in up to 76% of men (mean Q_{max} increase 3.7-4.3 mLs or 24-38%) (17,18). PDE5 inhibitors significantly improved QoL compared to placebo-treated patients.

Three trials compared the efficacy of PDE5 inhibitors (sildenafil or tadalafil) with or without α_1-blockers (alfuzosin or tamsulosin) (9,12,13). These trials were conducted in a small number of patients and with a limited follow-up of 6 to 12 weeks. The drug combination improved IPSS, Q_{max}, and post-void residual urine to a greater extent than the single drug alone of each class (Table 14), although the difference compared to PDE5 inhibitor or α_1-blocker alone was only statistically significant in one of the three trials (12).

Table 14: Efficacy of PDE5 inhibitors in adult men with LUTS who participated in clinical trials with EBM

4.7.5 *Tolerability and safety*

PDE5 inhibitors in general can cause headache, flushing, dizziness, dyspepsia, nasal congestion, myalgia, hypotension, syncope, tinnitus, conjunctivitis, or altered vision (blurred, discoloration). However, the frequencies of side-effects vary between the individual PDE5 inhibitors. The probability of developing priapism or acute urinary retention is considered minimal.

PDE5 inhibitors are contraindicated in patients using nitrates or the potassium channel opener, nicorandil, due to additional vasodilatation, which might cause hypotension, myocardial ischaemia in patients with coronary artery disease, or cerebrovascular strokes (5). Additionally, all PDE5 inhibitors should not be used in patients who are taking the α_1-blockers doxazosin or terazosin, have unstable angina pectoris, have had a recent myocardial infarction (previous 3 months) or stroke (previous 6 months), myocardial insufficiency NYHA > 2, hypotension, poorly controlled blood pressure, significant hepatic or renal insufficiency, or if non-arteritic anterior ischemic optic neuropathy (NAION) with sudden loss of vision is known or has appeared after previous use of PDE5 inhibitors. Sildenafil and vardenafil are also contraindicated in patients with retinitis pigmentosa. Caution is advised if PDE5 inhibitors are used together with other drugs which are metabolised by the same hepatic elimination pathway (CYP3A4), which is associated with an increased serum concentration of the PDE5 inhibitor.

4.7.6 *Practical considerations*

To date, PDE5 inhibitors have been officially licensed only for the treatment of erectile dysfunction and pulmonary arterial hypertension. Treatment beyond this indication (e.g. male LUTS) is still experimental and should not be used routinely in the clinical setting. Long-term experience in patients with LUTS is still lacking. The value of PDE5 inhibitors in the context of other available potent drugs (e.g. α_1-blockers, 5α-reductase inhibitors, or muscarinic receptor antagonists) remains to be determined. Insufficient information is available about combinations between PDE5 inhibitors and other LUTS medications.

4.7.7 *Recommendations*

	LE	GR
PDE5 inhibitors reduce moderate to severe male lower urinary tract symptoms.	1b	
PDE5 inhibitors are currently restricted to men with erectile dysfunction, pulmonary arterial hypertension, or to those who have lower urinary tract symptoms and participate in clinical trials.		A

4.8 Other new drugs

Several new drugs are currently under clinical investigation (phase II-III trials) of which none has been licensed for male LUTS so far. These new drugs target:

- the prostate, e.g. gonodotrophin-releasing hormone antagonists, oestrogen receptor antagonists, apoptosis-inducing agents, vaccines, vitamin D agonists, or androgen replacement therapies;
- the bladder, e.g. β_3-adrenoceptor agonists;
- the nervous system, e.g. neuromuscular blocking agents, tachykinin receptor antagonists. Published results of those drugs are preliminary and sparse. Therefore, these new drugs were excluded from further analyses, but will be re-evaluated for the next version of the guidelines on male LUTS.

5. SURGICAL TREATMENT

5.1 Transurethral Resection of the Prostate (TURP) and Transurethral Incision of the Prostate (TUIP)

*5.1.1 **Mechanism of action***

Transurethral resection of the prostate (TURP) was first performed in 1932. Whereas the material has changed substantially since the first procedure, the basic principle of TURP has remained unchanged. It is still, firstly, the removal of tissue from the transition zone of the prostate to reduce benign prostatic obstruction (BPO) and, secondly, to reduce lower urinary tract symptoms (LUTS).

TURP is still regarded as the gold standard for the treatment of LUTS secondary to BPO in prostates between 30 and 80 mL. However, there is no strong evidence in the literature regarding the upper size limit of the prostate suitable for TURP. The suggested threshold sizes reflect the Panel's opinion who has assumed that this limit depends on the surgeon's experience, resection speed, and resectoscope sizes. During the last decade, there has been a continuous decline in the rate of TURPs performed. In 1999, TURP represented 81% of all surgery for benign prostatic hypertrophy (BPH) in the USA, but by 2005, TURP represented only 39% of surgical procedures for BPH, due to the combined effect of fewer prostatic operations and more minimally-invasive procedures (1).

Transurethral incision of the prostate (TUIP) was initially described by Orandi in 1969. TUIP reduces LUTS secondary to BPO by splitting the bladder outlet without tissue removal. This technique has been rediscovered and may replace TURP as the first choice of treatment in selected men with benign prostate enlargement, especially men with prostate sizes ≤ 30 mL and without prostate middle lobes.

*5.1.2 **Operative procedure***

During TURP, hyperplastic prostatic tissue of the transition zone is removed endoscopically using special resectoscopes and cutting loops, which enable ablation of prostatic tissue in small slices that are then removed from the bladder at the end of surgery. The cutting of prostatic tissue and coagulation of blood vessels is achieved by using adaptable electrical current.

During the TUIP procedure, one or two cuts are made into the prostatic parenchyma and capsule, thereby reducing urethral resistance (BPO). The technique has been modified by several authors. The most popular unilateral incision is located at the 6 o'clock position and the most commonly performed bilateral incisions are at the 5 and 7 o'clock positions.

Urinary tract infections (UTIs) should be treated prior to TURP or TUIP (2,3). The routine use of prophylactic antibiotics in TURP has been well evaluated with a considerable number of RCTs. Three systematic reviews of the available RCTs resulted in similar conclusions favouring the use of antibiotic prophylaxis (4-6). Antibiotic prophylaxis significantly reduces bacteriuria, fever, sepsis, and the need for additional antibiotics after TURP. There was also a trend towards higher efficacy in favour of short-course antibiotic administration than for a single-dose regimen (4). However, further studies are required to define the optimal antibiotic regimen and cost-effectiveness of antibiotic prophylaxis in TURP.

*5.1.3 **Efficacy***

5.1.3.1 Symptom improvement

TURP provides durable clinical outcomes, as shown by studies with a long follow-up of 8-22 years. There are no similar data on durability for any other surgical treatment for BPO (7). One study with a mean follow-up of 13 years reported a significant and sustained decrease in most symptoms and improvements in urodynamic parameters following TURP. The study also found that subjective and objective failures were associated with decreased detrusor contractility rather than BPO (8). A study in 577 men who underwent TURP reported excellent functional outcomes with a mean IPSS of 4.9 and a mean QoL score of 1.2 after 10 years of followup (9). A meta-analysis of 29 RCTs reported a mean LUTS improvement of 70.6% (95% CI: 66.4-75.5%) after TURP (10).

5.1.3.2 RCT comparison of TUIP with TURP

Eleven RCTs comparing TUIP with TURP are currently available (10-14) (Table 15). These studies evaluated similar LUTS improvements in patients with small prostates (< 20-30 mL) and no prostate median lobe (10-14). The findings are reported below.

Uroflowmetry: the mean Q_{max} increase following TURP was 125% with an absolute mean improvement of +9.7 mL/s (95% CI: 8.6-11.2 mL/s) (10). All RCTs comparing TUIP with TURP 12 months after the procedure reported a lower mean or median Q_{max} following TUIP with an overall mean Q_{max} improvement of 70% (95% CI: 27-112) (10,13).

Post-void residual: PVR volume decreased by 60.5% (95% CI: 48-71) after TURP (10). The decrease in PVR after TUIP varied across available studies, but was always lower than with TURP (10,13).

Re-treatment rate: a second prostatic operation, usually performed as TURP again, was reported at a constant rate of approximately 1-2% per year. The review analysing 29 RCTs found a re-treatment rate of 2.6% (96% CI: 0.5-4.7) after a mean follow-up of 16 months (10). In a recent large-scale study of 20,671 men, who underwent TURP in Austria, the overall reported re-treatment rates (including secondary TURP, urethrotomy, and bladder neck incision) were 5.8%, 12.3%, and 14.7% at 1, 5, and 8 years of follow-up, respectively (14). The incidence of secondary TURP was 2.9%, 5.8% and 7.4% for the same follow-up periods (14). Analyses of RCTs comparing TURP with TUIP showed that re-treatment was more likely following TUIP (17.5%) than after TURP (9%) (13).

5.1.4 ***Tolerability and safety***

5.1.4.1 Intra- and peri-operative complications

Mortality following prostatectomy has decreased constantly and significantly during the past decades and is less than 0.25% in contemporary series (10,15,16). In the most recent study of 10,564 men who underwent TURP, peri-operative mortality (during the first 30 days) was 0.1% (17). The risk of transurethral resection (TUR) syndrome has also decreased during the last decades to less than 1.1% (10,16). Risk factors associated with TUR syndrome are excessive bleeding with opening of venous sinuses, prolonged operation time, large prostates, and past or present nicotine abuse (17). No cases of TUR syndromes were recorded in patients undergoing TUIP. The incidence of blood transfusion following TURP in the analysis of 29 RCTs was 8.4% (95% CI: 3.9-13.4) (10). Contemporary real-life data from 10,564 TURP procedures reported procedure-related bleeding requiring blood transfusion in 2.9% of patients. The risk of bleeding following TUIP is negligible (10).

5.1.4.2 Long-term risk of mortality

The possibility of an increased long-term risk of mortality after TURP compared to open surgery has been raised by Roos et al. (15). However, these findings have not been replicated by others (18-20). Recently, data from 20,671 TURPs and 2,452 open prostatectomies (OP) showed that the 8-year incidence of myocardial infarction was identical after TURP (4.8%) and OP (4.9%). Similarly, mortality rates at 90 days (0.7% vs. 0.9%), one year (2.8% vs. 2.7%), 5 years (12.7% vs. 11.8%) and 8 years (20% vs. 20.9%) were almost identical (14).

5.1.4.3 Long-term complications

Urinary incontinence: the median probability of post-operative stress urinary incontinence ranges from 1.8% following TUIP to 2.2% following TURP (1-6,13,15). A meta-analysis of three trials investigating urinary incontinence showed no statistically significant difference between the TUIP and TURP groups, although there were fewer events in the TUIP group (13).

Urinary retention and UTIs: a recent meta-analysis found no statistically significant differences between TURP and TUIP in the development of urinary retention and UTIs (13).

Bladder neck stenosis and urethral stricture: the risk of developing urethral strictures after TURP is 3.8% (95% CI: 1.7-5.8) and after TUIP 4.1% (10). The risk of bladder neck stenoses is 4.7% (95% CI: 0.3-9.2) after TURP (10). A systematic review reported an overall incidence of 8.7% for strictures after TUIP, but did not distinguish between urethral strictures and bladder neck stenoses (13).

Sexual function: retrograde ejaculation results from resection/destruction of the bladder neck and is reported by 65.4% (95% CI 53.4-77.5) of patients after TURP and 18.2% after TUIP (10). There is a long-standing controversy on the impact of prostatectomy, particularly TURP, on erectile function. The only RCT that compared TURP to a 'wait and see' policy with a follow-up of 2.8 years reported identical rates of erectile dysfunction (ED) in both arms (19% and 21%, respectively) (21). In the analysis of 29 RCTs, the incidence of ED following TURP was 6.5% (95% CI: 0.2-12.7%) (10). The frequently reported increase in ED after TURP seems to be caused by confounding factors (e.g. age) rather than being the direct consequence of TURP.

5.1.5 ***Practical considerations***

TURP and TUIP are both effective primary treatments for men with BPO, BPE, and moderate-to-severe LUTS. The choice between TURP and TUIP should be primarily based on prostate volume, with prostates < 30 mL being mainly considered for TUIP and prostates of 30-80 mL for TURP. The advantages of TUIP are reduced bleeding incidents, shorter operation time, avoidance of TUR syndrome, minimal and shorter post-operative bladder irrigation, low risk of retrograde ejaculation, and shorter times for catheterisation and hospitalisation. The disadvantages are a higher rate of symptom recurrence and the need for additional surgery.

5.1.6 ***Modifications of TURP: bipolar Transurethral Resection of the Prostate***

5.1.6.1 Mechanism of action

One of the most important recent improvements in TURP is the incorporation of plasmakinetic bipolar technology (B-TURP). To date, five types of bipolar resection devices have been developed: the plasmakinetic (PK) system (Gyrus), Vista Coblation/CTR (controlled tissue resection) system (ACMI) [withdrawn], transurethral

resection in saline (TURis) system (Olympus), Karl Storz, and Wolf (22). The devices differ in the way in which bipolar current flow is delivered to achieve the plasmakinetic effect.

5.1.6.2 Operative procedure

Prostatic tissue removal during B-TURP is identical to monopolar TURP. In contrast to monopolar TURP, B-TURP uses a specialised resectoscope loop, which incorporates both the active and return electrodes. It permits electrosurgical tissue cutting in a conductive saline medium. After activation of the high frequency current, the physiological saline around the loop is heated up to the boiling point. The resulting bubbles create an environment with high electrical resistance; the voltage between electrode and saline solution spikes forms an arc. The tissue is heated indirectly by the heat of the ignition of the arc; this enables both resection and coagulation. As with other endoscopic operations, UTIs should be treated before the procedure and prophylactic antibiotic therapy is advised.

5.1.6.3 Efficacy

The efficacy of bipolar TURP devices has been demonstrated in case series and RCTs. Three systematic reviews have provided important information on the efficacy of bipolar TURP (23-25). Almost identical outcomes were reported with monopolar and bipolar TURP concerning the improvement of Q_{max} (10.5 mL/s vs. 10.8 mL/s) and the AUA-SS/IPSS (-15.2 vs. -15.1) (23).

Long-term results of B-TURP are still awaited. In a RCT comparing B-TURP with plasmakinetic energy with a mean follow-up of 18.3 months, the re-operation rate was 4.1% and 2.1% for the PK system and TURP, respectively (26). In a recent study with a follow-up of 3 years, the initially observed significant improvements remained durable for the bipolar and monopolar arm in terms of IPSS (6.8 vs. 6.2) and Q_{max} (20.5 vs. 21.5 mL/s) (27).

5.1.6.4 Tolerability and safety

The overall rate of adverse events was significantly lower with B-TURP compared to monopolar TURP (28.6% vs. 15.5%) (23). Main advantages of B-TURP include reduced blood loss and decreased incidences of postoperative clot retention and blood transfusions. Both post-operative catheterisation and hospitalisation times were shorter with bipolar TURP compared to monopolar TURP; this was thought to be due to reduced bleeding associated with improved coagulation abilities. Post-operative storage symptoms, particularly dysuria, were less common with B-TURP. However, most of these results were trends favouring B-TURP rather than statistically significant differences (23).

TUR syndrome has not been reported with B-TURP, due to the use of physiological saline irrigation fluid and reduced fluid absorption during the procedure (23,24). Several RCTs have suggested that urethral strictures are more common with B-TURP, with possible contributory factors being a larger resectoscope size (27F), the type of return electrode, and higher current densities (22). However, the most recent systematic review of RCTs did not reveal statistically significant differences between monopolar and bipolar TURP treatment arms (1.7% vs 2.4, respectively, $p = 0.280$) (24). Nevertheless, larger studies with increased numbers of patients and/or longer follow-ups may change these results. Regarding the impact of B-TURP on sexual function, it was found that post-operative retrograde ejaculation (57 vs 60%) (24) or erectile dysfunction (both about 14%) (23) did not differ significantly between B-TURP and monopolar TURP.

5.1.6.5 Practical considerations

B-TURP offers an attractive alternative to monopolar TURP in patients with LUTS secondary to BPO with similar efficacy but lower morbidity. Furthermore, the safety of B-TURP allows more time for training and teaching of urology residents. However, since there remains a lack of sufficient long-term data, it is not possible to draw definite conclusions about the duration of improvements and advantages of B-TURP over monopolar TURP. The choice of B-TURP should currently be based on the availability of the bipolar armamentarium, the surgeon's experience, and the patient's preference.

5.1.7 *Recommendations*

	LE	GR
Monopolar TURP is the current surgical standard procedure for men with prostate sizes of 30-80 mL and moderate-to-severe LUTS secondary to BPO. Monopolar TURP provides subjective and objective improvement rates superior to medical or minimally invasive treatments. However, the morbidity of monopolar TURP is higher than for transur, bipolar TURP, drugs, or other minimally-invasive procedures.	1a	A
Bipolar TURP achieves short-term results comparable to monopolar TURP.	1a	A
TUIP is the surgical therapy of choice for men with LUTS secondary to BPO and prostate sizes < 30 mL without middle lobes.	1a	A

BPO = benign prostatic obstruction; LUTS = lower urinary tract symptoms; TUIP = transurethral incision of the prostate; TURP = transurethral resection of the prostate.

5.2 Open prostatectomy

*5.2.1 **Mechanism of action***

Open prostatectomy is the oldest surgical treatment modality for LUTS secondary to BPO. Obstructive prostatic adenomas are enucleated using the index finger, either from the inside of the bladder (Freyer procedure) or through the anterior prostatic capsule (Millin procedure), allowing unobstructed voiding.

5.2.2 ***Operative procedure***

Indications for surgery

The most frequent indication for surgical management is bothersome LUTS refractory to medical management (1,2). The following complications of BPH/BPE/BPO are considered strong indications for surgery:

- refractory urinary retention;
- recurrent urinary infection;
- recurrent haematuria refractory to medical treatment with 5-alpha reductase inhibitors;
- renal insufficiency due to BPE/BPO;
- bladder stones.

Increased PVR volume may also be used as an indication for surgery. However, there is great intra-individual variability and an upper limit requiring intervention has not been defined. Variables most likely to predict the outcome of prostatectomy are severity of LUTS, the degree of bother, and the presence of BPO.

Procedure

A transurethral balloon catheter is inserted and the bladder is filled with saline solution. Access to the bladder or anterior prostatic capsule is obtained through a midline or transverse suprapubic incision.

Transvesical procedure (Freyer)

A transverse incision is made in the anterior bladder wall. The index finger is then placed in the urethra and with forward pressure towards the symphysis, the urethral mucosa is broken, and the plane between the surgical capsule and the adenomas is defined. The prostatic adenomas are then bluntly separated from the capsule with the finger. Special care must be taken when dividing the urethra at the apex in order not to harm the urethral sphincter. Haemostatic sutures are placed in the posterior corners of the cavity and the posterior margin, taking care not to include the ureteral orifices. Post-operative haemostasis might be obtained using gauze packing and/or traction on a large balloon catheter. For sufficient drainage, both a transurethral and a suprapubic catheter are placed.

Transcapsular procedure (Millin)

A transverse incision is made in the anterior prostatic capsule and the adenomas freed bluntly with a scissor and the index finger. Care is taken when dividing the urethra. Many surgeons will resect the posterior bladder neck to avoid late bladder neck stricture. The prostatic capsule is closed after insertion of a transurethral balloon catheter for drainage.

Peri-operative antibiotics

A known urinary tract infection should be treated before surgery (10,11). The routine use of prophylactic antibiotics remains controversial. However, antibiotics are recommended in patients on catheterisation prior to surgery.

5.2.3 ***Efficacy***

Open prostatectomy is the treatment of choice for large glands (> 80-100 mL). Associated complications include large bladder stones or bladder diverticula (4-6). Three recent RCTs have shown that Holmium laser enucleation and PVP lead to similar outcomes compared to open prostatectomy in men with large glands (> 70, 80 and 100 mL) at a significantly lower complication rate (7-9).

5.2.3.1 Treatment outcome

The results of open prostatectomy studies for treating BPH-LUTS or BPO are summarised in Table 16.

- LUTS: open prostatectomy results in an improvement of LUTS of 63-86% and in the IPSS Quality of Life score of 60-87% (8,9,12).
- Uroflowmetry: the mean increase of Q_{max} following open prostatectomy is 375% (range, 88-677%) (8,9,12) in absolute terms +16.5-20.2 mL/s (6,8,9,12).
- PVR: a reduction of 86-98% is seen in the PVR volume after open prostatectomy (8,9,12).

5.2.3.2 Long-term outcome and re-treatment rate

A favourable long-term outcome is common after open prostatectomy. A secondary prostatic operation has not been reported in the open prostatectomy arm in randomised studies up to 5 years follow-up (8,9,12) (Table 17).

5.2.4 *Tolerability and safety*

Intra-/peri-operative complications

Mortality following open prostatectomy has decreased significantly during the past two decades and is less than < 0.25% in contemporary series (13) (Table 17). The estimated need for blood transfusion following is about 7-14% (9,12,13).

Long-term complications

Long-term complications are incontinence and bladder neck contracture and urethral stricture. The risk of developing stress incontinence is up to 10% (4), while the risk for developing bladder neck contracture and urethral stricture is about 6% (7-9).

5.2.5 *Practical considerations*

Open prostatectomy is the most invasive, but also the most effective and durable, procedure for the treatment of LUTS secondary to BPO. Only Holmium enucleation delivers similar results, but with less morbidity. In the absence of an endourological armamentarium and a Holmium laser, open prostatectomy appears to be the treatment of choice for men with prostates > 80-100 mL and drug-treatment-resistant LUTS secondary to BPO. The choice between the Freyer or Millin procedures depends upon the surgeon's preference.

Table 16: Results of open prostatectomy studies for treating BPH-LUTS or BPO

Studies	Duration (weeks)	Patients (*n*)	Change in symptoms (IPSS)		Change in Q_{max}		Change in PVR		Change in prostate volume		LE
			Absolute	%	mL/s	%	mL	%	mL	%	
Kuntz et al. 2008 (9)	260	32	-18.2	86	21.4	677	-287	98			1b
Skolarikos et al. 2008 (8)	78	60	-12.5	63	7	86	-77	86	-86	88	1b

5.3 Transrethral Microwave Therapy (TUMT)

5.3.1 *Mechanism of action*

Microwave thermotherapy of the prostate works by emitting microwave radiation through an intra-urethral antenna in order to deliver heat into the prostate. Tissue is destroyed by being heated at temperatures above cytotoxic thresholds (> 45°C) (coagulation necrosis). Heat is mainly produced by electrical dipoles (water molecules) oscillating in the microwave field and electric charge carriers (ions) moving back and forth in the microwave field. It is also thought that the heat generated by TUMT also causes apoptosis and denervation of α-receptors, thereby decreasing the smooth muscle tone of the prostatic urethra.

5.3.2 *Operative procedure*

Transurethral microwave therapy is a registered trademark of Technomed Medical Systems, the pioneer of microwave thermotherapy. Currently, the main devices in the field of microwave thermotherapy are the Prostatron™ device (Urologix, Minneapolis, MN, USA), Targis™ (Urologix, Minneapolis, MN, USA), CoreTherm™ (ProstaLund, Lund, Sweden), and TMx-2000™ (TherMatrx Inc, Northbrook, ILL, USA). Most published data on thermotherapy has been on the Prostatron device.

Conceptually, TUMT devices are all similar in delivering microwave energy to the prostate with some type of feedback system. All TUMT devices consist of a treatment module that contains the microwave generator with a temperature measurement system and a cooling system. The main difference between TUMT devices is the design of the urethral applicator. The applicator consists of a microwave catheter connected to the module, which is inserted into the prostatic urethra. Differences in the characteristics of applicators have a significant effect on the heating profile (1). Other less important differences between TUMT devices are found in the catheter construction, cooling systems, treatment time, and monitoring of TUMT effects (2).

*5.3.3 **Efficacy***

5.3.3.1 Clinical outcome

A systematic review of all available RCTs on TUMT attempted to assess therapeutic efficacy (Table 18) (3) in different TUMT devices and software, including Prostatron (Prostatsoft 2.0 and 2.5) and ProstaLund Feedback. Weighted mean differences (WMD) were calculated with a 95% confidence interval (CI) for the between-treatment differences in pooled means. The review found that TUMT was somewhat less effective than transurethral resection of the prostate (TURP) in reducing LUTS. The pooled mean symptom score for men undergoing TUMT decreased by 65% in 12 months compared to 77% in men undergoing TURP, which is a WMD of -1.83 in favour of TURP. TURP achieved a greater improvement in Q_{max} (119%) than TUMT (70%), with a WMD of 5.44 mL/s in favour of TURP (3).

Similarly, a pooled analysis of three studies (two RCTs and one open label) of ProstaLund Feedback TUMT (PLFT) with 12-month follow-up showed that the responder rate was 85.3% in the PLFT group and 85.9% in the TURP group (4). In addition, pooled IPSS data indicated that a subjective, non-inferior improvement with PLFT compared to TURP (4). However, one-sided 95% CI analysis showed that the non-inferiority of PLFT compared to TURP did not reach the predetermined level, even though both PLFT and TURP appeared to improve Q_{max} significantly.

Previously, urinary retention was considered to be a contraindication for TUMT. Nowadays, level 2b evidence studies have reported an 80-93% success rate for TUMT, defined as the percentage of patients who regained their ability to void spontaneously (5-7). However, these studies had a short follow-up (≤12 months), which makes it difficult to estimate the durability of TUMT outcome in patients with retention. In a study with a longer follow-up of up to 5 years, treatment failure was 37.8% in the retention group, with a cumulative risk of 58.8% at 5 years (8). One RCT compared TUMT with the α_1-blocker, terazosin (9). After 18 months' follow-up, treatment failure in the terazosin-treated patients (41%) was significantly greater than in TUMT patients (5.9%), with TUMT also achieving a greater improvement in IPSS and Q_{max} (10).

5.3.3.2 Durability

Low-energy TUMT has disappointing results for durability. Several studies have reported a re-treatment rate after low-energy TUMT as high as 84.4% after 5 years (11-14), while other studies have reported re-treatment rates of 19.8-29.3% after high-energy TUMT, though with a lower mean follow-up of 30-60 months (15-18). The re-treatment rate due to treatment failure has also been estimated by a systematic review of randomised TUMT trials (3). The trials had different follow-up periods and the re-treatment rate was expressed as the number of events per person per year of follow-up. The re-treatment rate was 0.075/person years for patients treated by TUMT and 0.010/person years for TURP.

However, a prospective, randomised, multicentre study after 5 years has obtained comparable clinical results with TUMT to those seen with TRUP. The study compared TUMT (PLFT; the Core-Therm device) and TURP (19). No statistically significant differences were found in Q_{max} and IPSS between the two treatment groups at 5 years. In the TUMT group, 10% needed additional treatment versus 4.3% in the TURP arm. These data suggest that, at 5 years, clinical results obtained with PLFT-TUMT were comparable to those seen after TURP. It should be noted that most durability studies have a high attrition rate; in this study, less than half of the initial group of patients treated were analysed at 4-5 years. In addition, patients who remained in the study were likely to represent the best data (responders).

*5.3.4 **Tolerability and safety***

Treatment is well tolerated, even though most patients experience perineal discomfort and urinary urgency and require pain medication prior to or during therapy. Pooled morbidity data of randomised studies comparing TUMT and TURP have been published (3,4,20). Catheterisation time, incidence of dysuria/urgency and urinary retention were significantly less with TURP, while the incidence of hospitalisation, haematuria, clot retention, transfusions, transurethral resection (TUR) syndrome, and urethral strictures were significantly less for TUMT. In a systematic review of randomised trials (3), the re-treatment rate due to strictures during follow-up was estimated and expressed as the number of events per person per year of follow-up. TURP patients (5.85/100 person years) were more likely than TUMT patients (0.63/100 person years) to require surgical re-treatment for strictures (meatal, urethral, or bladder neck). Pooled data showed that TUMT had less impact on sexual

function (erectile dysfunction, retrograde ejaculation) than TURP (3,4,20).

5.3.5 *Practical considerations*

Endoscopy is essential because it is important to identify the presence of an isolated enlarged middle lobe or an insufficient length of the prostatic urethra. Reported low morbidity and the absence of any need for anaesthesia (spinal or general) make TUMT a true outpatient procedure, providing an excellent option for older patients with co-morbidities at high operative risk and, therefore, unsuitable for invasive treatment (21). Independent baseline parameters predicting an unfavourable outcome include advanced age of the patient, small prostate volume, mild-to-moderate bladder outlet obstruction and a low amount of energy delivered during treatment (22). However, it should be remembered that a predictive factor for a particular device cannot necessarily be applied to other devices.

Table 18: Efficacy of TUMT. Absolute and relative changes compared to baseline are listed for symptoms (IPSS), maximum urinary flow rate (Q_{max}), post-void residual urine (PVR), and prostate volume (PVol)

Trials	Duration (weeks)	Patients (n)	Change IPSS (absolute [%])	Change Q_{max} (mL/s, [%])	Change QoL (absolute [%])	Change PVR (absolute [%])	Change PVol (absolute [%])	LE

5.4 Transurethral Needle Ablation (TUNA™) of the prostate

5.4.1 ***Mechanism of action***

The TUNA™ procedure works by inducing a coagulative necrosis within the transition zone of the prostate. As a result of scar maturation, there may be a reduction in transition zone volume and, therefore, a reduction of BPO. There may also be a poorly understood neuromodulatory effect.

5.4.2 ***Operative procedure***

The TUNA™ device delivers low-level radiofrequency energy to the prostate via needles inserted transurethrally into the prostatic parenchyma. The needles are insulated, except at their tips, so that energy is only delivered into the prostatic parenchyma and not to the urethra. Needles are placed under direct vision using an attachment to the standard cystoscope. TUNA™ is carried out under anaesthetic (local or general) or sedation.

5.4.3 ***Efficacy***

Several, non-randomised, clinical trials have documented the clinical efficacy of TUNA™ with a fairly consistent outcome (3-7). Symptomatic improvement has ranged from 40-70%. Improvements in Q_{max} vary widely from 26-121% in non-retention patients. A recent report with 5 years' follow-up in 188 patients demonstrated symptomatic improvement in 58% and improved flow in 41%. However, 21.2% of patients required additional treatment (8).

5.4.3.1 Randomised clinical trials

TUNA™ has been compared with TURP in randomised studies (8-11) with varying follow-up. The studies found both TUNA™ and TURP produced symptomatic improvement. However, TURP produced greater symptom improvement and a better QoL than TUNA™, as well as a significant improvement in Q_{max} after TUNA™ (Table 19). More detailed comparisons between TUNA™ and TURP can be found in some very high-quality and comprehensive, systematic reviews and meta-analyses (12,13).

5.4.3.2 Impact on bladder outlet obstruction

Seven clinical studies on the impact of TUNA™ on BPO (14,15) have demonstrated a statistically significant decrease in maximum detrusor pressure or detrusor pressure at Q_{max}, even though a number of patients were still obstructed following TUNA™ therapy.

There is no convincing evidence that prostate size is significantly reduced following TUNA™ (6). Recent reports have suggested that gadolinium-enhanced MRI can be used to assess TUNA™-related treatment effects (16).

5.4.3.3 Durability

Because most studies have been short-to-medium term, concerns have been risen about the durability of effects. Even short term (12 months), up to 20% of patients treated with TUNA™ need to be re-treated with TURP (1). A recent French report described a failure rate (incorporating re-treatment) of up to 50% over a 20-month period (17).

*5.4.4 **Tolerability and safety***

TUNA™ is usually performed as an outpatient procedure under local anaesthesia, although intravenous sedation is sometimes required (1). Post-operative urinary retention is seen in 13.3-41.6% of patients and lasts for a mean of 1-3 days; within 1 week, 90-95% of patients are catheter-free (1). Irritative voiding symptoms up to 4-6 weeks are common (2). Continence status is not affected.

*5.4.5 **Practical considerations***

Few selection criteria have been identified. However, TUNA™ is unsuitable for patients with prostate volumes > 75 mL or isolated bladder neck obstruction. Because TUNA™ cannot treat median lobes effectively it is not clear whether men with significant median lobes will experience the benefit in published studies. There is anecdotal evidence for TUNA™ in men receiving aspirin and anti-coagulants. TUNA™ can be performed as a day-case procedure and is associated with fewer side-effects compared to TURP (e.g. bleeding, erectile dysfunction, urinary incontinence). However, there remain concerns about the durability of the effects achieved by TUNA™.

*5.4.6 **Recommendations***

	LE	GR
Transurethral needle ablation™ is an alternative to transurethral resection of the prostate for patients who wish to defer/avoid (complications of) transurethral resection of the prostate, but patients should be aware of significant re-treatment rates and less improvement in symptoms and quality of life.	1a	A

Table 19: Summary of comparative level of evidence (LE) 1 data (TUNA™ vs TURP) (12)

	TUNA™	TURP	TUNA™ vs TURP 95% CI	LE
Symptoms (IPSS): mean (% improvement)				
3 months (8,10)	-12 (56%)	-14 (62%)	-2 (-0.9 to 3.1)	1b

5.5 Laser treatments of the prostate

5.5.1 ***Holmium Laser Enucleation (HoLEP) and Holmium Laser Resection of the Prostate (HoLRP)***

5.5.1.1 Mechanism of action

The holmium:yttrium-aluminum-garnet (Ho:YAG) laser (2140 nm) is a pulsed, solid-state laser that has been used in urology for a variety of endourological applications in soft tissues and for the disintegration of urinary calculi (1). The wavelength of the Ho:YAG laser is strongly absorbed by water. This means that the area of tissue coagulation and the resulting tissue necrosis is limited to 3-4 mm, which is enough to obtain adequate haemostasis (2). Peak power produces intense, non-thermal, localised, tissue destruction, resulting in precise and efficient cutting of prostatic tissue. Resection is usually performed when the prostate is smaller than 60 mL, while enucleation is used for larger glands.

5.5.1.2 Operative procedure

Instrumentation for this technique includes a 550 µm, end-firing, quartz fibre and an 80 W Ho:YAG laser. A continuous-flow resectoscope is required with a working element, while physiological saline solution is used as an irrigant. The basic principle of the HoLRP technique is retrograde resection of the prostate and fragmentation of resected tissue inside the bladder to allow its evacuation through the operating channel of the resectoscope (2,3). The introduction of holmium laser enucleation (HoLEP) has been a significant improvement. Mimicking open prostatectomy, the prostatic lobes are completely enucleated and pushed into the bladder, before being fragmented and aspirated afterwards by a morcellator (8).

5.5.1.3 Efficacy

Gilling et al. (4) has presented the results of a prospective RCT comparing TURP with HoLRP. To date, 120 patients have been enrolled with urodynamically-confirmed BPO (Schäfer grade ≥ 2) and prostate sizes < 100 mL (Table 20). Preliminary analysis has revealed a significantly longer mean resection time (42.1 vs. 25.8 minutes) for HoLRP patients, while symptomatic and urodynamic improvement were equivalent in both treatment groups. In 2004, long-term results with a minimum follow-up of 4 years were published (7), which showed that there was no difference in urodynamic parameters between HoLRP and TURP after 48 months.

Gilling et al. (9) reported long-term data with a mean follow-up of 6.1 years, indicating that HoLEP results were durable and most patients remained satisfied with their procedure. Two meta-analyses, which analyzed available RCTs comparing HoLEP and TURP (10,11), reported a significantly longer operation time with HoLEP (Table 20). Symptom improvements were comparable, but Q_{max} at 12 months was significantly better with HoLEP (11). In prostates > 100 mL, HoLEP proved to be as effective as open prostatectomy for improving micturition, with equally low re-operation rates at 5-years' follow-up (12).

5.5.1.4 Tolerability and safety

No major intra-operative complications have been described; however, the technique is a surgical procedure that requires relevant endoscopic skills. There are no specific limitations to the procedure. Patients taking anticoagulant medication and those with urinary retention can be treated safely (6). Dysuria was the most common peri-operative complication with an incidence of approximately 10% (2,4,5). Compared to TURP, HoLRP has a significantly shorter catheterisation time (20.0 vs. 37.2 hours), shorter hospitalisation time (26.4 vs. 47.4 hours) (4), and peri-operative morbidity (7). Potency, continence, symptom scores and major morbidity at 48 months were identical between HoLRP and TURP (7). Retrograde ejaculation occurred in 75-80% of patients; no post-operative impotence has been reported (2). Both meta-analyses found that HoLEP resulted in a significantly shorter catheterisation time and hospital stay, reduced blood loss and fewer blood transfusions, but had a longer operation time than TURP (10,11).

5.5.2 ***532 nm ('Greenlight') laser vaporisation of prostate***

5.5.2.1 Mechanism of action

Vaporisation of prostatic tissue is achieved by a sudden increase in tissue temperature from 50°C to 100°C following the application of laser energy. A rapid increase in tissue temperature results in intracellular vacuoles (bubbles), followed by an increase in intracellular cell pressure. Once the cell pressure exceeds that compatible with cellular integrity, the vacuoles are released, as can be seen during the procedure. Because of the way in which tissue interacts with oxyhaemoglobin, laser vaporisation is increased within a wavelength range from 500-580 nm. Because of the green light emitted (λ=532 nm), this laser procedure is known as 'Greenlight' laser vaporisation.

It is important to include the wavelength or crystal used to produce the laser energy when describing the type of laser vaporisation used. This is because tissue interaction caused by laser energy varies according to the wavelength, applied energy, fibre architecture and tissue properties. This also means that the clinical results of different wavelengths are not comparable.

Table 20: Post-operative results of holmium resection (HoLRP) or enucleation (HoLEP) vs. transurethral resection of the prostate (TURP) open prostatectomy (OP) and 'Greenlight' laser vaporisation (KTP) vs. TURP. Absolute and relative changes compared to baseline, with regard to symptoms (AUA-SI/IPSS), maximum urinary flow rate (Q_{max}), post-void residual urine (PVR), and prostate volume

5.5.2.2 *Operative procedure*

Laser vaporisation of the prostate using an 80 W, 532 nm laser is performed by using a 600 µm side-firing laser fibre with a 70°-deflecting laser beam and a 30°-deflecting laser cystoscope. Cold sterile saline or water can be used for irrigation during the procedure. Under direct vision, vaporisation is performed with a fibre-sweeping technique, usually starting at the bladder neck and continuing with the lateral lobes and the apex (13). The visible, side-fired, laser beam leads to an immediate and apparent tissue ablation.

5.5.2.3 *Efficacy*

Numerous studies, predominantly with 80 W lasers, have been published in recent years (Table 20). The lack of long-term data means it is not yet possible to make final conclusions about the duration of improvement. A significant improvement in symptoms and voiding parameters and a re-operation rate comparable to TURP was reported in a 5-year follow-up study of 500 patients (14). Despite ongoing oral anticoagulation in 45% of the patients (n = 225), no severe intra-operative complications were observed. The mean catheterisation and post-operative hospitalisation time was 1.8 (0-10) and 3.7 (0-35) days, respectively.

Three years after photolaser vaporisation in men with mean vaporised prostate volumes of 28 ± 42 mL, the mean IPSS was 8.0, QoL score was 1.3, and Q_{max} was 18.4 mL/s. The re-treatment rate was 6.8%. Urethral and bladder neck strictures were observed in 4.4% and 3.6% of patients, respectively. However, follow-up was available only in a few patients. Significant improvements in voiding parameters at a follow-up of 12 months were demonstrated with urodynamic investigation (15). At 12 months' follow-up, the mean urethral opening pressure (Pdetopen; 76.2 vs. 37.4 cm H_2O) and detrusor pressure at Q_{max} (Pdetmax; 75 vs. 36.6 cm H_2O) were significantly reduced compared to baseline. The Q_{max} improved by 113% (mean 18.6 mL/s) compared to pre-operative Q_{max} (mean 7.9 mL/s).

To date, only two prospective RCTs and three non-randomised trials have been published. The longest available follow-up of a RCT is only 12 months; this trial indicated that 532 nm laser vaporisation was equivalent to TURP in symptom improvement (20). Both groups showed a significant increase in Q_{max} from baseline. In the TURP group, flow increased from 8.7 to 17.9 mL/s (149%) and in the laser vaporisation group from 8.5 to 20.6 mL/s (167%). The IPSS decreased from 25.4 to 12.4 (50%) in the TURP group and from 26 to 12 (50%) in the laser vaporisation group. Laser vaporisation also resulted in significant decreases (averaging 119 mL pre-operatively in the TURP group and 147 mL in the laser vaporisation group), with reductions to 37 and 27 mL, respectively. Similar trends were seen concerning bother and quality of life scores.

5.5.2.4 *Tolerability and safety*

Safety was shown in various, prospective, non-randomised trials in patients with oral anticoagulation, urinary retention, or prostates > 80 ml (16-19). Regarding intra-operative safety, 532 nm laser vaporisation was reported to be superior to TURP in non-randomised trials (21,22). It is also an effective technique when compared to TURP, producing equivalent improvements in flow rates and IPSS with the advantages of markedly reduced length of hospital stay, duration of catheterisation, and adverse events in a randomised trial. The duration of catheterisation was significantly less in the laser vaporisation than the TURP group, with a mean (range) of 13 (0–24) hours versus 44.7 (6–192) hours. Additionally, the length of hospital stay was significantly shorter with laser vaporisation, with a mean (range) of 1.09 (1–2) and 3.6 (3–9) days in the laser vaporisation and TURP groups, respectively (23).

5.5.2.5 *Practical considerations*

Despite the efficacy of TURP in terms of tissue removal and reduction of BPO, a higher rate of peri-operative complications has resulted in an ongoing search for less invasive and safer surgical techniques. Based on the wavelength and power, laser can be used either for coagulation, vaporisation, or cutting ('enucleation'). Non-thermal effects, also known as 'ablation', also result in tissue destruction. Functional results will therefore differ in terms of peri-operative handling of different laser devices, including learning curve, debulking issue, durability of results, and type of complications. The treatment choice how to reduce BPO is dependent on the availability of the armamentarium, patient's choice, concomitant morbidity or drug use, and experience of the surgeon.

Several types of new generation lasers for prostate surgery have emerged during the last decade, including the holmium:YAG, potassium titanyl phosphate:yttrium aluminum garnet (KTP:YAG), thulium:yttrium aluminium garnet (thulium:YAG), light blue optics:yttrium aluminium garnet (LBO:YAG) and the diode lasers. Energy can be transmitted through a bare, right-angle or interstitial fibre. Each laser has wavelength-specified energy–tissue interaction. Prostatic tissue destruction results from both thermal and non-thermal effects. In 2009, published data were only available for HoLEP, 80 W Greenlight PV (photoselective vaporisation), and thulium:YAG laser prostatectomy. Only a few articles have been published on thulium:YAG prostatectomy, which may be used as a vaporising, coagulating, or cutting laser. The lack of published data means that firm conclusions are not yet possible with regard to the different laser treatments.

5.5.2.6 Recommendations

	LE	GR
HoLEP and 532 nm laser vaporisation of the prostate are minimally-invasive alternatives to TURP in men with LUTS secondary to BPO which lead to immediate, objective and subjective improvements comparable to TURP.	1b	A
With regard to intra-operative safety, 532 nm laser vaporisation is superior to TURP and should be considered in patients receiving anticoagulant medication or with a high cardiovascular risk.	3	B
With regard to long-term complication rates, results are only available for HoLEP, and are comparable to TURP.	1b	A

TURP = transurethral resection of the prostate; LUTS = lower urinary tract symptoms; BPO = benign prostatic obstruction.

5.6 Prostate stents

5.6.1 ***Mechanism of action***

The use of an endoprosthesis to preserve luminal patency is a well-established concept, while in 1980 Fabian first describing stenting of the prostatic urethra to relieve BPO (1). Prostatic stents were primarily designed as an alternative to an indwelling catheter in patients unfit for surgery because of co-morbidity. However, prostatic stents have also been assessed by several studies as a primary treatment option in patients without significant co-morbidities (2,3).

A prostatic stent requires a functioning detrusor, so that the bladder still has the ability to empty itself. This is in contrast to an indwelling catheter, which drains the bladder passively (4). Stents can be temporary or permanent. Permanent stents are biocompatible, allowing epithelialisation, so that eventually they become embedded in the urethra. Temporary stents do not epithelialise and may be either biostable or biodegradable. Temporary stents can provide short-term relief from BPO in patients temporarily unfit for surgery or after minimally invasive treatment (MIT) (4).

5.6.2 ***Operative procedure***

Stent insertion is mostly performed in an outpatient setting under local anaesthesia. Prior to stent insertion, the length of the prostatic urethra is measured to determine the stent length. After the patient has been placed in the lithotomy position, the stent is advanced through the urethra until the tip of the prostatic urethral segment is positioned in the bladder. It is important that the stent is not positioned inside the external urethral sphincter as it may cause stress urinary incontinence. To confirm proper positioning, abdominal ultrasonography or cystoscopy is performed. Removal of a temporary stent is achieved by pulling the retrieval suture, until the stent is completely retracted, or by using graspers under endoscopic guidance. It can be difficult to remove permanent stents in cases of stent migration, stent encrustation or epithelial in-growth, and general anaesthesia is usually needed. In general, antibiotic prophylaxis is not necessary unless there has been a positive urine culture.

5.6.3 *Efficacy*

There have been several small case studies on a range of stents of different designs and materials, which have provided a low level of evidence for their use. Table 21 describes the most important studies (2,5-9). All studies during follow-up have observed a significant attrition rate. There is only one RCT that has compared two versions of a blind-placement prostatic stent (BPS) for BPO (10), and there have been no studies comparing stents with sham or other treatment modalities. The BPS system is a temporary stent consisting of a soft silicone stent, retrieval line, and delivery device, with the difference between BPS-1 and BPS-2 being an additional 2-cm bulbar segment. This bulbar segment results in a significantly lower migration rate with BPS-2 (5%) compared with BPS-1 (85%), but the bulbar segment also caused significant discomfort (10). BPS-2 also has better symptom scores and voiding function than BPS-1, but only Q_{max} reached statistical significance. The results from this study appear to indicate that stent design has a critical role in the efficacy and safety of prostatic stents (10).

5.6.3.1 *Permanent stents (UroLume endourethral prosthesis)*

The main representative of the permanent stents is the UroLume endourethral prosthesis. A recent systematic review identified 20 case series, with a total of 990 patients who received the UroLume stent (11). The 10 studies that reported symptom scores demonstrated improved symptoms following stent insertion, although the timing of assessment varied between studies. The reported decrease in Madsen-Iversen scores ranged from 7.9 to 14.3 points, while the IPSS decreased by 10-12.4 points (11). Additionally, the mean Q_{max} increased between 4.2 and 13.1 mL/s following stent insertion. The pooled data from studies with patients using permanent transurethral catheters showed that 84% of patients (148/176) regained the ability to void spontaneously after UroLume treatment, with the mean Q_{max} ranging from 8.8 to 20 mL/s. At 12 years of follow-up, the mean IPSS, Q_{max} and PVR were 10.82, 11.5 mL/s and 80 mL, respectively (12).

5.6.3.2 *Non-epitheliasing (temporary) prostatic stent (Memokath)*

The best data on non-epitheliasing prostatic stent are provided by a systematic review of the efficacy of Memokath, a self-expanding metallic prostatic stent (13). In total, 14 case series with 839 patients were reviewed. Analysis of the seven studies reporting symptom scores found that Memokath insertion was associated with a reduction of 11-19 points in the IPSS and a reduction of 9 points in the Madsen-Iversen score. However, it is important to note that the assessment was made at different times after stent placement. Similarly, stent insertion resulted in a Q_{max} increase of 3 to 11 ml/s, although again the time of assessment was variable after placement (13).

5.6.4 ***Tolerability and safety***

In general, stents are subject to misplacement, migration, poor tolerability because of exacerbation of LUTS, and encrustation (4). The main adverse events immediately following stent placement include perineal pain or irritative voiding symptoms in most patients.

The systematic review of the UroLume reported a 16% failure rate (104/666) within 12 months of insertion, mainly due to stent misplacement or migration (37%) or recurrent obstructive or irritative voiding symptoms (14%). The overall failure rate at 5 years was 27% (50/188 stents), although many patients were lost to follow-up or died with the stent in situ (11). In the study with the longest follow-up, 18% of the patient population (11 men) completed 12 years of follow-up with the Urolume stent in situ, whereas 29 stents were removed (failure rate, 47%) and 22 patients (34%) died of diseases non related to male LUTS.

5.6.5 ***Practical considerations***

In search for the ideal prostatic stent, a range of different stent types has been developed and undergone clinical study. Because of the side effects and high migration rate, prostatic stents have a limited role in the treatment of BPO. Prostatic stents remain an alternative to transurethral catheterisation for men who have (recurrent) urinary retention and are at high risk for surgery.

5.6.6 ***Recommendations***

	LE	GR
Prostatic stents are an alternative to catheterisation for men unfit for surgery. Stents may have a role in the temporary relief of benign prostatic obstruction after minimally invasive treatment.	3	C

Table 21: Efficacy of stents: key studies

		Symptoms		Q_{max} (mL/s)		Failure rate (follow-up in months)	LE
Stent	***n***	**Pre-operative**	**Post-operative**	**Pre-operative**	**Post-operative**		
Urolume (P) (2)	91	14.1	4.7	9.3	17.1	Overall	3
	44	R	4.6	R	13.7	15.5% (18 mos)

5.7 Emerging operations

5.7.1 ***Intra-prostatic ethanol injections***

5.7.1.1 Mechanism of action

Absolute (dehydrated, 95-98%) ethanol is injected into the prostatic parenchyma for the treatment of LUTS secondary to BPO. The precise mechanism of action in both humans and animals remains unclear. The use of ethanol was investigated in the canine model and demonstrated the ability of ethanol to cause inflammation, coagulative necrosis with protein denaturation and cell membrane lysis, and, finally, atrophy and ablation of prostatic tissue resulting in cavity formation (1-4). Tissue necrosis was typically wedge-shaped (4). The volume of injected ethanol correlated only moderately with the size of tissue necrosis (4). Intra-prostatic cavity formation appeared in the canine model after 7 days (3).

5.7.1.2 Operative procedure

Liquid dehydrated ethanol or ethanol gel is injected into the prostatic parenchyma with a 20-22 gauge needle either transurethrally, transperineally, or transrectally. The transurethral approach (TEAP or TUEIP) has been used more frequently (5-14) than the transperineal (11,15,16) or transrectal approaches (11).

Specific devices have been developed for the transurethral delivery of ethanol (InecTx™ in the USA and Prostaject™ in Europe) (17). There is no consensus on the number of injection sites or injection volumes, which depend on total prostate volume, urethral length and/or presence of a prostate median lobe, and have ranged from 2 mL to 25 mL of ethanol per patient in different studies (with the injection volume being up to 42% of the volume of the prostate).

Local anaesthesia supplemented by conscious sedation may be considered, although regional or general anaesthesia were chosen by most patients. The procedure is usually completed within approximately 30 minutes. The majority of patients need an indwelling catheter after the procedure.

5.7.1.3 Efficacy

So far, 12 trials (5-16) have been published (Table 22), with the majority having investigated men refractory to medical treatment. Only one trial investigated patients with urinary retention (10). None of these trials was randomised against TURP or other minimally invasive procedures for BPH-LUTS or BPO. Mean follow-up varied among studies from 12 to 208 weeks (3-48 months).

The majority of trials demonstrated a significant reduction in symptoms (IPSS -41% to -71%) and PVR (-6% to -99%) as well as a significant improvement in the maximum urinary flow rate (Qmax +35% to +155%) and QoL (IPSS-QoL -47% to -60%). Prostate volume decreased significantly in approximately half the trials (-4% to -45%). After an initial strong reduction in prostate volume, 1-2 years post-operatively prostate size increased again, although LUTS and peak urinary flow remained significantly improved (8). No predictive efficacy parameter or dose-response relationship has been found (9,12).

Several trials demonstrated a considerable number of retreatments within the first year after the procedure (usually treated by a second ethanol injection, TURP, or open prostatectomy). Little is known about the durability of clinical effects later than 1 year after the operation; one trial with a mean follow-up of 3 years showed a retreatment rate of 41% (8).

Table 22: Results of intra-prostatic ethanol injections for treating BPH-LUTS or BPO in men refractory to medical treatment or in urinary retention

Trials	Duration (weeks)	Patients (n)	Change in symptoms (IPSS)		Change in Q_{max}		Change in PVR		Change in prostate volume		Level of evidence

*Absolute and relative changes compared with baseline are listed with regard to symptoms (IPSS), maximum urinary flow rate (Qmax), post-void residual urine (PVR), and prostate volume. [a] = significant compared with baseline (indexed whenever evaluated); † = patients with urinary retention; * = three study arms comparing transurethral, transrectal and transperineal injections.*

5.7.1.4 Tolerability and safety

Frequently reported adverse events included:

- perineal or abdominal discomfort/pain;
- bladder storage symptoms (≤ 40%);
- haematuria (≤ 40%);
- urinary tract infection or epididymitis;
- urinary retention.

Less frequently reported (< 5%) adverse events included:

- decreased libido;
- retrograde ejaculation;
- urgency urinary incontinence;
- urethral stenosis;
- erectile dysfunction.

Animal studies revealed a high percentage of urethral sphincter damage and stress urinary incontinence when ethanol was injected via the perineal route (1), but these complications have not been reported in humans (15,16). One man developed a big bladder stone six months after treatment, most probably due to calcification of sloshed necrotic prostatic masses (18). Two cases of severe complications after ethanol injections have been reported; bladder necrosis required cystectomy and urinary diversion (9).

5.7.1.5 Practical considerations

Intra-prostatic ethanol injections are considered to be a minimally invasive treatment option for patients with LUTS secondary to BPO. However, the mechanism of action, patient selection and application of ethanol (the number of injection sites and the injection volume) have not been well investigated, severe adverse events occurred in some patients, and long-term results are sparse. Intra-prostatic ethanol injections are therefore still regarded as experimental and should be used only in trials.

Randomised-controlled trials with long-term follow-up comparing ethanol injections with TURP, other minimally invasive procedures, or drugs are needed to be able to judge adequately the value of this treatment modality.

5.7.1.6 Recommendations

	LE	GR
Intra-prostatic ethanol injections for LUTS due to BPO are still experimental.	3	
Intra-prostatic ethanol injections should be performed only in clinical trials.		C

LUTS = lower urinary tract symptoms; BPO = benign prostatic obstruction.

*5.7.2 **Intra-prostatic botulinum toxin injections***

5.7.2.1 Mechanism of action

BTX is the exotoxin of the bacterium *Clostridium botulinum*. This 150 kDa toxin is the most potent neurotoxin known in humans, and causes botulism (food-borne, wound or infant). Seven subtypes of BTX are known (types A-G), of which subtypes A and B have been manufactured for use in humans.

Experience with intra-prostatic injections for the treatment of LUTS/BPO exists only for BTX-A. The precise mechanism of action has been evaluated in experimental animals but is not fully understood. BTX-A blocks the release of neurotransmitters (e.g. acetylcholine or norepinephrine) from pre-synaptic nerves (1). BTX-A directly or indirectly reduces LUTS by induction of apoptoses of prostatic (epithelial) cells leading to tissue atrophy and prostate size reduction (2-4), inhibition of sensory neurons in the prostate and reduction of afferent signals to the central nervous system (3), and/or relaxation of smooth muscle cells in the prostatic parenchyma and reduction of BPO (4-6). Down-regulation of 1A adrenergic receptors in the prostate may contribute to smooth muscle cell relaxation (3). The latter two mechanisms are summarised as chemical denervation that possibly has a negative influence on prostate growth.

5.7.2.2 Operative procedure

Under ultrasound visualisation, BTX-A can be injected into the prostatic parenchyma transperineally, transurethrally or transrectally, using a 21-23 gauge needle. The transperineal approach has been described most frequently (7-13); the transurethral (5) and transrectal routes (14,15) have also been used but applied less often. Botox™ (Allergan, Irving, CA, USA) was employed in all but one study (13).

Different therapeutic doses (100-300 units Botox™ or 300-600 units Dysport™) and dilutions (25-50 units Botox™/mL or 75 units Dysport™/mL) were used in various studies, but doses and dilutions have not been systematically tested. Doses of 100 units Botox™ have been suggested for prostate sizes < 30 mL, 200 units for sizes between 30 mL and 60 mL, and 300 units for sizes > 60 mL (9). For Dysport™, 300 units were used for prostate sizes < 30 mL, and 600 units for sizes > 30 mL were used (13). The majority of patients were treated without anaesthesia, local anaesthesia, or sedation.

5.7.2.3 Efficacy

So far, 11 trials have been published (Table 23 investigating intra-prostatic BTX-A injections in patients with BPH-LUTS who required or were resistant to medical therapy, or patients with an indwelling urethral catheter due to acute or chronic urinary retention (5,14,15). Only two trials were randomised, one against injection of saline solution (7), the other against α_1-blocker therapy (12).

The majority of patients in the published trials received only a single injection of BTX-A and mean follow-up ranged between 12 and 120 weeks (3 to 30 months). All trials reported significant improvements with regard to symptoms (IPSS -39% to -79%) and urinary flow rate (Q_{max} +27% to +122%), or a decrease of prostate volume (-11% to -61%). Post-void residual urine decreased in all studies, but reduction was significant in only approximately half of the trials. BTX-A injection therapy was significantly superior to saline injection in the randomised-controlled trial with regard to symptom and Q_{max} improvement as well as PVR and prostate volume reduction; all parameters were significantly different compared with baseline or saline solution within the first treatment month (7).

In patients with urinary retention before BTX-A injections, 80-100% of men could void spontaneously within one month of the operation, and maintained voiding throughout the follow-up period.

Little is known about the long-term effects and durability of the treatment; prostate volume seems to increase again after 6-12 months (11,14) despite stable improvements in symptoms, Q_{max} and PVR. Retreatment rates with BTX-A were as high as 29% (11).

Table 23: Results of intra-prostatic botulinum toxin (Botox™) injections for treating LUTS/BPH, BPO or urinary retention

Trials	Duration (weeks)	Patients (n)	Change in symptoms (IPSS)		Change in Q_{max}		Change in PVR		Change in prostate volume		Level of evidence
			Absolute	%	mL/s	%	mL	%	mL	%	
Maria *et al.* 2003 (7)*	52	30	-14.4[a,b]	-62	+6.9[a,b]	+85	-102[a,b]	-81	-32[a,b]	-61	1b

*Absolute and relative changes compared with baseline are listed with regard to symptoms (IPSS), maximum urinary flow rate (Q_{max}), post-void residual urine (PVR), and prostate volume. a = significant compared with baseline (indexed whenever evaluated); b = significant compared with placebo (saline solution) or α1-blockers; † = patients with acute or chronic urinary retention; * = Botox™; ‡ = Dysport™.*

5.7.2.4 Tolerability and safety

BTX-A injections were well tolerated in all studies, and no systemic adverse events have yet been reported to have arisen from BTX-A. There was no need for post-operative analgesia.

Adverse events were dysuria in ≤ 19%, haematuria in ≤ 14%, and acute prostatitis in one patient (2%). Urinary retention occurred in ≤ 6%, but many patients received a transurethral catheter or performed clean intermittent catheterisation during the early post-operative period (one week to one month) (8,14).

5.7.2.5 Practical considerations

BTX-A injections into the prostatic parenchyma seem to be a promising and quick minimally invasive treatment modality with low morbidity for patients who are refractory to medical treatment or in urinary retention. However, despite the excellent and homogeneous outcomes in published trials, BTX-A has been injected into only a few patients, and all trials have a limited follow-up. Only two randomised-controlled trials have been published so far. Trials with a larger number of patients, randomisation against saline injections, drugs, TURP, or other minimally invasive treatments, and long-term follow-up are therefore necessary to judge adequately

the value of intra-prostatic BTX-A injections in the context of other available medical or surgical treatments of LUTS/BPO.

5.7.2.6 Recommendations

	LE	GR
Intra-prostatic botulinum toxin injections for lower urinary tract symptoms due to benign prostatic obstruction or urinary retention are still experimental.	3	
Intra-prostatic botulinum toxin injections should be performed only in clinical trials.		C

5.8 Summary treatment

The choice of treatment depends on:

- findings assessed during evaluation;
- treatment preferences of the individual patient;
- ability of the treatment modality to change assessed findings;
- expectations to be met in terms of speed of onset, efficacy, side-effects, quality of life, and disease progression.

Table 24 provides differential information about conservative, medical and surgical treatment options described in the EAU Guidelines on Male LUTS, including BPO. Note that treatment modalities may be combined leading to different effects.

Table 24: Speed of onset and influence on basic parameters with conservative or surgical treatment modalities for the management of non-neurogenic male LUTS. Note that the drug treatment studies have typically used data after a run-in phase as baseline, whereas those of interventional treatments did not.

Treatment	Onset	LUTS	Uroflowmetry (Q_{max})	Prostate size	PVR	Disease progression
Conservative treatments						
Watchful waiting, behavioural treatment	months	+	+	-	-	?
α-adrenoceptor antagonists	days	++	++	-	- / +	+++ (symptoms)
5α-reductase inhibitors	months	+	++	+ - ++	-	+++ (retention)
Muscarinic receptor antagonists	weeks	++ (storage symptoms)	-	-	+ (increase)	?
Plant extracts	weeks	+	- / +	-	-	+
α-adrenoceptor antagonists + 5α-reductase inhibitors	days	++	++	+ -++	- / +	+++ (symptoms + retention)
α-adrenoceptor antagonists + muscarinic receptor antagonists	days	++	++	-	- / +	?
PDE5-inhibitors	weeks	++	-	-	-	?
Surgical treatments	After catheter removal					
TURP–TUIP	hours	++++	++++	+++	++++	++++
Open prostatectomy	hours	++++	++++	++++	++++	++++
TUMT	weeks	+++	+++	++	++	+++
TUNA	weeks	+++	+++	++	+	++
HoLEP	hours	++++	++++	++++	++++	++++
KTP	days	+++	+++	++	++	+++
Prostate stents	hours	++	++	-	+++	?
Ethanol injections prostate	weeks	++	++	+	+	?
Botulinum toxin injections prostate	weeks	++	+++	+	+	?

LUTS = Lower Urinary Tract Symptoms; Q_{max} = maximum urinary flow rate; PVR = post-void residual urine

Key to Table:

-	no influence
+	mild influence
++	moderate influence
+++	strong influence
++++	very strong influence
?	unknown

Behavioural with or without medical treatments are usually the first choice of therapy. A flowchart illustrating conservative and medical treatment choices according to evidence-based medicine and patients' profiles is provided in Figure 3.

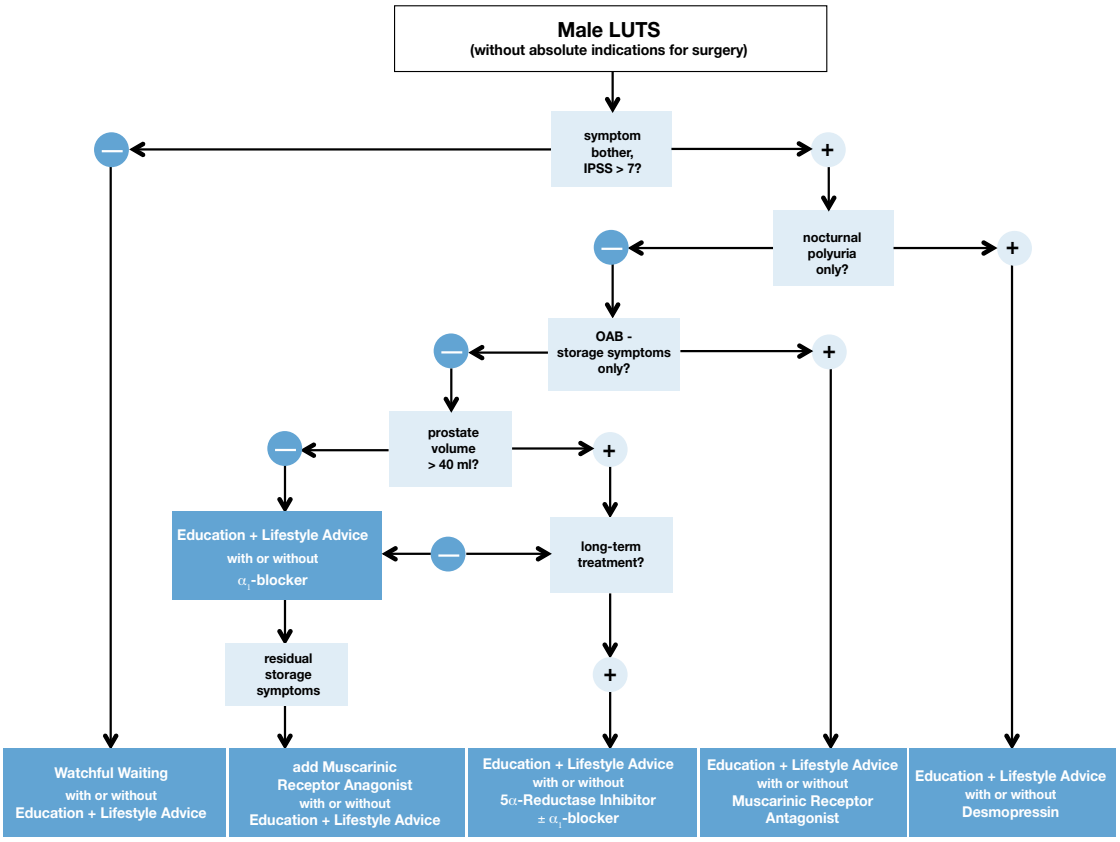

Figure 3: Treatment algorithm of male lower urinary tract symptoms (LUTS) using medical and/or conservative treatment options. Treatment decisions depend on results assessed during initial evaluation (◊). Minus (–) indicate the absence and plus (+) the presence of the condition.

Surgical treatment is usually required when patients have experienced recurrent or refractory urinary retention, overflow incontinence, recurrent urinary tract infections, bladder stones or diverticula, treatment-resistant macroscopic hematuria due to BPH/BPE, or dilatation of the upper urinary tract due to BPO, with or without renal insufficiency (absolute operation indications, need for surgery). Additionally, surgery is usually needed when patients have had insufficient relief in LUTS or PVR after conservative or medical treatments (relative operation indications). The choice of the surgical technique depends primarily on prostate size, co-morbidities of the patient, and the ability to have anaesthesia but also on patients' preferences, willingness to accept surgery-associated side effects, availability of the surgical armamentarium, and experience of the surgeon with these operation techniques. A flowchart illustrating surgical treatment choices according to evidence-based medicine and patients' profiles is provided in Figure 4.

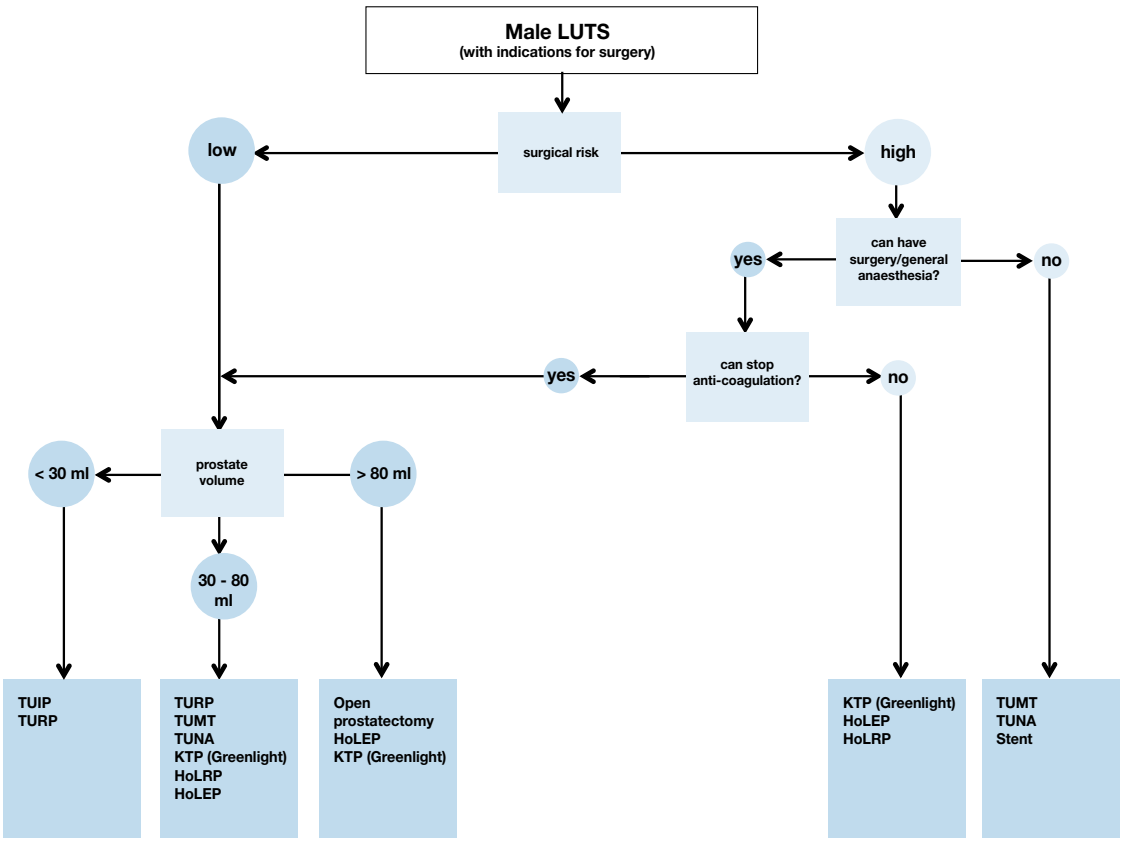

Figure 4: Treatment algorithm of bothersome lower urinary tract symptoms (LUTS) refractory to conservative/medical treatment or in cases of absolute operation indications. Note that this flowchart has been stratified by the patient's ability to have anaesthesia, cardiovascular risk, and prostate size; however, the choice of the surgical techniques also depends on patients' preferences, willingness to accept surgery-associated side effects, availability of the armamentarium, and surgeon's experience with the operation technique.

HoLEP = Holmium Laser Enucleation of the Prostate; HoLRP = Holmium Laser Resection of the Prostate; KTP = K^+-titanyl-phosphate laser ("greenlight"); TUIP = Transurethral Incision of the Prostate; TUMT = Transurethral Microwave Therapy; TUNA = Transurethral Needle Ablation of the prostate; TURP = Transurethral Resection of the Prostate.

6. FOLLOW-UP

6.1 Watchful waiting – behavioural

Patients who elect to pursue a WW policy should be reviewed at 6 months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following are recommended at follow-up visits:

- I-PSS
- Uroflowmetry and post-void residual urine volume.

6.2 Medical treatment

Patients receiving α-blockers, muscarinic receptor antagonists, or the combination of α-blockers with 5α-reductase inhibitors or muscarinic receptor antagonists should be reviewed 4 to 6 weeks after drug initiation in order to determine treatment response. If patients gain symptomatic relief in the absence of troublesome adverse events, drug therapy may be continued.

Patients should be reviewed at 6 months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following tests are recommended at follow-up visits:

- I-PSS;
- Uroflowmetry and post-void residual urine volume.

Patients receiving 5α-reductase inhibitors should be reviewed after 12 weeks and 6 months to determine their response and adverse events. Follow-up visits are similar to the above mentioned drugs. The following are recommended at follow-up visits:

- I-PSS;
- Uroflowmetry and post-void residual urine volume.

Patients receiving desmopressin, serum sodium concentration should be measured at day 3 and 7 as well as after 1 month and, if serum sodium concentration has remained normal, every 3 months subsequently. The following tests are recommended at follow-up visits:

- Serum-sodium concentration;
- Frequency-volume chart.

After dose adjustment, follow-up should be repeated likewise.

6.3 Surgical treatment

Patients after prostate surgery should be reviewed 4 to 6 weeks after catheter removal in order to evaluate treatment response and adverse events. If patients have symptomatic relief and are without adverse events no further re-assessment is necessary. The following tests are recommended at follow-up visit after 4 to 6 weeks:

- I-PSS;
- Uroflowmetry and post-void residual urine volume.

6.4 Recommendations

	LE	GR
Follow-up for all conservative or operative treatment modalities is based on empirical data or theoretical considerations but not on evidence based studies.	3-4	C

7. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations.

AVP	arginine vasopressin
BOO(I)	bladder outlet obstruction (index)
BPE	benign prostatic enlargement
BPH	benign prostatic hyperplasia
BPO	benign prostatic obstruction
cGMP	cyclic guanosine monophosphate
CombAT	combination of avodart® and tamsulosin
DHT	dihydrotestosterone
EBM	evidence-based medicine
eNOS	endothelial
ER	extended release
GITS	gastrointestinal therapeutic system
IFIS	intra-operative floppy iris syndrome
IPSS	international prostate symptom score
IR	immediate release
LUTS	lower urinary tract symptoms
MR	modified release
MTOPS	medical therapy of prostatic symptoms
NAION	non-arteritic anterior ischemic optic neuropathy
NO	Nitric oxide
NOS	NO synthases
nNOS	neuronal
n.s.	not significant
OCAS	oral controlled absorption system
PDE	phosphodiesterase
PSA	prostate specific antigen
PVR	post-void residual urine
Qmax	maximum urinary flow rate during free uroflowmetry
QoL	quality of life
RR	relative risk
SHBG	sexual hormone binding globulin
SR	sustained release
tmax	time to maximum plasma concentration
t½	elimination half-life
TUIP	transuretrual incision of the prostate
TUMT	transretrual microwave therapy
TUNA™	transuretrual needle ablasion
TURP	transurethral resection of the prostate
WW	watchful waiting

Conflict of interest

All members of the Male LUTS working group have provided disclosure statements on all relationships that they have and that might be perceived to be a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on

Male Sexual Dysfunction:

Erectile dysfunction and premature ejaculation

E. Wespes, E. Amar, I. Eardley, F. Giuliano, D. Hatzichristou, K. Hatzimouratidis, F. Montorsi, Y. Vardi

European Association of Urology

TABLE OF CONTENTS PAGE

1. BACKGROUND

1.1 Introduction

Erectile dysfunction (ED, impotence) and premature ejaculation (PE) are the two main complaints in male sexual medicine. New oral therapies have completely changed the diagnostic and therapeutic approach to ED and the Guidelines Office of The European Association of Urology (EAU) has appointed an Expert Panel to update previously published EAU guidelines for ED or impotence (1).

The update is based on a review of available scientific information, current research, and clinical practice in the field (1,2). The Expert Panel has also identified critical problems and knowledge gaps, setting priorities for future clinical research.

Level of evidence (LE) and grade of recommendation (GR) have been included in these guidelines when possible. The aim of this practice is to provide transparency between the underlying evidence and the recommendation made (3).

2. DIAGNOSIS

2.1 Epidemiology and risk factors

Erection is a neurovascular phenomenon under hormonal control. It includes arterial dilatation, trabecular smooth muscle relaxation, and activation of the corporeal veno-occlusive mechanism (1).

Erectile dysfunction has been defined as the persistent inability to attain and maintain an erection sufficient to permit satisfactory sexual performance. Although ED is a benign disorder, it affects physical and psychosocial health and has a significant impact on the quality of life (QoL) of sufferers and their partners and families (2).

*2.1.1 **Epidemiology***

Recent epidemiological data have shown a high prevalence and incidence of ED worldwide. The first large-scale, community-based study of ED was the Massachusetts Male Aging Study (MMAS). The study reported an overall prevalence of 52% ED in non-institutionalised 40- to 70-year-old men in the Boston area in the USA (3); specific prevalences for minimal, moderate, and complete ED were 17.2%, 25.2%, and 9.6%, respectively. In the Cologne study of men aged 30-80 years old, the prevalence of ED was 19.2%, with a steep age-related increase from 2.3% to 53.4% (4). In the National Health and Social Life Survey (NHSLS), the prevalence of sexual dysfunctions (not specific ED) was 31% (5). The incidence rate of ED (new cases per 1,000 men annually) was 26 in the MMAS study (6), 65.6 (mean follow-up of 2 years) in a Brazilian study (7), and 19.2 (mean follow-up of 4.2 years) in a Dutch study (8). Differences between these studies can be explained by differences in methodology and in the ages and socio-economic status of the populations studied.

*2.1.2 **Risk factors***

Erectile dysfunction shares common risk factors with cardiovascular disease (e.g. lack of exercise, obesity, smoking, hypercholesterolaemia, metabolic syndrome), some of which can be modified. In the MMAS, men who began exercising in midlife had a 70% reduced risk for ED compared to sedentary men and a significantly lower incidence of ED over an 8-year follow-up period of regular exercise (9). A multicentre, randomised, open-label study in obese men with moderate ED compared 2 years of intensive exercise and weight loss with a control group given general information about healthy food choices and exercise (10). Significant improvements in body mass index (BMI) and physical activity scores, as well as in erectile function, were observed in the lifestyle intervention group. These changes were highly correlated with both weight loss and activity levels.

However, it should be emphasised that controlled prospective studies are necessary to determine the effects of exercise or other lifestyle changes in prevention or treatment of ED.

*2.1.3 **Post-radical prostatectomy erectile dysfunction (ED)***

Radical prostatectomy (RP) in any form (open, laparoscopic, or robotic) is a widely performed procedure for patients with clinically localised prostate cancer (PCa) and a life expectancy of at least 10 years. This procedure may lead to treatment-specific sequelae affecting health-related QoL. This outcome has become increasingly important with the more frequent diagnosis of PCa in younger patients (11-13). Research has shown that about 25-75% of men experience post-operative ED (14).

Post-RP ED is multifactorial. Cavernosal nerve injury induces pro-apoptotic (loss of smooth muscle) and pro-fibrotic (increase in collagen) factors within the corpora cavernosa. These changes may also be caused by poor oxygenation due to changes in the blood supply to the cavernosa.

Because pre-operative potency is a major factor associated with the recovery of erectile function after surgery, patients being considered for a nerve-sparing radical prostatectomy (NSRP) should ideally be potent (15). It is also clear that cavernosal nerves must be preserved to ensure erectile function recovers after RP. In addition, the role of vascular insufficiency is of increasing interest in post-operative ED (16,17).

2.2 Managing ED: implications for everyday clinical practice

Advances in basic and clinical research in ED during the past 15 years have led to the development of several new treatment options for ED, including new pharmacological agents for intracavernous, intraurethral, and, more recently, oral use (18-20). Treatment strategies have also changed following the poor outcomes seen in long-term follow-up of reconstructive vascular surgery (21,22).

An increasing number of men are seeking help for ED due to the great media interest in ED and the availability of effective and safe oral drug therapy. However, there are many physicians evaluating and treating ED without appropriate background knowledge and clinical experience. Thus, some men with ED may receive little or no evaluation before treatment and will therefore not receive treatment for any underlying disease that may be causing their ED. Other men without ED may be requesting treatment simply to enhance their sexual performance. Given this situation, these EAU guidelines for the diagnosis and treatment of ED are a necessity.

2.3 Conclusions on epidemiology and risk factors

Conclusions	LE
Erection is a neurovascular phenomenon under hormonal control in a physiologenic environment.	2b
ED is common worldwide.	3
ED shares several risk factors with cardiovascular disease.	3
Lifestyle modification (intensive exercise and a decrease in body mass index) can improve erectile function.	1b
ED is a symptom, not a disease. Some men may not be properly evaluated or receive treatment for an underlying disease or condition that may be causing ED.	4
Radical prostatectomy is a common cause of ED.	3

ED = erectile dysfunction.

2.5 Diagnosis

2.5.1 ***Basic work-up***

The first step in evaluating ED is always a detailed medical and psychological history of patients and partners

(1,2). Often it is not possible to include the partner at the patient's first visit, but an effort should be made to include the partner at the second visit. The pathophysiology of ED may be vasculogenic, neurogenic, hormonal, anatomical, drug-induced, or psychogenic (Table 1) (3) and taking a medical history may reveal one of the many common disorders associated with ED.

It is important to establish a relaxed atmosphere during history-taking. This will make it easier to ask questions about erectile function and other aspects of sexual history, particularly when patients do not find it easy to talk about their problem. It will also make it easier to explain the diagnosis and therapeutic approach to the patient and his partner.

Table 1: Pathophysiology of ED

Vasculogenic
- Cardiovascular disease
- Hypertension
- Diabetes mellitus
- Hyperlipidaemia
- Smoking
- Major surgery (radical prostatectomy) or radiotherapy (pelvis or retroperitoneum)
Neurogenic
Central causes
- Multiple sclerosis
- Multiple atrophy
- Parkinson's disease
- Tumours
- Stroke
- Disk disease
- Spinal cord disorders
Peripheral causes
- Diabetes mellitus
- Alcoholism
- Uraemia
- Polyneuropathy
- Surgery (pelvis or retroperitoneum, radical prostatectomy)
Anatomical or structural
- Peyronie's disease
- Penile fracture
- Congenital curvature of the penis
- Micropenis
- Hypospadias, epispadias
Hormonal
- Hypogonadism
- Hyperprolactinemia
- Hyper- and hypo-thyroidism
- Cushing's disease
Drug-induced
- Antihypertensives (diuretics and beta-blockers are the most common causes)
- Antidepressants
- Antipsychotics
- Antiandrogens
- Antihistamines
- Recreational drugs (heroin, cocaine, methadone)
Psychogenic
- Generalised type (e.g. lack of arousability and disorders of sexual intimacy)
- Situational type (e.g. partner-related, performance-related issues or due to distress)

2.5.1.1 Sexual history

The sexual history may include information about previous and current sexual relationships, current emotional status, onset and duration of the erectile problem, and previous consultations and treatments. A detailed description should be made of the rigidity and duration of both erotic and morning erections and of problems with arousal, ejaculation, and orgasm. Validated questionnaires, such as the International Index for Erectile

Function (IIEF), help to assess all sexual function domains (erectile function, orgasmic function, sexual desire, ejaculation, intercourse, and overall satisfaction), as well as the impact of a specific treatment modality (4).

2.5.1.2 Physical examination

Every patient must be given a physical examination focused on the genitourinary, endocrine, vascular, and neurological systems (1). A physical examination may reveal unsuspected diagnoses, such as Peyronie's disease, prostatic enlargement or cancer, or signs and symptoms suggesting hypogonadism (small testes, alterations in secondary sexual characteristics, diminished sexual desire, and changes in mood) (2). A rectal examination should be performed in every patient older than 50 years. Blood pressure and heart rate should be measured if they have not been assessed in the previous 3-6 months. Particular attention must be given to patients with cardiovascular disease (*see* Section 2.5.2).

2.5.1.3 Laboratory testing

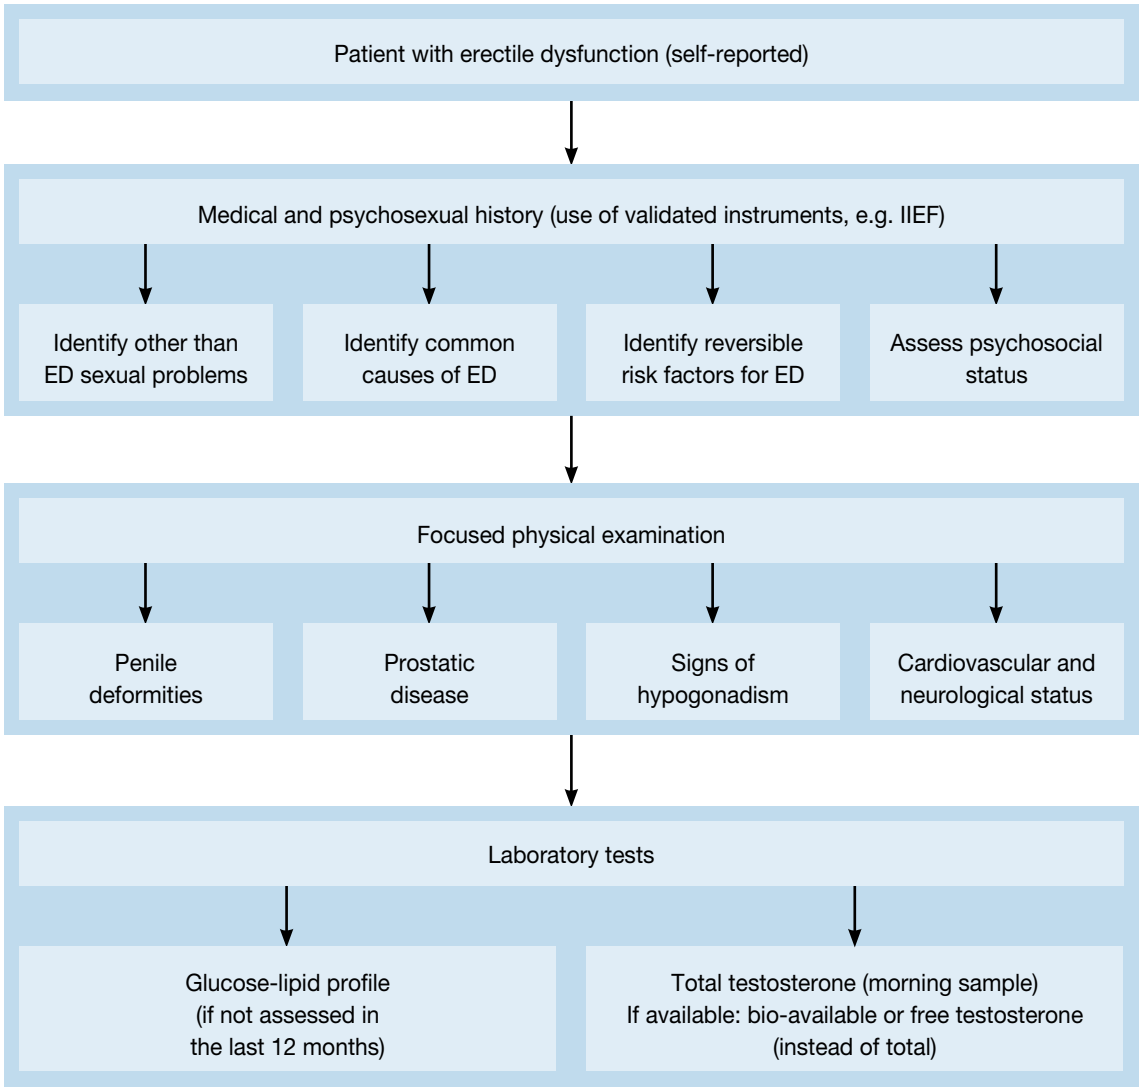
Laboratory testing must be tailored to the patient's complaints and risk factors. All patients must undergo a fasting glucose and lipid profile if not assessed in the previous 12 months. Hormonal tests must include a morning sample of total testosterone. Tests that measure bioavailable or calculated-free testosterone are preferred to total testosterone tests because they are better at establishing hypogonadism.

Additional laboratory tests must be considered only in selected patients, e.g. prostate-specific antigen (PSA) for detection of prostate cancer.

Additional hormonal tests, e.g. prolactin, follicle-stimulating hormone (FSH), luteinising hormone (LH), must be carried out when low testosterone levels are detected. If any abnormality is observed, referral to another specialist may be necessary (5,6).

Figure 1 gives the minimal diagnostic evaluation (basic work-up) in patients with ED.

Figure 1: Minimal diagnostic evaluation (basic work-up) in patients with ED



ED = erectile dysfunction; IIEF = International Index of Erectile Function.

2.5.2 *Cardiovascular system and sexual activity: the patient at risk*

Patients who seek treatment for sexual dysfunction have a high prevalence of cardiovascular disease. The cardiac risks associated with sexual activity are well established. Recent epidemiological studies have emphasised the association between cardiovascular and metabolic risk factors and sexual dysfunction in both men and women (7).

There has been an intensive investigation of the pharmacological properties of phosphodiesterase type 5 (PDE5) inhibitors, including their effects on cardiac smooth muscle activity and overall cardiovascular safety. The EAU Guidelines recommendations given here for using PDE5 inhibitors in PE have been adapted from previously published recommendations from consensus conferences on sexual dysfunction and cardiac risk (8,9).

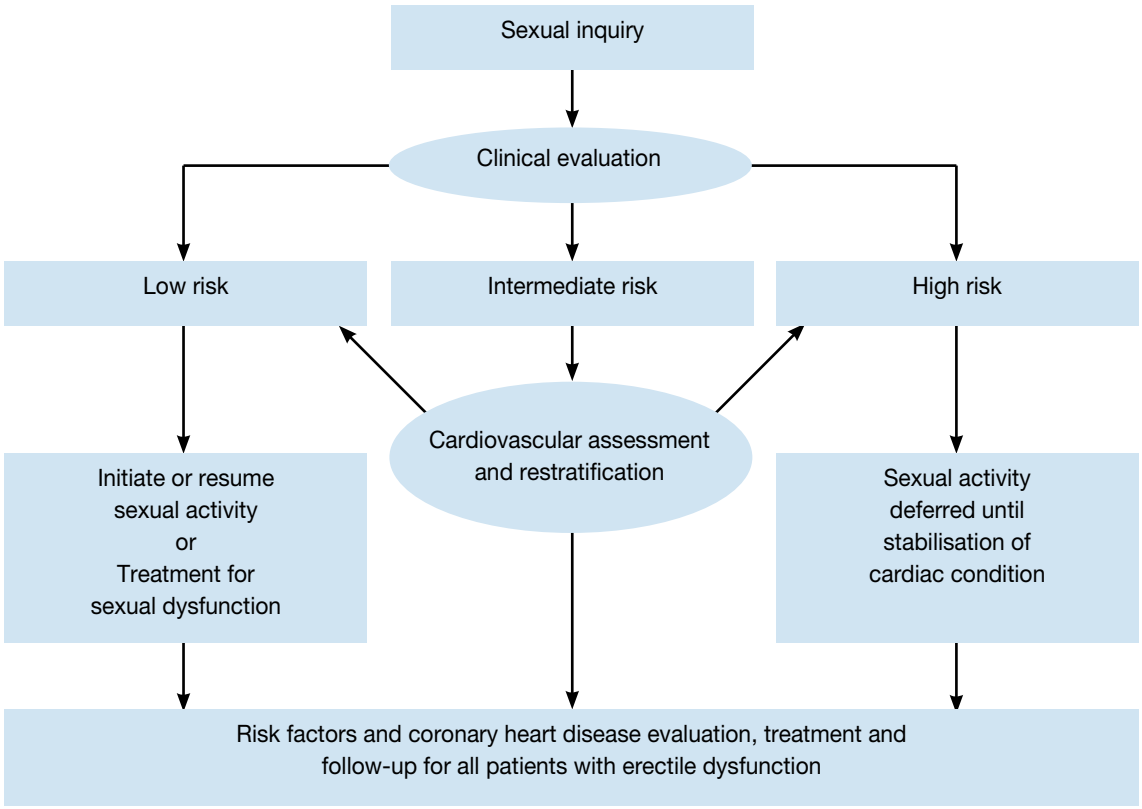
Patients with ED can be stratified into three cardiovascular risk categories (Table 2), which can be used as the basis for a treatment algorithm for initiating or resuming sexual activity (Figure 2). It is also possible for the clinician to estimate the risk of sexual activity in most patients from their level of exercise tolerance, determined when taking the patient's history.

Table 2: Cardiac risk stratification

Low-risk category	Intermediate-risk category	High-risk category
Asymptomatic, < 3 risk factors for CAD (excluding gender)	≥ 3 risk factors for CAD (excluding gender)	High-risk arrhythmias
Mild, stable angina (evaluated and/or being treated)	Moderate, stable angina	Unstable or refractory angina
Uncomplicated previous MI	Recent MI (> 2, < 6 weeks)	Recent MI (< 2 weeks)
LVD/CHF (NYHA class I)	LVD/CHF (NYHA class II)	LVD/CHF (NYHA class III/IV)
Post-successful coronary revascularisation	Non-cardiac sequelae of atherosclerotic disease (e.g. stroke, peripheral vascular disease)	Hypertrophic obstructive and other cardiomyopathies
Controlled hypertension		Uncontrolled hypertension
Mild valvular disease		Moderate-to-severe valvular disease

CAD = coronary artery disease; CHF = congestive heart failure; LVD = left ventricular dysfunction; MI = myocardial infarction; NYHA = New York Heart Association.

Figure 2: Treatment algorithm for determining level of sexual activity according to cardiac risk in ED



2.5.2.1 *Low-risk category*

The low-risk category includes patients who do not have any significant cardiac risk associated with sexual activity. Low risk is typically implied by the ability to perform exercise of modest intensity, which is defined as six or more 'metabolic equivalents of energy expenditure in the resting state' (METs) without symptoms. According to current knowledge of the exercise demand or emotional stress associated with sexual activity, low-risk patients do not need cardiac testing or evaluation before the initiation or resumption of sexual activity or therapy for sexual dysfunction.

2.5.2.2 *Intermediate-risk or indeterminate-risk category*

The intermediate- or indeterminate-risk category consists of patients with an uncertain cardiac condition or patients whose risk profile requires testing or evaluation before the resumption of sexual activity. Based upon the results of testing, these patients may be moved to either the high- or low-risk group. A cardiology consultation may be needed in some patients to help the primary physician determine the safety of sexual activity.

2.5.2.3 *High-risk category*

High-risk patients have a cardiac condition that is sufficiently severe and/or unstable for sexual activity to carry a significant risk. Most high-risk patients have moderately to severely symptomatic heart disease. High-risk individuals should be referred for cardiac assessment and treatment. Sexual activity should be stopped until the patient's cardiac condition has been stabilised by treatment or a decision made by the cardiologist and/or internist that it is safe to resume sexual activity.

2.5.3 ***Specialised diagnostic tests***

Most patients with ED can be managed within the sexual care setting, but some patients may need specific diagnostic tests (Tables 3 and 4).

2.5.3.1 *Nocturnal penile tumescence and rigidity (NPTR)*

The nocturnal penile tumescence and rigidity assessment should be done on at least two nights. A functional erectile mechanism is indicated by an erectile event of at least 60% rigidity recorded on the tip of the penis that lasts for 10 min or more (10).

2.5.3.2 *Intracavernous injection test*

The intracavernous injection test gives limited information about vascular status. A positive test is a rigid erectile response (unable to bend the penis) that appears within 10 min after the intracavernous injection and lasts for 30 min (11). This response indicates a functional, but not necessarily normal, erection, as the erection may co-exist with arterial insufficiency or veno-occlusive dysfunction (12). A positive test shows that a patient will respond to the intracavernous injection programme. The test is inconclusive as a diagnostic procedure and Duplex ultrasound of the penile arteries should be requested.

2.5.3.3 *Duplex ultrasound of penile arteries*

A peak systolic blood flow higher than 30 cm/s and a resistance index higher than 0.8 are generally considered normal (11). Further vascular investigation is unnecessary when a Duplex examination is normal.

2.5.3.4 *Arteriography and dynamic infusion cavernosometry or cavernosography*

Arteriography and dynamic infusion cavernosometry or cavernosography (DICC) should be performed only in patients who are being considered for vascular reconstructive surgery (13).

2.5.3.5 *Psychiatric assessment*

Patients with psychiatric disorders must be referred to a psychiatrist who is particularly interested in ED. In younger patients (< 40 years) with long-term primary ED, psychiatric assessment may be helpful before any organic assessment is carried out.

2.5.3.6 *Penile abnormalities*

Surgical correction may be needed for patients with ED due to penile abnormalities, e.g. hypospadias, congenital curvature, or Peyronie's disease with preserved rigidity. Success rates are high (*see* EAU Guidelines on Penile Curvature).

2.5.4 ***Patient education – consultation and referrals***

The consultation with the patient should include a discussion of the expectations and needs of both the patient and his partner. It should also review both the patient's and partner's understanding of ED and results of the

diagnostic tests, and provide a rational selection of treatment options. Patient and partner education are an essential part of ED management (14,15).

Table 3: Indications for specific diagnostic tests

Primary erectile disorder (not caused by organic disease or psychogenic disorder)
Young patients with a history of pelvic or perineal trauma who could benefit from potentially curative vascular surgery
Patients with penile deformities that might require surgical correction, e.g. Peyronie's disease, congenital curvature
Patients with complex psychiatric or psychosexual disorders
Patients with complex endocrine disorders
Specific tests may be indicated at the request of the patient or his partner
Medicolegal reasons, e.g. implantation of penile prosthesis, sexual abuse

Table 4: Specific diagnostic tests

Nocturnal penile tumescence and rigidity (NTPR) using Rigiscan®
Vascular studies
- Intracavernous vasoactive drug injection
- Duplex ultrasound of the cavernous arteries
- Dynamic infusion cavernosometry or cavernosography (DICC)
- Internal pudendal arteriography
Neurological studies, e.g. bulbocavernosus reflex latency, nerve conduction studies
Endocrinological studies
Specialised psychodiagnostic evaluation

*2.5.5 **Guidelines for the diagnosis of ED***

	LE	GR
Clinical use of validated questionnaire related to ED may help to assess all sexual function domains and the effect of a specific treatment modality	3	B
Physical examination is needed in the initial assessment of men with ED to identify underlying medical conditions that may be associated with ED	4	B
Routine laboratory tests, including glucid-lipid profile and total testosterone, are required to identify and treat any reversible risk factors and lifestyle factors that can be modified	4	B
Specific diagnostic tests are indicated by only a few conditions	4	B

3. TREATMENT OF ERECTILE DYSFUNCTION

3.1 Treatment options

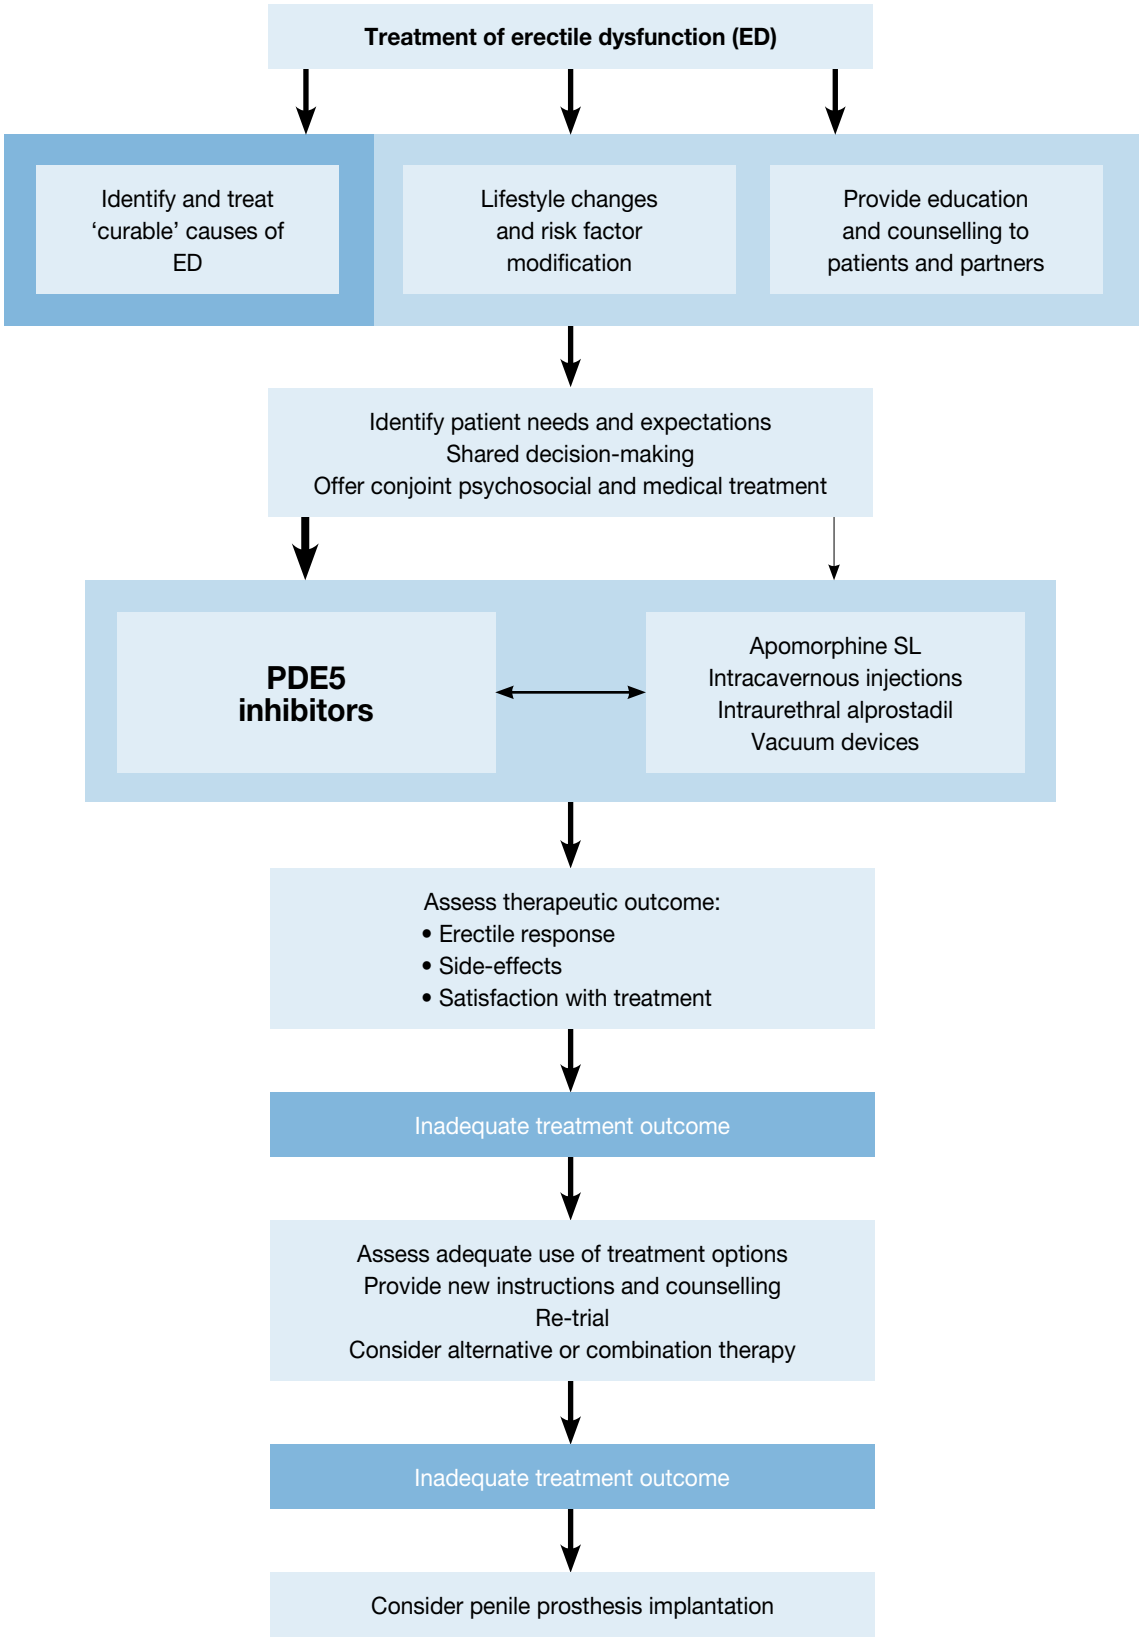
The primary goal in the management strategy of a patient with ED is to determine the aetiology of the disease and treat it when possible, and not to treat the symptom alone. Erectile dysfunction may be associated with modifiable or reversible factors, including lifestyle or drug-related factors. These factors may be modified either before, or at the same time as, specific therapies are used.

As a rule, ED can be treated successfully with current treatment options, but cannot be cured. The only exceptions are psychogenic ED, post-traumatic arteriogenic ED in young patients, and hormonal causes (e.g. hypogonadism, hyperprolactinaemia), which can be potentially cured with specific treatment.

Most men with ED will be treated with treatment options that are not cause-specific. This results in a structured treatment strategy that depends on efficacy, safety, invasiveness and cost, as well as patient preference (1). To counsel patients properly with ED, physicians must be fully informed of all treatment options.

The assessment of treatment options must consider the effects on patient and partner satisfaction and other QoL factors as well as efficacy and safety. A treatment algorithm for ED is given in Figure 3.

Figure 3: Treatment algorithm for ED



PDE5 inhibitor = phosphodiesterase type 5 inhibitor.

3.2 Lifestyle management in ED with concomitant risk factors

The basic work-up of the patient must identify reversible risk factors for ED. Lifestyle changes and risk factor modification must precede or accompany ED treatment.

The potential benefits of lifestyle changes may be particularly important in individuals with ED and specific comorbid cardiovascular or metabolic diseases, such as diabetes or hypertension (2-4). Besides improving erectile function, aggressive lifestyle changes may also benefit overall cardiovascular and metabolic health, with recent studies supporting the potential of lifestyle intervention to benefit both ED and overall health (5).

Although further studies are needed to make clear the role of lifestyle changes in the management of ED and related cardiovascular disease, lifestyle changes can be recommended alone or combined with PDE5 therapy. Some studies have suggested that the therapeutic effects of PDE5 inhibitors may be enhanced when other comorbidities or risk factors are aggressively managed (6). However, these results have yet to be confirmed in well-controlled, long-term studies. Because of the success of pharmacological therapy for ED, clinicians need to provide specific evidence for the benefits of lifestyle change and hopefully future research will show this.

3.3 Erectile dysfunction after radical prostatectomy (RP)

Use of pro-erectile drugs following RP is very important in achieving erectile function following surgery. Several trials have shown higher rates of erectile function recovery after RP in patients receiving any drug (therapeutic or prophylactic) for ED.

Historically, the treatment options for post-operative ED included intracavernous injections (7), urethral microsuppository (8), vacuum device therapy (9), and penile implants (10). Intracavernous injections and penile implants are still suggested as second- and third-line treatments, respectively, when oral compounds are not adequately effective or contraindicated for post-operative patients (*see* Sections 3.8 and 3.9).

The management of post-RP ED has been revolutionised by the advent of PDE5 inhibitors, with their demonstrated efficacy, ease of use, good tolerability, excellent safety, and positive impact on QoL. At present, PDE5 inhibitors are the first-line choice of oral pharmacotherapy for post-RP ED in patients who have undergone a nerve-sparing (NS) surgical approach. The choice of PDE5 inhibitors as first-line treatment is controversial because the experience (surgical volume) of the surgeon is a key factor in preserving post-operative erectile function in addition to patient age and NS technique (11-13). In fact, PDE5 inhibitors are most effective in patients who have undergone a rigorous NS procedure, which is more commonly performed by the largest-volume surgeons (12,13).

The early use of a high dose of sildenafil after RP is associated with the preservation of smooth muscle within the human corpora cavernosa (14). Daily sildenafil also resulted in a greater return of spontaneous normal erectile function post RP compared to placebo following bilateral nerve-sparing RP (NSRP) in patients who were fully potent before surgery (15,16). The response rate to sildenafil treatment for ED after RP in different trials ranged from 35% to 75% among those who underwent NSRP and from 0% to 15% among those who underwent non-NSRP (15-18).

The effectiveness of both tadalafil and vardenafil as on-demand treatment has also been evaluated in post-RP ED:

- A large multicentre trial in Europe and USA studied tadalafil in patients with ED following a bilateral NS procedure. Erectile function was improved in 71% of patients treated with tadalafil 20 mg versus 24% treated with placebo, while the rate of successful intercourse attempts was 52% with tadalafil 20 mg versus 26% with placebo (19).
- Similarly, vardenafil has been tested in patients treated with ED following either a unilateral or bilateral NS procedure in a multicentre, prospective, placebo-controlled, randomised North American study (20). Following bilateral NSRP, erectile function improved by 71% and 60% with vardenafil, 20 mg and 10 mg, respectively. An extended analysis of the same patients undergoing NSRP has underlined the benefit of vardenafil compared to placebo regarding intercourse satisfaction, hardness of erection, orgasmic function, and overall satisfaction with sexual experience (21).

A randomised, double-blind, double-dummy, multicentre, parallel-group study in 87 centres across Europe, Canada, South Africa and the USA, compared on-demand and nightly dosing of vardenafil in men with ED following bilateral NSRP. In patients whose IIEF erectile function domain (IIEF-EF) score was ≥ 26 before surgery, vardenafil was efficacious when used on demand, supporting a paradigm shift towards on-demand dosing with PDE5 inhibitors in post-RP ED (22). Patients who do not respond to oral PDE5 inhibitors after NSRP should be treated with prophylactic intracorporeal alprostadil (23). A penile prosthesis remains a very satisfactory approach for patients who do not respond to either oral or intracavernous pharmacotherapy or to a vacuum device (24).

3.4 'Curable' causes of ED

3.4.1 ***Hormonal causes***

An endocrinologist's advice is essential for managing patients with hormonal abnormalities. Testosterone deficiency is either a result of primary testicular failure or secondary to pituitary/hypothalamic causes, including a functional pituitary tumour resulting in hyperprolactinaemia.

Testosterone replacement therapy (intramuscular, oral, or transdermal) is effective, but should only be used after other endocrinological causes for testicular failure have been excluded (25). Testosterone replacement is contraindicated in men with a history of prostate carcinoma or with symptoms of prostatism. Before initiating testosterone replacement, a digital rectal examination (DRE) and serum PSA test should be performed. Patients given androgen therapy should be monitored for clinical response and the development of hepatic or prostatic disease.

There is no contraindication for testosterone therapy in men with coronary artery disease who have been properly diagnosed with hypogonadism and/or ED. However, the haematocrit level should be monitored and a dose adjustment of testosterone may be necessary, especially in congestive heart failure.

Hormonal treatment is not always effective in the management of ED associated with hypogonadism (26).

3.4.2 ***Post-traumatic arteriogenic ED in young patients***

In young patients with pelvic or perineal trauma, surgical penile revascularisation has a 60-70% long-term success rate (27). The lesion must be demonstrated by Duplex ultrasound and confirmed by penile pharmaco-arteriography. Corporeal veno-occlusive dysfunction is a contraindication to revascularisation and must be excluded by DICC (9,10). Vascular surgery for veno-occlusive dysfunction is no longer recommended because of poor long-term results (28).

3.4.3 ***Psychosexual counselling and therapy***

For patients with a significant psychological problem, psychosexual therapy may be given either alone or with another therapeutic approach. Psychosexual therapy takes time and has had variable results (29).

3.5 First-line therapy

3.5.1 ***Oral pharmacotherapy***

The PDE5 enzyme hydrolyses cyclic guanosine monophosphate (cGMP) in the cavernosum tissue of the penis. Inhibition of PDE5 results in increased arterial blood flow leading to smooth muscle relaxation, vasodilatation, and penile erection (30).

Three potent selective PDE5 inhibitors have been approved by the European Medicines Agency (EMEA) and the US Food and Drug Administration (FDA) for treatment of ED. They are not initiators of erection and require sexual stimulation to facilitate an erection.

3.5.1.1 Sildenafil

Sildenafil, launched in 1998, was the first PDE5 inhibitor available on the market. Efficacy is defined as an erection with rigidity sufficient for vaginal penetration. Sildenafil is effective from 30 to 60 min after administration. Its efficacy is reduced after a heavy, fatty meal due to prolonged absorption. It is administered in 25, 50 and 100 mg doses. The recommended starting dose is 50 mg and should be adapted according to the patient's response and side-effects. Efficacy may be maintained for up to 12 h (31). The pharmacokinetic data of sildenafil are presented in Table 5. Adverse events (Table 6) are generally mild in nature and self-limited by continuous use. The drop-out rate due to adverse events is similar to placebo (32).

After 24 weeks in a dose-response study, improved erections were reported by 56%, 77% and 84% of men taking 25, 50 and 100 mg of sildenafil, respectively, compared to 25% of men taking placebo (33). Sildenafil statistically improved patient scores in IIEF, sexual encounter profile 2 (SEP2), SEP3, and general assessment question (GAQ) and treatment satisfaction.

The efficacy of sildenafil in almost every subgroup of patients with ED has been successfully established. In diabetic patients, 66.6% reported improved erections (GAQ) and 63% successful intercourse attempts compared to 28.6% and 33% of men taking placebo, respectively (34).

3.5.1.2 Tadalafil

Tadalafil, licensed for the treatment of ED as of February 2003, is effective from 30 min after administration, with peak efficacy after about 2 h. Efficacy is maintained for up to 36 h (35) and is not affected by food. It is administered in 10 and 20 mg doses. The recommended starting dose is 10 mg and should be adapted according to the patient's response and side-effects. Pharmacokinetic data of tadalafil are presented in Table 5. Adverse events (Table 6) are generally mild in nature, self-limited by continuous use. The drop-out rate due to adverse events is similar to placebo (36).

In pre-marketing studies, after 12 weeks of treatment and in a dose-response study, improved erections were reported by 67% and 81% of men taking 10 mg and 20 mg of tadalafil compared to 35% of men in the control placebo group (36). Tadalafil statistically improved patient scores in IIEF, SEP2, SEP3, and GAQ and treatment satisfaction. These results were confirmed in post-marketing studies (37).

Tadalafil also improved erections in difficult-to-treat subgroups. In diabetic patients, 64% reported improved erections (i.e. improved GAQ) versus 25% of patients in the control group and the change in the final score for IIEF-EF was 7.3 compared to 0.1 for placebo (38).

3.5.1.3 Vardenafil

Vardenafil, commercially available as of March 2003, is effective from 30 min after administration. Its effect is reduced by a heavy, fatty meal (> 57% fat). It is administered in 5, 10 and 20 mg doses. The recommended starting dose is 10 mg and should be adapted according to the patient's response and side-effects. In vitro, it is 10-fold more potent than sildenafil, though this does not necessarily mean greater clinical efficacy (39). Pharmacokinetic data of vardenafil are presented in Table 5. Adverse events (Table 6) are generally mild in nature and self-limited by continuous use, with a drop-out rate similar to placebo (40).

After 12 weeks in a dose-response study, improved erections were reported by 66%, 76% and 80% of men taking 5 mg, 10 mg and 20 mg of vardenafil, respectively, compared with 30% of men taking placebo (41). Vardenafil statistically improved patient scores for IIEF, SEP2, SEP3, and GAQ and treatment satisfaction. Efficacy was confirmed in post-marketing studies (42).

Vardenafil improved erections in difficult-to-treat subgroups. In diabetic patients, 72% reported improved erections (i.e. improved GAQ) compared to 13% of patients taking placebo and the final IIEF-EF score was 19 compared to 12.6 for placebo (43).

3.5.1.4 Choice or preference between the different PDE5 inhibitors

To date, no data are available from double- or triple-blind multicentre studies comparing the efficacy and/or patient preference for sildenafil, tadalafil, and vardenafil. Choice of drug will depend on the frequency of intercourse (occasional use or regular therapy, 3-4 times weekly) and the patient's personal experience. Patients need to know whether a drug is short- or long-acting, possible disadvantages, and how to use it.

3.5.1.5 On-demand or chronic use of PDE5 inhibitors

Animal studies have shown that chronic use of PDE5 inhibitors improves or prevents significantly the intracavernous structure alterations due to age, diabetes, or surgical damage (44-50).

In humans, a randomised study (n = 145) showed that daily tadalafil led to a significantly higher IIEF-EF score and higher completion of successful intercourse attempts compared to on-demand tadalafil (51). Two major double-blind, randomised studies, using daily 5 and 10 mg tadalafil for 12 weeks (n = 268) (52) and daily 2.5 and 5 mg tadalafil for 24 weeks (n = 286) (53), showed that daily dosing was well tolerated and significantly improved erectile function. However, these studies lacked an on-demand treatment arm. An open-label extension was carried out of both studies in 234 patients for 1 year and 238 patients for 2 years. Tadalafil, 5 mg once daily, was shown to be well tolerated and effective (54). Tadafil, 5 mg once daily, therefore provides an alternative to on-demand dosing of tadalafil for couples who prefer spontaneous rather than scheduled sexual activities or who anticipate frequent sexual activity, with the advantage that dosing and sexual activity no longer need to be temporally linked. Nevertheless, in the 1-year open-label 5 mg tadalafil extension study followed by 4 weeks of wash-out, erectile function was not maintained after discontinuation of therapy in most patients (about 75%).

A double-blind, placebo-controlled, multicentre, parallel-group study was conducted in 236 men with mild-to-moderate ED randomised to receive once-daily vardenafil 10 mg plus on-demand placebo for 12 or 24 weeks, or once-daily placebo plus on-demand vardenafil 10 mg for 24 weeks, followed by 4 weeks of wash-out (55). Despite preclinical evidence, the results suggested that once-daily dosing of vardenafil 10 mg does not offer any sustainable effect after cessation of treatment compared to on-demand administration in patients with mild-to-moderate ED.

Other studies (open-label, randomised, cross-over studies with limited patient numbers) showed that chronic, but not on-demand, tadalafil treatment improved endothelial function with sustained effect after its discontinuation (56,57). This was confirmed in another study of chronic sildenafil in men with type 2 diabetes (58).

Recently, in the first double-blind, placebo-controlled study, enrolling 298 men with diabetes and ED for 12 weeks, once-daily tadalafil 2.5 mg and 5 mg was efficacious and well tolerated. This regimen provides an alternative to on-demand treatment for some diabetic men (59).

However, when patients have the choice, it seems that they prefer on-demand rather than continuous therapy (60).

Table 5: Summary of the key pharmacokinetic data for the three PDE5 inhibitors used to treat ED*

Parameter	Sildenafil, 100 mg	Tadalafil, 20 mg	Vardenafil, 20 mg
Cmax	560 µg/L	378 µg/L	18.7 µg/L
Tmax	0.8-1 h	2 h	0.9 h
T1/2	2.6-3.7 h	17.5 h	3.9 h
AUC	1685 µg.h/L	8066 µg.h/L	56.8 µg.h/L
Protein binding	96%	94%	94%
Bioavailability	41%	NA	15%

Cmax: maximal concentration, Tmax: time-to-maximum plasma concentration; T1/2: plasma elimination half-time; AUC: area under curve or serum concentration time curve.

** Fasted state, higher recommended dose. Data adapted from EMEA statements on product characteristics.*

Table 6: Common adverse events of the three PDE5 inhibitors used to treat ED*

Adverse event	Sildenafil	Tadalafil	Vardenafil
Headache	12.8%	14.5%	16%
Flushing	10.4%	4.1%	12%
Dyspepsia	4.6%	12.3%	4%
Nasal congestion	1.1%	4.3%	10%
Dizziness	1.2%	2.3%	2%
Abnormal vision	1.9%		< 2%
Back pain		6.5%	
Myalgia		5.7%

3.5.1.6 Safety issues for PDE5 inhibitors

3.5.1.6.1 Cardiovascular safety

Clinical trial results and post-marketing data of sildenafil, tadalafil, and vardenafil have demonstrated no increase in myocardial infarction rates in patients receiving PDE5 inhibitors, as part of either double-blind, placebo-controlled trials or open-label studies, or compared to expected rates in age-matched male populations.

None of the PDE5 inhibitors had an adverse effect on total exercise time or time-to-ischaemia during exercise testing in men with stable angina (61,62). In fact, they may improve exercise tests. Sildenafil does not alter cardiac contractility, cardiac output or myocardial oxygen consumption according to available evidence. Chronic or on-demand use is well tolerated with a similar safety profile.

3.5.1.6.2 Nitrates are totally contraindicated with PDE5 inhibitors

Organic nitrates (e.g. nitroglycerine, isosorbide mononitrate, isosorbide dinitrate) and other nitrate preparations used to treat angina, as well as amyl nitrite or amyl nitrate ('poppers' used for recreation), are absolute contraindications with the use of PDE5 inhibitors. They result in cGMP accumulation and unpredictable falls in blood pressure and symptoms of hypotension. The duration of interaction between organic nitrates and PDE5 inhibitors depends upon the PDE5 inhibitor and nitrate used.

If a PDE5 inhibitor is taken and the patient develops chest pain, nitroglycerine must be withheld for at least 24 h if sildenafil (and probably also vardenafil) was used (half-life, 4 h), and for at least 48 h if tadalafil was used (half-life, 17.5 h).

If a patient develops angina while taking a PDE5 inhibitor, other agents may be given instead of nitroglycerine until the appropriate time has passed. If nitroglycerine must be re-introduced following administration of a PDE5 inhibitor, the patient should receive it only after an appropriate interval has elapsed, as described above, and under close medical observation.

3.5.1.6.3 Antihypertensive drugs

Co-administration of PDE5 inhibitors with antihypertensive agents (angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, calcium blockers, beta-blockers, diuretics) may result in small additive drops in blood pressure, which are usually minor. In general, the adverse event profile of a PDE5 inhibitor is not made worse by a background of antihypertensive medication, even when the patient is taking several

antihypertensive agents.

3.5.1.6.4 Alpha-blocker interactions
All PDE5 inhibitors show some interaction with alpha-blockers, which under some conditions may result in orthostatic hypotension.

- Sildenafil labelling currently advises that 50 or 100 mg of sildenafil should not be taken within 4 h following treatment with an alpha-blocker. This restriction does not apply to 25 mg dose of sildenafil.
- In the USA, vardenafil is absolutely contraindicated with alpha-blockers.
- Co-administration of vardenafil with tamsulosin is not associated with clinically significant hypotension (63).
- Tadalafil is contraindicated in patients taking alpha-blockers, except for tamsulosin, 0.4 mg (64).

These interactions are more pronounced when PDE5 inhibitors are given to healthy volunteers not previously taking alpha-blockers. Further research is needed into the interaction between other PDE5 inhibitors and other alpha-blockers (e.g. alfuzosin, once-daily), or mixed alpha-/beta-blockers (e.g. carvedilol, labetalol).

3.5.1.6.5 Dosage adjustment
Drugs that inhibit the CYP34A pathway will inhibit the metabolic breakdown of PDE5 inhibitors. They include ketoconazole, itraconazole, erythromycin, clarithromycin, and HIV protease inhibitors (ritonavir, saquinavir). Such agents may increase blood levels of PDE5 inhibitors, so that lower doses of PDE5 inhibitors are necessary.

However, other agents, such as rifampin, phenobarbital, phenytoin, and carbamazepine, may induce CYP3A4 and enhance the breakdown of PDE5 inhibitors, so that higher doses of PDE5 inhibitors are required.

Severe kidney or hepatic dysfunction may require dose adjustments or warnings.

3.5.1.7 Management of non-responders to PDE5 inhibitors
The two main reasons why patients fail to respond to a PDE5 inhibitor are either incorrect drug use or inefficacy of the drug. The management of a non-responder depends upon identifying the underlying cause.

3.5.1.7.1 Check that the patient has been using a licensed medication
There is a very large 'black market' in PDE5 inhibitors. The amount of active drug in these medications varies enormously and it is important to check how and from which source the patient has obtained his medication.

3.6.1.7.2 Check that the medication has been properly prescribed and correctly used
The main reason why a patient fails to use his medication correctly is inadequate counselling from his physician. The main ways in which a drug may be incorrectly used are:

- failure to use adequate sexual stimulation;
- failure to use an adequate dose;
- failure to wait an adequate amount of time between taking the medication and attempting sexual intercourse.

Lack of adequate sexual stimulation: PDE5 inhibitors depend for their action upon the release of nitric oxide (NO) by the parasympathetic nerves of the penis. The usual stimulus for NO release is sexual stimulation, and without adequate sexual stimulation (and NO release), the drugs cannot work.

Not enough time between taking the medication and intercourse attempt: Oral PDE5 inhibitors take different times to reach maximal plasma concentrations (65-67). Although pharmacological activity is achieved at plasma levels well below the maximal plasma concentration, there will be a period of time following oral ingestion of the medication during which the drug is ineffective. Even though all three drugs have an onset of action in some patients within 30 min of oral ingestion (68-70), most patients require a longer delay between taking the medication, with at least 60 min being required for men using sildenafil and vardenafil and up to 2 h being required for men using tadalafil.

Food may affect drug absorption: sildenafil's absorption can be delayed by a meal (65), while varenafil's absorption can be delayed by a fatty meal (71). Tadalafil's absorption is less affected provided there is enough delay between oral ingestion and an attempt at sexual intercourse (67).

Too much time between taking medication and intercourse attempt: It is also possible to wait too long after taking medication before attempting sexual intercourse. The half-life of sildenafil and vardenafil is about 4 h, suggesting that the normal window of efficacy is about 6-8 h following ingestion of the medication, though

responses following this time period are well recognised. Tadalafil had a longer half-life of about 17.5 h, so the window of efficacy is much longer at about 36 h.

Insufficient dose: For financial reasons, some physicians may prescribe only the lower doses of a medication. It is important to check that the patient has had an adequate trial of the maximal dose of the drug. Data suggests an adequate trial involves at least six attempts with a particular drug (72).

Benefit of education for a non-responding patient: Data from uncontrolled studies suggests patient education can help salvage an apparent non-responder to a PDE5 inhibitor. After emphasising the importance of dose, timing, and sexual stimulation to the patient, erectile function was effectively restored following re-administration of the relevant PDE5 inhibitor (73-76).

One study (74) went further, and in those patients who still did not respond to the PDE5 inhibitor, a second-line adjustment was instituted. Patients taking tadalafil were advised to wait at least 2 h between oral ingestion and attempting intercourse. Patients taking vardenafil were advised to use the drug only after a fast. In both patient groups, further apparent non-responders were 'salvaged'. No patients using sildenafil were included in this study.

3.5.1.7.3 Possible manoeuvres in patients correctly using a PDE5 inhibitor

When the patient is using an adequate dose of the drug properly and the response is still inadequate, there are a number of changes that may improve the efficacy of the medication, though the evidence supporting these interventions is limited.

Modification of associated risk factors: ED is typically a symptom of an underlying condition, such as diabetes, hypertension, dyslipidaemia, etc. Limited evidence suggests that, in a hypogonadal patient, normalisation of the serum testosterone might improve the patient's response to a PDE5 inhibitor (77). So far, modification of other risk factors, such as diabetic control, hypertension and dyslipidaemia, has not been shown to be effective in improving response to a PDE5 inhibitor.

Change the PDE5 inhibitor: A randomised trial suggested vardenafil might benefit non-responders to sildenafil (78), but the results are considered to overstate the benefits of switching PDE5 inhibitors because of poor study design. However, a randomised, open-label, crossover trial comparing sildenafil and tadalafil indicated that some patients might respond better to one PDE5 inhibitor than to another (79). According to the IIEF-EF score, 17% of patients had a better response (≥ 5 points) to tadalafil than to sildenafil, while 14% had a better response to sildenafil than tadalafil.

Although these differences might be explained by variation in drug pharmacokinetics, they do raise the possibility that, despite an identical mode of action, switching to a different PDE5 inhibitor might be helpful.

Regular dosing of PDE5 inhibitor: Two non-randomised trials have suggested that daily dosing with a PDE5 inhibitor might salvage some non-responders to intermittent dosing. In one trial (80), some men benefited from regular dosing with either vardenafil or tadalafil, while in the other trial (75) daily dosing with tadalafil salvaged some men who had failed to respond to intermittent dosing with a PDE5 inhibitor.

Currently, there are no randomised trials to support this intervention. Although tadalafil is licensed for daily dosing at a dose of 2.5 mg and 5 mg, neither sildenafil nor vardenafil are licensed for use in this way.

Introduction of an alternative therapeutic modality: If drug treatment fails, then the patient should be offered an alternative therapy, with intracavernosal injection therapy of with a vacuum erection device. Intraurethral therapy is usually ineffective in these patients.

3.5.1.8 Apomorphine sublingual

Apomorphine is a centrally acting dopamine agonist that improves erectile function by enhancing the natural central erectile signals that normally occur during sexual stimulation (81,82). It is administered sublingually on demand in 2 or 3 mg doses. Apomorphine has been approved for ED treatment in several countries but not in the USA.

Efficacy rates (erections sufficient for intercourse) range from 28.5% to 55% (83-85). Due to rapid absorption, 71% of erections are achieved within 20 min. The most common adverse events are nausea (7%), headache (6.8%) and dizziness (4.4%). These events are generally mild in nature and self-limited (85). Severe events, such as syncope, are extremely rare (< 0.2%) (86).

Apomorphine is not contraindicated in patients taking nitrates or antihypertensive drugs (of all classes) and it does not affect vital signs (87,88). There was no marked improvement in sexual desire, but a slight improvement in orgasmic function was noticed.

Comparative studies clearly show that apomorphine is associated with significantly lower efficacy and satisfaction rates than sildenafil (89-91). The most significant strength of apomorphine is its safety profile (92). Even in pre-marketing studies, apomorphine significantly improves erectile function, intercourse, and overall satisfaction domains of the IIEF compared to placebo.

Its use is limited to patients with mild-to-moderate ED or psychogenic causes of sexual dysfunction due to reduced efficacy rates. It may also be a first-line treatment in patients with certain contraindications for the use of PDE5 inhibitors, e.g. nitrates.

3.5.1.9 Other oral agents

Several other drugs have been used in the treatment of ED with various mechanisms of action (93), but today there is no place for these drugs in the treatment of ED.

- Yohimbine is a centrally and peripherally active alpha-2 adrenergic antagonist used as an aphrodisiac for almost a century.
- Delequamine is a more specific and selective alpha-2 adrenergic antagonist than yohimbine.
- Trazodone is a serotonin reuptake inhibitor (antidepressant) associated with prolonged erections and priapism. It is also a non-selective alpha-adrenergic antagonist in the corporal smooth muscle cells.
- L-arginine is a nitric oxide donor and nalmefene/naltrexone is an opioid-receptor antagonist.
- Red Korea ginseng is a formulation with an unknown mechanism of action (though it may possibly act as a nitric oxide donor).
- Limaprost is an alprostadil derivative for oral use.
- An oral formulation of phentolamine (non-selective alpha-adrenergic antagonist) has undergone phase III clinical trials (94).

Randomised trials have shown that yohimbine and trazodone have a similar efficacy to placebo in patients with organic causes of ED (95,96). Oral phentolamine had efficacy rates (erections sufficient for intercourse) of about 50% (94), but possible carcinogenesis in animal models stopped further development. Efficacy data on Red Korea ginseng suggested it might have a role in treatment of ED (97). There are no efficacy data on the other drugs listed above.

3.6 Topical pharmacotherapy

Several vasoactive drugs (2% nitroglycerine, 15-20% papaverine gel, and 2% minoxidil solution or gel) have been used for topical application to the penis. To overcome the poor drug absorption through the thick and dense tunica albuginea, several drug absorption enhancers have been developed for combination with vasoactive drugs (98). The combination (Topiglan™) of alprostadil gel 1% with 5% SEPA® (absorption enhancer) resulted in an erection sufficient for vaginal penetration in 38.9% of patients compared to 6.9% of placebo-treated patients (99). Adverse events include skin and glans erythema, burning sensation, allergic reactions, and side-effects in the partner (hypotension, headache) due to vaginal absorption.

No topical therapy has been approved and currently these agents have no role in treatment of ED.

3.7 Vacuum constriction devices

Vacuum constriction devices (VCD) provide passive engorgement of the corpora cavernosa together with a constrictor ring placed at the base of the penis to retain blood within the corpora. Thus, erections with these devices are not normal since they do not use physiological erection pathways. Efficacy, in terms of erections satisfactory for intercourse, is as high as 90%, regardless of the cause of ED and satisfaction rates range between 27% and 94% (100). Men with a motivated, interested, and understanding partner report the highest satisfaction rates. Long-term use of VCDs decreases to 50-64% after 2 years (101). Most men who discontinue use of VCDs do so within 3 months.

The commonest adverse events include pain, inability to ejaculate, petechiae, bruising, and numbness, which occur in less than 30% of patients (102). Serious adverse events (skin necrosis) can be avoided if patients remove the constriction ring within 30 min. Vacuum constriction devices are contraindicated in patients with bleeding disorders or on anticoagulant therapy.

Vacuum constriction devices are generally unacceptable to younger patients. They may be the treatment of choice in well-informed older patients with infrequent sexual intercourses and comorbidities requiring a non-invasive, drug-free management of ED.

3.8 Second-line therapy

Patients not responding to oral drugs may be offered intracavernous injections. Success rate is high (85%) (100). Intracavernous administration of vasoactive drugs was the first medical treatment for ED more than 20 years ago (103).

*3.8.1 **Intracavernous injections***

3.8.1.1 Alprostadil

Alprostadil (Caverject™, Edex/Viridal™) is the first and only drug approved for intracavernous ED treatment (104). It is the more efficacious monotherapy for intracavernous treatment in 5-40 µg doses. The erection appears after 5-15 min and lasts according to the dose injected. An office-training programme (one or two visits) is required for the patient to learn the correct injection process. In cases of limited manual dexterity, the technique may be taught to their partners. The use of an automatic special pen that avoids a view of the needle can resolve fear of penile puncture and simplifies the technique.

Efficacy rates for intracavernous alprostadil of more than 70% have been found in general ED populations, as well as in patient subgroups (e.g. diabetes or cardiovascular disease), with reported sexual activity after 94% of the injections and satisfaction rates of 87-93.5% in patients and 86-90.3% in partners (105-107).

Complications of intracavernous alprostadil include penile pain (50% of patients, after 11% of injections), prolonged erections (5%), priapism (1%), and fibrosis (2%) (108). Pain is usually self-limited after prolonged use. It can be alleviated with the addition of sodium bicarbonate or local anaesthesia (109,110). Fibrosis requires temporary discontinuation of the injection programme for several months. Systemic side-effects are uncommon. The most common is mild hypotension especially when using higher doses.

Contraindications include men with a history of hypersensitivity to alprostadil, men at risk of priapism, and men with bleeding disorders.

Despite these favourable data, intracavernous pharmacotherapy is associated with high drop-out rates and limited compliance. Drop-out rates of 41-68% have been described (111-113), with most drop outs occurring within the first 2-3 months. In a comparative study, alprostadil monotherapy had the lowest discontinuation rates (27.5%) compared to overall drug combinations (37.6%), with an attrition rate after the first few months of therapy of 10% per year. Reasons for discontinuation included desire for a permanent modality of therapy (29%), lack of a suitable partner (26%), poor response (23%) (especially among early drop out patients), fear of needles (23%), fear of complications (22%), and lack of spontaneity (21%). Careful counselling of patients during the office-training phase as well as close follow-up is important in addressing patient withdrawal from an intracavernous injection programme (114).

Today, intracavernous pharmacotherapy is considered a second-line treatment. Patients not responding to oral drugs may be offered intracavernous injections with a high success rate of 85%. Most long-term injection users can switch to sildenafil despite underlying pathophysiology (115-117). However, almost one-third of long-term intracavernous injections users who subsequently responded also to sildenafil preferred to continue with an intracavernous injection programme (117,118).

Action to be taken with a prolonged erection

After 4 h of erection, patients are advised to consult their physician to avoid any damage to the intracavernous muscle, which would provoke permanent impotence. A 19-gauge needle is used to aspirate blood and thereby decrease intracavernous pressure. This simple method is usually sufficient to make the penis flaccid. However, if the penis becomes rigid again after this, an intracavernous injection of phenylephrine is required, starting at a dose of 200 µg every 5 min and increasing to 500 µg if necessary. The risk of having a prolonged erection during following subsequent injections cannot be predicted. When this problem occurs, the dose is usually reduced for the next injection.

3.8.1.2 Combination therapy

Combination treatment enables a patient to take advantage of the different modes of action of the drugs being used, as well as alleviating side-effects by using lower doses of each drug.

- Papaverine (20-80 mg) was the first oral drug used for intracavernous injections. It is only used in combination therapy today due to its high incidence of side-effects as monotherapy.
- Phentolamine has been used in combination therapy to increase efficacy. As monotherapy, it produces a poor erectile response.
- Sparse data in the literature support the use of other drugs, such as vasoactive intestinal peptide (VIP), NO donors (linsidomine), forskolin, potassium channel openers, moxisylyte or calcitonin gene-related peptide (CGRP), usually combined with the main drugs (119,120). Most combinations are not standardised and some drugs have limited availability worldwide.
- Papaverine (7.5-45 mg) plus phentolamine (0.25-1.5 mg), and papaverine (8-16 mg) plus phentolamine (0.2-0.4 mg) plus alprostadil (10-20 µg), have been widely used with improved efficacy rates, although they have never been licensed for ED (121-123). The triple combination regimen of papaverine, phentolamine and alprostadil had the highest efficacy rates, reaching 92%; this combination had similar side-effects as alprostadil monotherapy, but a lower incidence of penile pain due to lower doses of alprostadil. However, fibrosis was more common (5-10%) when papaverine was used

(depending on total dose). In addition, mild hepatotoxicity has been reported with papaverine (124). Despite high efficacy rates, 5-10% of patients will not respond to combination intracavernous injections. The combination of sildenafil with intracavernous injection of the triple combination regimen may salvage as many as 31% of patients who do not respond to the triple combination alone (125). However, combination therapy was associated with an incidence of adverse effects in 33% of patients, including dizziness in 20% of patients.

This strategy can be considered in carefully selected patients before proceeding to a penile implant.

3.8.1.3 Intraurethral alprostadil

A specific formulation of alprostadil (125-1000 µg) in a medicated pellet (MUSE™) has been approved for use in ED (126). A vascular interaction between the urethra and the corpora cavernosa enables drug transfer between these structures (127). Erections sufficient for intercourse were achieved in 30-65.9% of patients. In clinical practice, only the higher doses (500 and 1000 µg) have been used with low consistency rates (127-129). The application of a constriction ring at the root of the penis (ACTIS™) may improve efficacy (130).

The most common adverse events are local pain (29-41%) and dizziness (1.9-14%). Penile fibrosis and priapism are very rare (< 1%). Urethral bleeding (5%) and urinary tract infections (0.2%) are adverse events related to the mode of administration.

Efficacy rates are significantly lower than intracavernous pharmacotherapy (131). Intraurethral pharmacotherapy is a second-line therapy and provides an alternative to intracavernous injections in patients who prefer a less invasive, though less efficacious, treatment.

3.9 Third-line therapy (penile prostheses)

The surgical implantation of a penile prosthesis may be considered in patients who do not respond to pharmacotherapy or who prefer a permanent solution to their problem. Two types of prosthesis exist: malleable (semi-rigid) and inflatable (two- or three-piece).

Most patients prefer the three-piece inflatable devices due to the more 'natural' erections obtained. However, the two-piece inflatable prosthesis can be a reliable option with fewer mechanical complications and is easier to implant. A semi-rigid prosthesis provides a constantly rigid penis and may be suitable in older patients with infrequent sexual intercourse (132). The inflatable prosthesis is much more expensive. In several countries, patients are reimbursed for the cost of the prosthesis provided the ED has an organic cause and the patient has undergone a complete impotence assessment.

Prosthesis implantation has one of the highest satisfaction rates (70-87%) among treatment options for ED based on appropriate consultation (133-137).

*3.9.1 **Complications***

The two main complications of penile prosthesis implantation are mechanical failures and infection. Several technical modifications of the most commonly used three-piece prosthesis (AMS 700CX/CXM™ and Mentor Alpha I™) resulted in mechanical failure rates of less than 5% at 5-year follow-up (136,137). Careful surgical technique with proper antibiotic prophylaxis against Gram-positive and Gram-negative bacteria reduced infections rates to 2-3%. The infection rate may be further reduced to 1% by implanting an antibiotic-impregnated prosthesis (AMS Inhibizone™) or hydrophilic-coated prosthesis (Mentor Titan™) (138,139). Although diabetes is considered to be one of the main risk factors for infection, this is not supported by current data (132). Infections, as well as erosions, are significantly higher (9%) in patients with spinal cord injuries (9%) (132). Infection requires removal of the prosthesis, antibiotic administration and re-implantation after 6-12 months. However, salvage therapy with removal and re-implantation at the same time, after copious irrigation of the corpora with multi-drug solutions, had an 82% success rate (140).

*3.9.2 **Conclusion***

Penile implants are an attractive solution for patients who do not respond to oral therapy (141).

3.10 Guidelines on the treatment of ED

	LE	GR
Lifestyle changes and risk factor modification must precede or accompany ED treatment.	1b	A
Pro-erectile treatments have to be given at the earliest opportunity after radical prostatectomy.	1b	A
When a curable cause of ED is found, the cause must be treated first.	1b	B
PDE5 inhibitors are first-line therapy.	1a	A
Daily administration of PDE5 inhibitors may improve results and restore erectile function.	1b	A

Inadequate/incorrect prescription and poor patient education are the main causes of a lack of response to PDE5 inhibitors.	3	B
Testosterone replacement restores efficacy in hypogonadic non-responders to PDE5 inhibitors.	1b	B
Apomorphine can be used in mild-to-moderate ED or psychogenic causes or in patients with contraindications for the use of PDE5 inhibitors.	1b	B
A vacuum constriction device can be used in patients with a stable relationship.	4	C
Intracavernous injection is second-line therapy.	1b	B
Penile implant is third-line therapy.	4	C

PDE5 inhibitor = phosphodiesterase type 5 inhibitor; ED = erectile dysfunction.

4. PREMATURE EJACULATION (PE)

4.1 Introduction

Although PE is a very common male sexual dysfunction, it is poorly understood. Patients are often unwilling to discuss their symptoms and many physicians do not know about effective treatments. As a result, patients may be misdiagnosed or mistreated (1). In addition, there is currently no registered pharmacological treatment for PE.

These guidelines provide an evidence-based analysis (2) of published data on definition, clinical evaluation and treatment. It provides recommendations to clinicians on the diagnosis and treatment of PE, without pre-empting physician judgement on individual cases.

4.2 Definition of PE

*4.2.1 **Overview***

There have previously been two official definitions of PE, neither of which were universally accepted:

- In the Diagnostic and Statistical Manual of Mental Disorders IV-Text Revision (DSM-IV-TR), PE is defined as a '*persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it. The clinician must take into account factors that affect duration of the excitement phase, such as age, novelty of the sexual partner or situation, and recent frequency of sexual activity*' (3).
- In the World Health Organization's International Classification of Diseases-10 (ICD-10), PE is defined as '*the inability to delay ejaculation sufficiently to enjoy lovemaking, which is manifested by either an occurrence of ejaculation before or very soon after the beginning of intercourse (if a time limit is required: before or within 15 seconds of the beginning of intercourse) or ejaculation occurs in the absence of sufficient erection to make intercourse possible. The problem is not the result of prolonged absence from sexual activity*' (4).

Recently, two more definitions have been proposed:

- The Second International Consultation on Sexual and Erectile Dysfunction defined PE as '*ejaculation*

with minimal stimulation and earlier than desired, before or soon after penetration, which causes bother or distress, and over which the sufferer has little or no voluntary control' (5).

- The International Society for Sexual Medicine (ISSM) has adopted a completely new definition of PE which is the first evidence-based definition, '*Premature ejaculation is a male sexual dysfunction characterised by ejaculation which always or nearly always occurs prior to or within about one minute of vaginal penetration; and inability to delay ejaculation on all or nearly all vaginal penetrations; and negative personal consequences, such as distress, bother, frustration and/or the avoidance of sexual intimacy*'. It must be noted that this definition is limited to men with lifelong PE who engage in vaginal intercourse since there are insufficient objective data to propose an evidence-based definition for acquired PE (6).

All four definitions have taken into account the time to ejaculation, the inability to control or delay ejaculation, and negative consequences (bother/distress) from PE. However, the major point of debate is quantifying the time to ejaculation, which is usually described by intravaginal ejaculatory latency time (IELT). Several proposals for updating the definition of PE in the forthcoming DSM-V and ICD-11 have been presented (7-11).

4.2.2 ***Classifications***

Premature ejaculation is classified as 'lifelong' (primary) or 'acquired' (secondary) (12). Lifelong PE is characterised by onset from the first sexual experience, remains so during life and ejaculation occurs too fast (before vaginal penetration or < 1-2 min after). Acquired PE is characterised by a gradual or sudden onset following normal ejaculation experiences before onset and time to ejaculation is short (usually not as short as in lifelong PE).

Recently, two more PE syndromes have been proposed (11):

- 'Natural variable PE' is characterised by inconsistent and irregular early ejaculations, representing a normal variation in sexual performance.
- 'Premature-like ejaculatory dysfunction' is characterised by subjective perception of consistent or inconsistent rapid ejaculation during intercourse, while ejaculation latency time is in the normal range or can even last longer. It should not be regarded as a symptom or manifestation of true medical pathology.

The addition of these new types may aid patient stratification, diagnosis and treatment, but their exact role remains to be defined (13).

4.3 Epidemiology of PE

4.3.1 ***Prevalence***

The major problem in assessing the prevalence of PE is the lack of an accurate (validated) definition at the time the surveys were conducted (14). However, epidemiological research has consistently shown that PE, at least according to the DSM-IV definition, is the most common male sexual dysfunction, with prevalence rates of 20-30% (15-17).

The highest prevalence rate of 31% (men aged 18-59 years) was found by the USA NHSLS study (16). Prevalence rates from 18 to 29 years, 30 to 39 years, 40 to 49 years and 50 to 59 years were 30%, 32%, 28% and 55%, respectively. These high prevalence rates may be a result of the dichotomous scale (yes/no) in a single question asking if ejaculation occurred too early, as the prevalence rates in European studies have been significantly lower. A British mailed questionnaire survey estimated that the prevalence rate of PE was between 14% (3 months) and 31% (life-time) (18). A French telephone survey of men aged 18 to 69 years estimated the life-time prevalence of early ejaculation at 15%, including 5% who often had experienced ejaculation prior to penetration and 10% who often had ejaculated too rapidly after vaginal intromission (19). A Swedish interview reported an overall prevalence rate of 9% in men aged 18 to 74 years (20), with prevalence by age being 4% for 18-24 years, 7% for 25-34 years, 8% for 35-49 years, 8% for 50-65 years and 14% for 66-74 years. A Danish study about sexual problems using a questionnaire (12 questions) and an interview (23 questions) reported the prevalence rate for PE to be 14% in men aged 51 years (21). An Italian questionnaire survey recorded a prevalence rate of 21% (22). Finally, in a self-administered questionnaire survey in the Netherlands, the prevalence rate was 13% in men aged 50-78 years (23).

The prevalence of PE in the Premature Ejaculation Prevalence and Attitudes (PEPA) survey (a multinational, internet-based survey) was 22.7% (24.0% in the USA, 20.3% in Germany, and 20.0% in Italy) (17). The Global Study of Sexual Attitudes and Behaviors (GSSAB) survey was conducted in men between 40 and 80 years old in 29 different countries using personal and telephone interviews and self-completed mailed questionnaires; it confirmed that the worldwide prevalence of PE was almost 30%. Except for a low reported rate of PE in Middle Eastern countries (10-15%), prevalence was relatively similar throughout the rest of the world (15). Finally, the prevalence rate of PE was 18% in a five-country European Observational study using the IELT and the Premature Ejaculation Profile (PEP) (24), comparable to those obtained in a similarly designed USA observational study (25).

Further research is needed on the prevalence of lifelong and acquired PE. Limited data suggests that the prevalence of lifelong PE, defined as IELT < 1-2 min, is about 2-5% (20, 25). These results are supported by the moderate genetic influence on PE (26) and low prevalence rates of IELT < 1 min (27).

*4.3.2 **Pathophysiology and risk factors***

The aetiology of PE is unknown, with little data to support suggested biological and psychological hypotheses, including anxiety, penile hypersensitivity, and 5-HT receptor dysfunction (5). In addition, the pathophysiology of PE is largely unknown. In contrast to ED, there is no impairment of the physiological events leading up to the forceful expulsion of sperm at the urethral meatus.

A significant proportion of men with ED also experience PE (15). High levels of performance anxiety related to ED may worsen PE, with a risk of misdiagnosing PE instead of the underlying ED.

According to the NHLS, the prevalence of PE is not affected by age (16,17), unlike ED, which increases with age. Premature ejaculation is not affected by marital or income status (16). However, PE is more common in blacks, Hispanic men and men from Islamic backgrounds (28,29) and may be higher in men with a lower educational level (15,16). Other risk factors may include a genetic predisposition (30), poor overall health status and obesity (16), prostate inflammation (31,32), thyroid hormone disorders (33), emotional problems and stress (16,34), and traumatic sexual experiences (1516).

In the only published study on risk modification/prevention strategies (35), successful eradication of causative organisms in patients with chronic prostatitis and PE produced marked improvements in IELT and ejaculatory control compared to untreated patients.

4.4 Impact of PE on QoL

Men with PE are more likely to report low satisfaction with their sexual relationship, low satisfaction with sexual intercourse, difficulty relaxing during intercourse, and less frequent intercourse (36,37). However, the negative impact of PE extends beyond sexual dysfunction. PE has a detrimental effect on self-confidence and the relationship with the partner, and may cause mental distress, anxiety, embarrassment and depression (36, 38). Sex drive and overall interest in sex does not appear to be affected by PE (39). However, the partner's satisfaction with the sexual relationship decreased with increasing severity of the man's condition (40).

Despite the serious psychological and QoL consequences of PE, few men seek treatment. In the GSSAB survey, 78% of men who self-reported a sexual dysfunction sought no professional help or advice for their sexual problems (15), with men more likely to seek treatment for ED than for PE (15). In the PEPA survey, only 9% of men with self-reported PE consulted a doctor (17).

The main reasons for not discussing PE with their physician are patient embarrassment and a belief that there is no treatment. Physicians are often uncomfortable discussing sexuality with their patients usually because of embarrassment and a lack of training or expertise in treating PE (41,42). Physicians need to encourage patients to talk about PE.

4.5 Diagnosis of PE

Diagnosis of PE is based on the patient's medical and sexual history (43,44). History should classify PE as lifelong or acquired and determine whether PE is situational (under specific circumstances or with a specific partner) or consistent. Special attention should be given to the duration time of ejaculation, degree of sexual stimulus, impact on sexual activity and QoL, and drug use or abuse. It is also important to distinguish PE from ED.

Many patients with ED develop secondary PE caused by the anxiety associated with difficulty in attaining and maintaining an erection (45). Furthermore, some patients are not aware that loss of erection after ejaculation is normal and may erroneously complain of ED, while the actual problem is PE (46).

There are several overlapping definitions of PE, with four shared factors (Table 7), resulting in a multidimensional diagnosis (47).

Table 7: Common factors in different definitions of ED

Time to ejaculation assessed by IELT
Perceived control
Distress
Interpersonal difficulty related to the ejaculatory dysfunction

*4.5.1 **Intravaginal ejaculatory latency time (IELT)***

The use of IELT alone is not sufficient to define PE, as there is significant overlap between men with and without PE (24,25). Moreover, IELT has a significant direct effect on perceived control over ejaculation, but not

a significant direct effect on ejaculation-related personal distress or satisfaction with sexual intercourse (48). In addition, perceived control over ejaculation has a significant direct effect on both ejaculation-related personal distress and satisfaction with sexual intercourse (each showing direct effects on interpersonal difficulty related to ejaculation).

In everyday clinical practice, self-estimated IELT is sufficient. Self-estimated and stopwatch-measured IELT are interchangeable and correctly assign PE status with 80% sensitivity and 80% specificity (49). Specificity can be improved further to 96% by combining IELT with a single-item patient-reported outcome (PRO) on control over ejaculation and satisfaction with sexual intercourse (scale ranging from 0 = very poor to 4 = very good) and on personal distress and interpersonal difficulty (0 = not at all to 4 = extremely). However, stopwatch-measured IELT is necessary in clinical trials.

*4.5.2 **PE assessment questionnaires***

The need to assess PE objectively has led to the development of several questionnaires based on the use of PROs (47). Only two questionnaires can discriminate between patients who have PE and those who do not:

- Premature Ejaculation Diagnostic Tool (PEDT: five-item questionnaire based on focus groups and interviews from the USA, Germany and Spain. Assesses control, frequency, minimal stimulation, distress and interpersonal difficulty (50,51).
- Arabic Index of Premature Ejaculation (AIPE): seven-item questionnaire developed in Saudi Arabia assesses sexual desire, hard erections for sufficient intercourse, time to ejaculation, control, satisfaction for the patient and partner, anxiety or depression (52).

These tools are a significant step in simplifying the methodology of PE drug studies, though further cross-cultural validation is needed (53).

Other questionnaires used to characterise PE and determine treatment effects include the PEP (25), Index of Premature Ejaculation (IPE), (54) and Male Sexual Health Questionnaire Ejaculatory Dysfunction (MSHQ-EjD) (55). Currently, their role is optional in everyday clinical practice.

*4.5.3 **Physical examination and investigations***

Physical examination is part of the initial assessment of men with PE. It includes a brief examination of the vascular, endocrine and neurological systems to identify underlying medical conditions associated with PE or other sexual dysfunctions, such as chronic illness, endocrinopathy, autonomic neuropathy, Peyronie's disease, urethritis or prostatitis. Laboratory or physiological testing should be directed by specific findings from history or physical examination and is not routinely recommended (44).

4.6 Guidelines recommendations on the diagnosis of PE

	LE	GR
Diagnosis and classification of PE is based on medical and sexual history. It should be multidimensional and assess IELT, perceived control, distress and interpersonal difficulty due to the ejaculatory dysfunction.	1a	A
Clinical use of self-estimated IELT is adequate. Stopwatch-measured IELT is necessary in clinical trials.	2a	B
Patient-reported outcomes (PROs) have the potential to identify men with PE. Further research is needed before PROs can be recommended for clinical use.	3	C
Physical examination may be necessary in initial assessment of PE to identify underlying medical conditions that may be associated with PE or other sexual dysfunctions, particularly ED.	3	C
Routine laboratory or neurophysiological tests are not recommended. They should only be directed by specific findings from history or physical examination.	3	C

4.8 Treatment

In many relationships, PE causes few, if any, problems. In such cases, treatment should be limited to psychosexual counselling. Before beginning treatment, it is essential to discuss patient expectations thoroughly. Erectile dysfunction, in particular, or other sexual dysfunction or genitourinary infection (e.g. prostatitis), should be treated first or at the same time as PE.

Various behavioural techniques have demonstrated benefit in treating PE and are indicated for patients uncomfortable with pharmacological therapy. In lifelong PE, behavioural techniques are not recommended for first-line treatment. They are time-intensive, require the support of a partner and can be difficult to do. In addition, long-term outcomes of behavioural techniques for PE are unknown.

Pharmacotherapy is the basis of treatment in lifelong PE. Since no drug for PE has been approved by

the EMEA or FDA, all medical treatments are off-label indications. Only chronic selective serotonin reuptake inhibitors (SSRIs) and on-demand topical anaesthetic agents have consistently shown efficacy in PE. Again, long-term outcomes for pharmacological treatments are unknown.

An evidence-based analysis of all current treatment modalities was performed. Levels of evidence and grade of recommendation are provided and a treatment algorithm is presented (Figure 3).

4.8.1 ***Psychological/behavioural strategies***

Behavioural strategies mainly include the 'stop-start' programme developed by Semans (1) and its modification, the 'squeeze' technique, proposed by Masters and Johnson.

- In the 'stop-start' programme, the partner stimulates the penis until the patient feels the urge to ejaculate. At this point, he instructs his partner to stop, waits for the sensation to pass and then stimulation is resumed.
- The 'squeeze' technique is similar but the partner applies manual pressure to the glans just before ejaculation until the patient loses his urge.

Both these procedures are typically applied in a cycle of three pauses before proceeding to orgasm. Behavioural strategies are based on the hypothesis that PE occurs because the man fails to appreciate the sensations of heightened arousal and to recognise the feelings of ejaculatory inevitability. Re-training may attenuate stimulus-response connections by gradually exposing the patient to progressively more intense and more prolonged stimulation, while maintaining the intensity and duration of the stimulus just below the threshold for triggering the response.

There are several modifications of these techniques making comparison difficult.

Masturbation before anticipation of sexual intercourse is a technique used by many younger men. Following masturbation, the penis is desensitised resulting in greater ejaculatory delay after the refractory period is over. In a different approach, the man learns to recognise the signs of increased sexual arousal and how to keep his level of sexual excitement below the intensity that elicits the ejaculatory reflex. Efficacy is similar to the 'start-stop' programme (2).

Overall, success rates of 50-60% have been reported short term (3,4). However, there is no controlled research to support the efficacy of behavioural techniques, while a double-blind, randomised, crossover study showed that pharmacological treatment (chlomipramine, sertraline, paroxetine and sildenafil) resulted in greater IELT prolongation than behavioural therapy (5). Furthermore, clinical experience suggests that improvements achieved with these techniques are generally not maintained long term (6,7).

4.8.1.1 Guideline recommendation on the psychological/behavioural treatment of PE

	LE	GR
Psychological/behavioural therapies may be attempted but no clinical data exists supporting prolonged effect.	3	C

4.8.2 ***Topical anaesthetic agents***

The use of local anaesthetics to delay ejaculation is the oldest form of pharmacological therapy for PE (8). Several trials (9,10) support the hypothesis that topical desensitising agents reduce the sensitivity of the glans penis so delaying ejaculatory latency, but without adversely affecting the sensation of ejaculation.

4.8.2.1 Lidocaine-prilocaine cream

In a randomised, double-blind, placebo-controlled trial, lidocaine-prilocaine cream increased the IELT from 1 min in the placebo group to 6.7 min in the treatment group (11). In another randomised, double-blind, placebo-controlled trial, lidocaine-prilocaine cream significantly increased the stopwatch-measured IELT from 1.49 to 8.45 min while no difference was recorded in the placebo group (1.67 to 1.95 min) (12). Lidocaine-prilocaine cream (5%) is applied for 20 to 30 min prior to intercourse. Prolonged application of topical anaesthetic (30 to 45 min) may result in loss of erection due to numbness of the penis in a significant percentage of men (11). A condom is required to avoid diffusion of the topical anaesthetic agent into the vaginal wall causing numbness in the partner. Alternatively, the condom may be removed prior to sexual intercourse and the penis washed clean of any residual active compound. Although no significant side-effects have been reported, topical anaesthetics are contraindicated in patients or partners with an allergy to any component of the product.

An aerosol formulation of lidocaine 7.5 mg plus prilocaine 2.5 mg (Topical Eutectic Mixture for Premature Ejaculation, TEMPE (13) has been evaluated in a phase II study (14). Intravaginal ejaculatory latency time increased from a baseline of 1 min to 4.9 min in the TEMPE-treated group compared to an increase from baseline of 0.9 min to 1.6 min ($p < 0.01$) in the placebo-treated group. It has been suggested that lidocaine-prilocaine can penetrate the glans within 5–10 min, but penetrates intact keratinised skin less easily, reducing

penile numbness and ED (14,15).

Finally, in a randomised, double-blind, placebo-controlled, parallel-group study, lidocaine-prilocaine cream showed similar efficacy to combination with sildenafil (50 mg before coitus) and significantly better efficacy than sildenafil alone (16). However, no specific data on estimated IELT were provided.

4.8.2.2 SS-cream

SS-cream is a topical anaesthetic agent made from the extracts of nine herbs. It is applied to the glans penis 1 h before and washed off immediately prior to coitus. SS-cream increased the vibratory threshold in a dose-dependent fashion, as well as the latency and amplitude of somatosensory-evoked potentials measured at the glans penis (17,18). In a double-blind, randomised, placebo-controlled study (19), application of 0.2 g SS-cream improved IELT from 1.37 min to 10.92 min in the treatment group versus 2.45 min in the placebo group. Sexual satisfaction improved by 82% in the treatment group versus 20% in the placebo group. Mild local burning and mild pain were reported by 18.5% of patients. No adverse effects on sexual function or partner or systemic side-effects were observed.

SS-cream.	1B	A

*4.8.3 **Selective serotonin reuptake inhibitors***

Ejaculation is mediated by a spinal ejaculation generator (20, 21) and by descending supraspinal modulation from several brain regions. The neurotransmitter 5-hydroxytryptamine (5-HT, serotonin) is also involved in ejaculatory control. The retarding effect of 5-HT on ejaculation is probably due to central activation (i.e. spinally and supraspinally) of 5-HT1B and 5-HT2C receptors, while stimulation of 5-HT1A receptors precipitates ejaculation.

Selective serontonin reuptake inhibitors (SSRIs) are used to treat mood disorders, but can delay ejaculation and are therefore widely used 'off-label' for PE. As in depression, SSRIs must be given for 1 to 2 weeks to be effective in PE (22). Chronic SSRI administration causes prolonged increases in synaptic cleft serotonin, which desensitise the 5-HT1A and 5-HT1B receptors (23). Clomipramine, the most serotoninergic tricyclic antidepressant, was first reported in 1973 as an effective PE treatment (24). Selective serontonin reuptake inhibitors have revolutionised treatment of PE, but they have also changed our understanding of PE since the first publication on paroxetine in 1970 (25). Today, daily treatment with SSRIs has become the first choice of treatment in PE. Commonly used SSRIs include citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline, all of which have a similar pharmacological mechanism of action.

A systematic review and meta-analysis of all drug treatment studies reported that, despite methodological problems in most studies, there still remained several, well-designed, double-blind, placebo-controlled trials supporting the therapeutic effect of daily SSRIs on PE (26). Open-design studies and studies using subjective reporting or questionnaires showed greater variation in ejaculation delay than double-blind studies in which the ejaculation delay was prospectively assessed with a stopwatch.

Based on this meta-analysis, SSRIs were expected to increase the geometric mean IELT by 2.6-fold to 13.2-fold. Paroxetine was found to be superior to fluoxetine, clomipramine and sertraline. Sertraline was superior to fluoxetine, whereas the efficacy of clomipramine was not significantly different from fluoxetine and sertraline. Paroxetine was evaluated in doses of 20-40 mg, sertraline 25-200 mg, fluoxetine 10-60 mg and clomipramine 25-50 mg; there was no significant relationship between dose and response among the various drugs. There is limited evidence that citalopram may be less efficacious compared to other SSRIs, while fluvoxamine may not be effective (27,28).

Ejaculation delay may start a few days after drug intake, but it is more evident after 1 to 2 weeks since receptor desensitisation requires time to occur. While efficacy may be maintained for several years, tachyphylaxis (decreasing response to a drug following chronic administration) may occur after 6 to 12 months (24).

Common side-effects of SSRIs include fatigue, drowsiness, yawning, nausea, vomiting, dry mouth, diarrhoea and perspiration; they are usually mild and gradually improve after 2 to 3 weeks (24). Decreased libido, anorgasmia, anejaculation and ED have been also reported.

In one controlled trial, on-demand use of clomipramine (but not paroxetine), 3 to 5 h before intercourse, was reported to be efficacious, though IELT improvement was inferior compared to daily treatment with the same drug (29). However, on-demand treatment may be combined with an initial trial of daily treatment or concomitant low-dose daily treatment reducing adverse effects (30,31).

4.8.3.1 *Dapoxetine*

Dapoxetine is a potent SSRI, which has been designed as an on-demand oral treatment for PE. It is quickly absorbed with a Tmax of 1.5 h and is rapidly cleared, avoiding accumulation.

An integrated analysis of two, double-blind, randomised, controlled trials (1,958 patients) with dapoxetine was published (32). Dapoxetine, 30 and 60 mg, was administered 1 to 3 h before intercourse. Intravaginal ejaculatory latency time improved from a baseline of 0.9 min to 1.75 min, 2.78 min and 3.32 min in the patient groups treated with placebo, 30 mg dapoxetine, and 60 mg dapoxetine, respectively. Improved ejaculation control was reported by 51% and 58% of patients in the 30 mg and 60 mg groups, respectively. Both dapoxetine doses were effective on the first dose. Common adverse events for 30 mg and 60 mg doses of dapoxetine, respectively, were nausea (8.7%, 20.1%), diarrhoea (3.9%, 6.8%), headache (5.9%, 6.8%), and dizziness (3.0%, 6.2%).

In a subanalysis of these two studies (33), 32% of men reported a two-category (from a 5-point scale, 'very poor' to 'very good') or greater increase in control and satisfaction with sexual intercourse after treatment. More than 95% of those men rated their PE as 'slightly better', 'better', or 'much better' on the global impression of change (7-point scale, 'much worse' to 'much better') while 67.1% gave ratings of 'better' or 'much better.' They also had greater improvements in IELT than men with less than a two-category increase in control, with a mean (SD) change from baseline of 3.7 (4.3) vs 0.77 (1.8) min, respectively. The proportions of men with a two-category or greater increase in control with dapoxetine 30 and 60 mg were 36.3% and 44.5%, respectively (vs 15% with placebo).

In another randomised, double-blind, parallel-group, placebo-controlled, phase II trial including 1,162 men in 22 countries (34), mean average IELT increased from 0.9 min at baseline (all groups) to 1.9 min, 3.2 min, and 3.5 min with placebo and dapoxetine 30 mg and dapoxetine 60 mg, respectively, at study end point. The geometric mean IELT increased from 0.7 min at baseline to 1.1 min, 1.8 min, and 2.3 min, respectively, at study end point. All PEP measures and IELTs improved significantly with dapoxetine versus placebo at week 12 and week 24 ($p < 0.001$ for all). The most common adverse effects were nausea, dizziness, diarrhea, and headache. Adverse effects led to discontinuation in 1.3%, 3.9%, and 8.2% of subjects with placebo and dapoxetine 30 mg. Finally, in a randomised, double-blind, placebo controlled, phase III trial (1,238 men in USA and Canada), dapoxetine reduced the personal distress and interpersonal difficulty associated with PE (35).

Dapoxetine has been approved (December 2008) for the on-demand treatment of PE in seven European countries (Sweden, Austria, Finland, Germany, Spain, Italy and Portugal). This is currently the first and only drug approved for such an indication.

4.8.3.2 *Guideline recommendation on the treatment of PE*

	LE	GR
Selective serotonin receptor inhibitors (SSRIs).	1A	A

4.8.4 ***Phosphodiesterase type 5 inhibitors***

Several recent studies have supported the therapeutic role of PDE5 inhibitors in PE. They may reduce performance anxiety due to better erections and may down-regulate the erectile threshold to a lower level of arousal so that greater arousal is required to achieve the ejaculation threshold. However, many of the mechanisms involved remain speculative (33,36-38).

There is only one well-designed, randomised, double-blind, placebo-controlled study comparing sildenafil to placebo (39). Although IELT was not significantly improved, sildenafil increased confidence, the perception of ejaculatory control and overall sexual satisfaction, reduced anxiety and decreased the refractory time to achieve a second erection after ejaculation.

In another randomised, double-blind, placebo-controlled study, lidocaine-prilocaine had similar efficacy to combination with sildenafil (50 mg before intercourse), while the efficacy of sildenafil was similar to placebo (no IELT data provided) (16). In contrast, in a randomised, double-blind, parallel group study, sildenafil significantly improved IELT and satisfaction and reduced overall anxiety compared to several SSRIs and the 'pause-squeeze' technique. From a baseline of IELT at 1 min, IELT improved to 15 min with sildenafil, 4 min with clomipramine, 3 min with sertraline, 4 min with paroxetine and 3 min with the 'pause-squeeze' technique (5).

Finally, several open-label studies showed that sildenafil combined with an SSRI is superior to SSRI monotherapy. Sildenafil combined with paroxetine improved IELT significantly and satisfaction versus paroxetine alone (40). Sildenafil combined with sertraline improved IELT and satisfaction significantly versus sertraline alone (41). Sildenafil combined with paroxetine and psychological and behavioural counselling significantly improved IELT and satisfaction in patients in whom other treatments failed (42). Finally, sildenafil combined with behavioural therapy significantly improved IELT and satisfaction versus behavioural therapy alone (43).

There are limited data on the efficacy in PE of other PDE5 inhibitors (tadalafil and vardenafil) (37, 38). Overall, the role of PDE5 inhibitors in PE patients without ED is not established, with only minimal double-blind placebo controlled data are available.

4.8.4.1 Guidelines recommendation on the use of PDE5 inhibitors for the treatment of PE

	LE	GR
In patients presenting with PE, a trial of PDE5 inhibitors may be attempted.	2B	C

*4.8.5 **Other drugs***

Adrenergic blockade for PE aims to decrease the sympathetic tone of the seminal tract and therefore delay ejaculation (44). Tramadol is a centrally acting analgesic agent that combines opioid receptor activation and re-uptake inhibition of serotonin and noradrenaline.

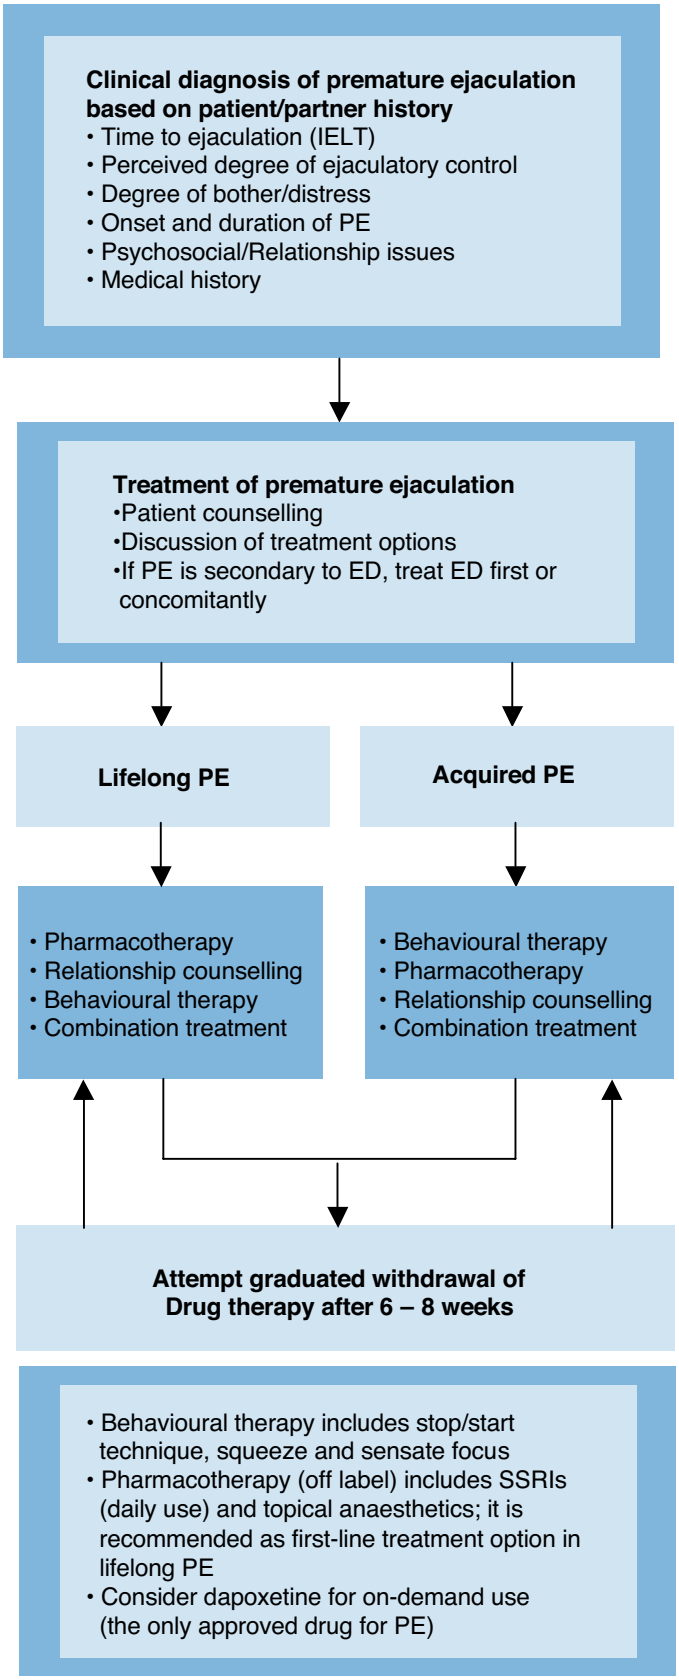
Research suggests that the alpha-1 adrenergic antagonists, terazosin and alfuzosin (45,46), and tramadol (47,48) may have some efficacy in PE. However, further research is needed to investigate their role fully. Currently they are not recommended in clinical practice (49).

*4.8.6 **Guideline recommendations on the treatment of PE***

	LE	GR
ED, other sexual dysfunction or genitourinary infection (e.g. prostatitis) should be treated first.	2a	B
Behavioural techniques have demonstrated benefit in treating PE. However, they are time intensive, require the support of a partner and can be difficult to do.	3	C
Pharmacotherapy is the basis of treatment in lifelong PE.	1a	A
Daily SSRIs are first-line, off-label, pharmacological treatment for PE. The pharmacokinetic profile of SSRIs is not amenable to pm dosing.	1a	A
Dapoxetine, a short-acting SSRI, has already been approved for the on-demand treatment of PE in seven European Countries.	1a	A
Topical anaesthetic agents provide viable alternatives to SSRIs (off-label).	1b	A
Recurrence is likely after treatment cessation.	1b	A
Behavioural therapy may augment pharmacotherapy to enhance relapse prevention.	3	C

ED = erectile dysfunction; PE = premature ejaculation; SSRI = selective serotonin reuptake inhibitor; pm = on-demand adminstration.

Figure 4: Management of PE*



* Adapted from Lue et al. 2004 (49).
ED = erectile dysfunction; PE = premature ejaculation; IELT = intravaginal ejaculatory latency time; SSRI = selective serotonin receptor inhibitor.

5. CONCLUSION

Modern treatment of ED has been revolutionised by the worldwide availability of three PDE5 inhibitors for oral use – sildenafil, tadalafil and vardenafil. These drugs have high efficacy and safety rates, even in difficult-to-treat populations, such as patients with diabetes mellitus or who have undergone RP. Patients should be encouraged to try all three PDE5 inhibitors. Patients should make up their own minds about which compound has the best efficacy, while also considering other factors, such as time of onset, duration of action, window of opportunity and how side-effects affect them individually.

Treatment options for patients who do not respond to oral drugs, or for whom drugs are contraindicated, include intracavernous injections, intraurethral alprostadil, vacuum constriction devices, or implantation of a penile prosthesis.

It is very important that the physician warns the patient that sexual intercourse is a vigorous physical activity, which increases heart rate as well as cardiac work. Physicians should assess the cardiac fitness of patients prior to treating ED.

Any successful pharmacological treatment for erectile failure demands a degree of integrity of the penile mechanisms of erection. Further studies of individual agents and synergistic activity of available substances are underway. The search for the ideal pharmacological therapy for erectile failure aims to fulfil the following characteristics: good efficacy, easy administration, freedom from toxicity and side-effects, with a rapid onset and a possible long-acting effect.

Premature ejaculation is another very common male sexual dysfunction, with prevalence rates of 20% to 30%. Four major definitions of PE are currently used and the most widely accepted classification of PE includes “lifelong” (primary) and “acquired” (secondary) forms (syndromes).

Diagnosis of PE in everyday clinical practice is based on medical and sexual history assessing IELT, perceived control, distress, and interpersonal difficulty related to the ejaculatory dysfunction. Physical examination and laboratory testing may be needed in selected patients only.

Pharmacotherapy is the basis of treatment in lifelong PE including daily dosing of SSRIs and topical anaesthetics. Behavioural techniques may be efficacious as a monotherapy or in combination with pharmacotherapy, but they can be difficult to perform. In every case, recurrence is likely to occur after treatment withdrawal.

6. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

5-HT	5-hydroxytryptamine
AIPE	Arabic Index of Premature Ejaculation
AUC	area under curve - serum concentration time curve
BMI	body mass index
CAD	coronary artery disease
cGMP	cyclic guanosine monophosphate
CGRP	calcitonin gene-related peptide
CHF	congestive heart failure
Cmax	maximal concentration
DICC	dynamic infusion cavernosometry or cavernosography
DRE	digital rectal examination
DSM-IV-TR	Diagnostic and Statistical Manual of Mental Disorders IV-Text Revision
EAU	European Association of Urology
ED	erectile dysfunction
EMEA	European Medicines Agency
FDA	(US) Food and Drug Administration
FSH	follicle-stimulating hormone
GAQ	General Assessment Question
GR	grade of recommendation
GSSAB	Global Study of Sexual Attitudes and Behaviors
ICD-10	International Classification of Diseases-10
IELT	intravaginal ejaculatory latency time
IIEF	International Index for Erectile Function
IIEF-EF	International Index for Erectile Function - erectile function domain
IPE	Index of Premature Ejaculation
ISSM	International Society for Sexual Medicine
LE	level of evidence
LH	luteinising hormone
LVD	left ventricular dysfunction
MET	metabolic equivalent of energy expenditure in the resting state
MI	myocardial infarction
MMAS	Massachusetts Male Aging Study
MSHQ-EjD	Male Sexual Health Questionnaire Ejaculatory Dysfunction
NHSLS	National Health and Social Life Survey
NS	nerve sparing
NO	nitric oxide
NPTR	nocturnal penile tumescence and rigidity
NSRP	nerve-sparing radical prostatectomy
NYHA	New York Heart Association
PCa	prostate cancer
PDE5	phosphodiesterase type 5 [inhibitors]
PE	premature ejaculation
PEDT	Premature Ejaculation Diagnostic Tool
PEP	Premature Ejaculation Profile
PEPA	Premature Ejaculation Prevalence and Attitudes
PRO	Patient reported outcome
PSA	prostate-specific antigen
QoL	quality of life
RP	radical prostatectomy
SEP	sexual encounter profile
SSRI	selective serotonin reuptake inhibitor
TEMPE	topical eutectic mixture for premature ejaculation
Tmax	time to maximum plasma concentration
VCD	vacuum constriction devices
VIP	vasointestinal peptide

Conflict of interest

All members of the Male Sexual Dysfunction guidelines working group have provided disclosure statements of all relationships which they have and which may be perceived as a potential source of conflict of interest. This information is kept on file in the European Association of Urology Central Office database. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel - and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on

Penile Curvature

E. Wespes (chairman), K. Hatzimouratidis (vice-chair), I. Eardley,
F. Giuliano, D. Hatzichristou, I. Moncada, A. Salonia, Y. Vardi

Association
of Urology

TABLE OF CONTENTS PAGE

1. INTRODUCTION

Penile curvature can be congenital or acquired. Congenital curvature is discussed in these guidelines as a distinct pathology in the adult population without any other concomitant abnormality present (such as urethral abnormalities). For paediatric congenital penile curvature, please refer to the EAU Guidelines on Paediatric Urology, Chapter 7, Congenital Penile Curvature.

Acquired curvature is secondary due to La Peyronie's disease (referred as Peyronie's disease in this text), which was named by a French physician, François Gigot de La Peyronie, in 1743 – although he was not the first one to describe this disease (1).

2. METHODOLOGY

A systematic literature search of the Medline database was performed by panel members. The controlled vocabulary of the Medical Subject Headings (MeSH) database uses the specific term 'penile induration' for Peyronie's disease. There is no specific MeSH term for congenital penile curvature. In order to identify relevant articles, search included the MeSH terms 'congenital abnormalities', 'penis/*abnormalities' and 'male' as well as the free text term 'congenital penile curvature'. Since this is the first time guidelines on this topic are published, the search includes all relevant articles published up to January 2012. A total of 48 articles were identified for congenital penile curvature while this number was 1200 for Peyronie's disease. The panel reviewed all these records and selected the articles with the highest evidence available. However, in several subtopics only articles with low levels of evidence were available and discussed accordingly.

2.1 Level of evidence and grade of recommendation

The level of evidence (LE) and grade of recommendation (GR) provided in this guideline follow the listings in Tables 1 and 2. The aim of grading the recommendations is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials
1b	Evidence obtained from at least one randomised trial
2a	Evidence obtained from one well-designed controlled study without randomisation
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities

**Modified from Sackett et al. (2).*

It should be noted that when recommendations are graded, there is not an automatic relationship between the level of evidence and the grade of recommendation. The availability of RCTs may not necessarily translate into a grade A recommendation if there are methodological limitations or disparities in the published results. Conversely, an absence of high-level evidence does not necessarily preclude a grade A recommendation if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations in which corroborating studies cannot be performed, perhaps for ethical or other reasons. In this case, unequivocal recommendations are considered helpful for the reader. Whenever this occurs, it has been clearly indicated in the text with an asterisk as 'upgraded based on panel consensus'. The quality of the underlying scientific evidence is a very important factor, but it has to be balanced against benefits and burdens, values and preferences and costs when a grade is assigned (3–5).

The EAU Guidelines Office does not perform cost assessments, nor can they address local/national preferences in a systematic fashion. However, whenever such data are available, the expert panels will include the information.

Table 2: Grade of recommendation*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial
B	Based on well-conducted clinical studies, but without randomised clinical trials
C	Made despite the absence of directly applicable clinical studies of good quality

**Modified from Sackett et al. (2).*

2.2 Publication history

The present Penile Curvature guidelines are a new publication that underwent a blinded peer-review process before publication. The standard procedure will be an annual assessment of newly published literature in this field, guiding future updates. An ultra-short reference document is being published alongside this publication. All documents are available with free access through the EAU website Uroweb (http://www.uroweb.org/guidelines/online-guidelines/).

2.3 Potential conflict of interest statement

The expert panel have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guidelines/online-guidelines/.

3. CONGENITAL PENILE CURVATURE

3.1 Epidemiology and physiopathology

Congenital curvature is rare: one study reports an incidence of less than 1% (6) while another suggests it is more common with prevalence rates of 4-10% in the absence of hypospadias (7).

There is no evident cause of congenital penile curvature. A single study analysing the ultrastructure of the tunica albuginea has demonstrated widening and fragmentation of collagen fibres, with complete disappearance of striation and transformation into electron-dense, fibrous, granulated material and elastin accumulation (8).

3.2 Patient evaluation

Taking medical and sexual history are usually sufficient to establish the diagnosis of congenital penile curvature. Physical examination during erection is only useful to document curvature and exclude other pathologies (9). Erectile function is normal but it can be compromised by excessive curvature.

3.3 Treatment

Only androgens have been tried for congenital penile curvature with no improvement in adults (10). Therefore, the treatment of this pathology is only surgical. Surgical treatments for congenital penile curvature generally share the same principles as in Peyronie's disease (presented in detail in the next section) but can be performed at any time in adults. Notably, most operations for Peyronie's disease have been described first for congenital penile curvature (11). Plication techniques are used almost exclusively with high curvature correction rates (67-97%) (12-14). The use of grafting material in isolated congenital penile curvature is very limited to draw any conclusions (15).

Conclusions on treatment	LE
Medical and sexual history are usually sufficient to establish the diagnosis of congenital penile curvature. Physical examination during erection is useful for documentation of the curvature and exclusion of other pathologies.	3
Surgery is the only treatment option which can be performed at any time in adult life. Plication techniques have been used almost exclusively in isolated penile curvature with high curvature correction rates.	3

4. PEYRONIE'S DISEASE

4.1 Epidemiology, physiopathology and natural history

Epidemiological data on Peyronie's disease are limited. Prevalence rates of 0.4-9% have been published (16-22).

The etiology of Peyronie's disease is unknown. However, an insult (repetitive microvascular injury or trauma) to the tunica albuginea is the most widely accepted hypothesis on the etiology of the disease (23). Peyronie's disease starts with an acute inflammatory process. The acute inflammation is characterised by increased proliferation of the tunical fibroblasts, some of which differentiate into myofibroblasts, with excessive deposition of collagen, persistence of fibrin and elastin fragmentation. A prolonged inflammatory response will result in the remodelling of connective tissue into a dense fibrotic plaque (23-25). Penile plaque formation can result in curvature which, if severe, may prevent vaginal intromission. The most commonly associated comorbidities and risk factors are diabetes, hypertension, lipid abnormalities, ischaemic cardiopathy, erectile dysfunction, smoking, and excessive consumption of alcohol (21,22,26,27). Dupuytren's contracture is more common in patients with Peyronie's disease affecting 9-39% of patients (18,28-30) while 4% of patients with Dupuytren's contracture reported Peyronie's disease (28). However, it is still unclear if these factors contribute to the pathophysiology of Peyronie's disease. While the pathogenesis has to be clarified, younger men and Caucasian men are at increased risk for Peyronie's disease after radical pelvic surgery, e.g. radical prostatectomy (31).

Peyronie's disease can be a chronic and progressive disease. Two phases of the disease can be distinguished (32). The first is the acute inflammatory phase, which may be associated with pain in the flaccid state or painful erections and manifestation of a 'soft' nodule/plaque and penile curvature. The second is the fibrotic phase with the formation of hard palpable plaques that can be calcified, which also result in disease stabilisation. With time, penile curvature is expected to worsen in 30-50% of patients or stabilise in 47-67% of patients, while spontaneous improvement has been reported by only 3-13% of patients (27,33,34). An improvement in penile curvature is more likely to occur in the early stage of the disease, rather than in a later phase when the plaque has been formed and has become densely calcified (35). Pain is present in 35-45% of patients during the early stages of the disease (36). Pain tends to resolve with time in 90% of men, usually during the first 12 months after the onset of the disease (33,34).

In addition to physiological and functional alteration of the penis, affected men also suffer significant distress. Validated mental health questionnaires have shown that 48% of men with Peyronie's disease have mild or moderate depression, sufficient to warrant medical evaluation (37).

Conclusions	**LE**
Peyronie's disease is a connective tissue disorder, characterised by the formation of a fibrotic lesion or plaque in the tunica albuginea, which leads to penile deformity.	2
The contribution of associated comorbidities or risk factors (e.g. diabetes, hypertension, lipid abnormalities and Dupuytren's contracture) to the pathophysiology of Peyronie's disease is still unclear.	3
Two phases of the disease can be distinguished. The first phase is the acute inflammatory phase (painful erections, 'soft' nodule/plaque), and the second phase is the fibrotic/calcifying phase with formation of hard palpable plaques (disease stabilisation).	2
Spontaneous resolution is uncommon (3-13%) and most patients experience disease progression (30-50%) or stabilisation (47-67%). Pain is usually present during the early stages of the disease but tends to resolve with time in 90% of men.	2

4.2 Patient evaluation

The aim of the initial evaluation is to provide information on the presenting symptoms and their duration (erectile pain, palpable nodules, curvature, length, rigidity, and girth) and erectile function status. It is mandatory to obtain information on the distress provoked by the symptoms and the potential risk factors for erectile dysfunction and Peyronie's disease. Although a disease-specific questionnaire has been designed to collect data, it is yet a validated instrument suitable for use in clinical practice (38).

Major attention should be given to whether the disease is still active, as this will influence medical treatment or the timing of surgery. Patients who are still likely to have an active disease are those with short symptom

duration, pain during erection, or a recent change in penile curvature. It is often difficult to evaluate the end of the inflammatory phase, but resolution of pain and stability of the curvature for at least 3 months are well-accepted criteria of disease stabilisation and patients referral for surgical intervention when indicated (*see below* Section 4.4.4 Surgical treatment of penile curvature) (33).

The examination should start with a routine genitourinary assessment, which is then extended to the hands and feet for detecting possible Dupuytren's contracture or Ledderhose scarring of the plantar fascia (34). Penile examination consists generally of a palpable node or plaque. The whole of the penis should be examined. There is currently no standardised approach, but it is recommended to measure the penis dorsally from the base to the tip of the glans while at full stretch (34). Plaque size is measured in the erect penis. However, there is no correlation between plaque size and the degree of curvature (35). Measurement of length during erection is important because it impacts directly on treatment decisions (39). Girth-related changes are often self-reported by the patients.

Erectile function can be assessed using validated instruments such as the international index of erectile function (IIEF) (40). However, it should be noted that IIEF has not been validated specifically in Peyronie's disease patients. Erectile dysfunction is quite common (> 50%) in patients with Peyronie's disease but it is important to define if pre-dated or post-dated Peyronie's disease onset. It is mainly due to penile vascular disease (27,35). The presence of erectile dysfunction may impact on the treatment strategy (41).

Sonographic measurement of the plaque's size is inaccurate and operator dependent and it is not recommended in everyday clinical practice (42). Duplex ultrasonography may be required for the assessment of vascular parameters (41) (see also Section 2.5.3.3 and Table 3 in the EAU Guidelines on Male Sexual Dysfunction). An objective assessment of penile curvature with an erection is mandatory. This can be obtained by a home (self) photograph of a natural erection (preferably) or using a vacuum-assisted erection test or an intracavernosal injection using vasoactive agents (38).

Guidelines recommendations on the evaluation of Peyronie's disease	**LE**	**GR**
Medical and sexual history in patients with Peyronie's disease must include duration of the disease, penile pain, change of penile deformity, difficulty in vaginal intromission due to deformity, and erectile dysfunction.	2	B
Physical examination must include assessment of palpable nodules, penile length, extent of curvature (self-photograph, vacuum-assisted erection test or pharmacological-induced erection) and any other possibly related diseases (Dupuytren's contracture, Ledderhose disease).	2	B
Sonographic measurement of the plaque's size is inaccurate and operator dependent. It is not recommended in everyday clinical practice.	3	C
Duplex ultrasonography is required to ascertain vascular parameters associated to erectile dysfunction.	2	B

4.3 Non-operative treatment

Conservative treatment of Peyronie's disease is primarily focused on patients in the early stage of disease, when symptoms are present and the plaque is not densely fibrotic or calcified (34,43). In this context, several options have been suggested, including oral pharmacotherapy, intralesional injection therapy and other topical treatments, which will be discussed in this section (Table 1). The role of conservative treatment in men with stable/chronic disease has not yet been adequately defined (32,44). No single drug has been approved by the European Medical Association for the treatment of Peyronie's disease. Only potassium para-aminobenzoate (Potaba) has been classified as 'possibly effective' by the Food and Drug Administration for the treatment of Peyronie's disease.

The results of the studies on conservative treatment for Peyronie's disease are often contradictory making it difficult to provide recommendations in the everyday, real-life setting. This fact is due to several methodological problems including uncontrolled studies, limited number of patients treated, short term follow-up and different outcome measures (44). Moreover, the efficacy of conservative treatment in distinct patient population in terms of early (inflammatory) or late (fibrotic) phases of the disease is not yet available.

Table 1: Non-operative treatments for Peyronie's disease

Oral treatments
Vitamin E
Potassium para-aminobenzoate (Potaba)
Tamoxifen
Colchicine
Acetyl esters of carnitine
Pentoxifylline
Intralesional treatments
Steroids
Verapamil
Clostridial collagenase
Interferon
Topical treatments
Verapamil
Iontophoresis
Extracorporeal shock wave lithotripsy (SWL)
Traction devices
Vacuum devices

*4.3.1 **Oral treatment***

4.3.1.1 Vitamin E

Vitamin E (tocopherol, a fat-soluble compound that acts as a natural antioxidant to reduce the number of oxygen-free radicals produced in energy metabolism) is commonly prescribed by the majority of urologists at once or twice daily doses of 400 IU because of its wide availability, low cost and safety (45). Despite the fact that it has been suggested as a potential treatment option in patients with Peyronie's disease (46), a double-blind, placebo-controlled crossover study failed to show a significant effect on penile deformity or plaque size (47).

4.3.1.2 Potassium para-aminobenzoate (Potaba)

Potassium para-aminobenzoate is thought to exert an antifibrotic effect through an increase in oxygen uptake by the tissues, a rise in the secretion of glycosaminoglycans, and an enhancement of the activity of monoamine oxidases (48). Its role in the treatment of Peyronie's disease is due to preliminary studies that reported an improvement in penile curvature, penile plaque size, and penile pain during erection (49). In a prospective double-blinded controlled study in 41 patients with Peyronie's disease, potassium paraaminobenzoate (12 g/day for 12 months) improved penile pain significantly, but not penile curvature and penile plaque size (50). In another prospective, randomised, double-blind, placebo-controlled in 103 patients with Peyronie's disease, potassium para-aminobenzoate (4 x 3g/day for 12 months) decreased penile plaque size significantly, but had no effect on penile curvature or penile pain (51). However, the pre-existing curvature under potassium para-aminobenzoate remained stable, suggesting a protective effect on the deterioration of penile curvature. Treatment-emergent adverse events are nausea, anorexia, pruritus, anxiety, chills, cold sweats, confusion and difficulty in concentration, but no serious adverse events were reported.

4.3.1.3 Tamoxifen

Tamoxifen is a non-steroidal oestrogen receptor antagonist. Its proposed mechanism of action in Peyronie's disease involves the modulation of TGFβ1 secretion by fibroblasts. Preliminary studies reported that tamoxifen (20 mg twice daily for 3 months) improved penile pain, penile curvature, and reduced the size of penile plaque (52). However, a placebo-controlled, randomised study (in only 25 patients, at late stage of the disease with a mean duration of 20 months) using the same treatment protocol, failed to show any significant improvement in pain, curvature, or plaque size in patients with Peyronie's disease (53).

4.3.1.4 Colchicine

Colchicine is a medicine often used to treat acute attacks of gout. It has been introduced into the treatment

of Peyronie's disease on the basis of its anti-inflammatory effect (54). Preliminary results in 24 men showed that half of the men given colchicine (0.6-1.2 mg daily for 3-5 months) found that painful erections and penile curvature improved, while penile plaque decreased or disappeared in 50% (55). In another study in 60 men (colchicine 0.5-1 mg daily for 3-5 months with escalation to 2 mg twice daily), penile pain resolved in 95% and penile curvature improved in 30% (54). Similar results have been reported in another uncontrolled retrospective study in 118 patients. The study concluded that lateral curvature is the most commonly altered deformity, which mostly shifts to the dorsal size of the penis after colchicine therapy (56). Reported treatment-emergent adverse events with colchicine are gastrointestinal effects (nausea, vomiting, diarrhoea) that can be improved with dose escalation (54).

The combination of vitamin E and colchicine (600 mg/day and 1 mg every 12 hours, respectively) for 6 months in patients with early-stage Peyronie's disease resulted in significant improvement in plaque size and curvature, but not in pain compared to ibuprofen 400 mg/day for 6 months (57).

4.3.1.5 Acetyl esters of carnitine

Although the actual mechanism of action of acetyl esters of carnitine in patients with Peyronie's disease is unknown, it has been suggested that it can reduce intracellular calcium levels in endothelial cells (58). This may eventually suppress fibroblast proliferation and collagen production, thus reducing penile fibrosis. In a randomised, double-blind study in 48 patients with early-stage Peyronie's disease, patients were randomised to acetyl-L-carnitine (1 g twice daily) compared to tamoxifen (20 mg twice daily). After 3 months, acetyl-L-carnitine was significantly more effective than tamoxifen in pain and curvature reduction and in inhibiting disease progression but not in penile plaque size reduction (both drugs significantly reduced plaque size) (59). Tamoxifen induced significantly more side-effects.

Finally, the combination of intralesional verapamil (10 mg weekly for 10 weeks) with propionyl-l-carnitine (2 g/day for 3 months) significantly reduced penile curvature, plaque size, and disease progression compared to intralesional verapamil combined with tamoxifen (40 mg/day) for 3 months (60).

4.3.1.6 Pentoxifylline

Pentoxifylline is a non-specific phosphodiesterase inhibitor which down regulates TGFβ1 and increases fibrinolytic activity (61). Moreover, an increase of nitric oxide levels may be effective in preventing progression of Peyronie's disease or reversing fibrosis (62). Preliminary data from a case report showing that pentoxifylline (400 mg three times daily for 6 months) improved penile curvature and the ultrasonographic appearance of the plaque (62). In another study in 62 patients with Peyronie's disease, pentoxifylline treatment for 6 months appeared to stabilise or reduce calcium content in penile plaques (63).

4.3.1.7 Phosphodiesterase type 5 inhibitors (PDE5i)

The rationale for the use of PDE5i in Peyronie's disease comes from animal studies showing that they can reduce the collagen/smooth muscle and collagen III/I ratios and increase the apoptotic index in the Peyronie's disease-like plaque (64). In a retrospective controlled study, daily tadalafil (2.5mg for 6 months) resulted in statistically significant ($p < 0.05$) resolution of septal scar in 69% of patients compared to 10% in the control group (no treatment). However, this study included patients with isolated septal scars without evidence of penile deformity (65). Therefore, no recommendation can be given for PDEi in patients with Peyronie's disease.

4.3.2 ***Intralesional treatment***

Injection of pharmacologically active agents directly into penile plaques represents another treatment option. It allows a localised delivery of a particular agent that provides higher concentrations of the drug inside the plaque. However, delivery of the compound to the target area is difficult to ensure.

4.3.2.1 Steroids

Intralesional steroids are thought to act by opposing the inflammatory milieu responsible for Peyronie's plaque progression via inhibition of phospholipase A2 and suppression of the immune response and by decreasing collagen synthesis (66). In small, non-randomised studies, a decrease in penile plaque size and pain resolution was reported (67,68). In the only single-blind, placebo-controlled study with intralesional administration of betamethasone, no statistical significant changes in penile deformity, penile plaque size, and penile pain during erection were reported (69). Adverse effects include tissue atrophy, thinning of the skin and immune suppression (67).

4.3.2.2 Verapamil

The rationale for intralesional use of verapamil (a calcium channel antagonist) in patients with Peyronie's disease is based on in-vitro data that demonstrated transport of extracellular matrix molecules, which included

collagen, fibronectin, and glycosaminoglycans as a calcium-dependent process, along with a concomitant increase in collagenase activity, a modification of the inflammatory response in the early phase of the disorder, and the inhibition of fibroblast proliferation in the plaques (70,71). A number of studies have reported that intralesional verapamil injection may induce a significant reduction in penile curvature and plaque volume (72-76). These findings suggested that intralesional verapamil injections (multiple-puncture technique, 10 mg of verapamil diluted to 10 mL, distributed throughout the plaque every 2 weeks for a total of 12 consecutive sessions) could be advocated for the treatment of non-calcified acute phase or chronic plaques to stabilise disease progression or possibly reduce penile deformity, although large scale, placebo-controlled trials have not yet been conducted (72). Side effects are uncommon (4%) and minor including nausea, light-headedness, penile pain, and ecchymosis (72). However, in the only randomised, placebo-controlled study, no statistical significant differences on plaque size, penile curvature, penile pain during erection and plaque 'softening' were reported (77). Younger age and larger baseline penile curvature were found to be predictive of favourable curvature outcomes in a case-series study (78).

4.3.2.3 Clostridial collagenase

Clostridial collagenase is a chromatographically purified bacterial enzyme that selectively attacks collagen, which is known to be the primary component of the Peyronie's disease plaque (79-81). Conversely, clostridial collagenase injections received FDA approval for Dupuytren's contracture, with a similar mechanism of action (82). In a prospective randomised, placebo-controlled, double-blind study, comparing the effects on plaque size and penile deformity of intralesional purified clostridial collagenase (6,000-14,000 units) and saline placebo, the overall response was 36% while in the placebo arm it was 4% ($p < 0.007$) (79). Follow-up was only 3 months. The response rates were even higher in patients with smaller plaques and curvature less than 60º. The efficacy of intralesional collagenase injections (three injections of clostridial collagenase 10,000 unit/0.25 cm3 per injection administered over 7-10 days and subsequently administered over 7-10 days at 3 months) has been assessed over a non-placebo-controlled, short-term follow-up study conducted in a small population of men with Peyronie's disease (81). Although methodologically-biased, this study showed significant decreases from baseline in the deviation angle, in plaque width and in plaque length. The most commonly reported side effects were penile pain, contusions, and ecchymosis.

4.3.2.4 Interferon

Interferon α-2b has been shown to decrease fibroblast proliferation, extracellular matrix production and collagen production from fibroblasts and improved the wound healing process from Peyronie's disease plaques in vitro (83). Intralesional injections (5×10^6 units of interferon α-2b in 10 mL saline, two times per week for 12 weeks) significantly improved penile curvature, plaque size and density, and pain compared to placebo (84,85). Side effects include myalgias, arthralgia, sinusitis, fever and flu-like symptoms. They can be effectively treated with non-steroidal anti-inflammatory drugs before interferon injection.

4.3.3 ***Topical treatments***

4.3.3.1 Topical verapamil

In a small, randomised, placebo-controlled study, topical verapamil (gel 15% applied topically to the penile shaft twice daily) significantly improved penile curvature, plaque size, and penile pain (86). Moreover, treatment results significantly improved after 9 months compared to 3 months showing that a prolonged treatment period may be important. However, there is lack of evidence that topical verapamil applied to the penile shaft results in adequate levels of the active compound within the tunica albuginea (87).

4.3.3.2 Iontophoresis

Iontophoresis (also known as transdermal electromotive drug administration or electromotive drug administration [EMDA]) has been introduced to try and overcome limitations on the local uptake of the drugs themselves. Uncontrolled studies showed promising results in terms of improvement in penile curvature, plaque size and penile pain during erection (88-90).

In a randomised, double-blind, controlled study, iontophoresis with verapamil 5 mg and dexamethasone 8 mg resulted in a statistically significant improvement in penile curvature and plaque size (91). However, in another randomised, double-blind, placebo-controlled study, penile curvature was not statistically improved after iontophoresis with verapamil 10 mg (92). The method is not associated with any significant adverse event.

4.3.3.3 Extracorporeal shock wave lithotripsy (SWL)

The mechanism of action involved in SWL for Peyronie's disease is still unclear, but there are two hypotheses. In the first hypothesis, shock wave therapy works by directly damaging and remodelling the penile plaque. In the second hypothesis, SWL increases the vascularity of the area by generating heat resulting in an inflammatory reaction, with increased macrophage activity causing plaque lysis and eventually leading to

plaque resorption (93). Most uncontrolled studies failed to show significant improvements in patients with Peyronie's disease (94-96). In a prospective, randomised, double-blind, placebo-controlled study, four weekly treatment sessions of SWL, with each session consisting of 2000 focused shock waves, resulted in significant improvement only for penile pain (97).

4.3.3.4 Traction devices

The application of continuous traction in Dupuytren's contracture increases the activity of degradative enzymes (98). This initially leads to a loss of tensile strength and ultimately to solubilisation. It is followed by an increase in newly synthesised collagen (98). This concept has been applied in an uncontrolled study, including 10 patients with Peyronie's disease (the FastSize Penile Extender was applied as the only treatment for 2-8 hours/day for 6 months) (99). Penile curvature reduced in all men from 10° to 45°, with an average reduction of 33% (range: 51-34°). The stretched penile length increased to 0.5-2.0 cm. The erect girth increased to 0.5-1.0 cm, with a correction of hinge effect in four out of four men. There were no adverse events, including skin changes, ulcerations, hypoesthesia or diminished rigidity.

However, in another uncontrolled study in 15 patients with Peyronie's disease and a curvature of less than 50° (the Andropenis penile extender was applied for at least 5 hours per day for 6 months). The decrease in penile curvature was minimal (4°, the effect size was not reached), while the mean stretched and flaccid penile length increased by 1.3 and 0.83 cm, respectively, at 6 months (100).

4.3.3.5 Vacuum devices

The application of vacuum devices follows the same principles as traction devices. Their efficacy has been assessed in an uncontrolled study (31 patients completed the study) (101). They used a vacuum device for 10 min twice daily over a 12 week period. Penile pain reduced significantly ($p = 0.012$). Stretched penile length also increased significantly ($p = 0.029$) with a mean of 0.5 cm. Reduction of the curvature was reported in 67% of patients while 10% of them had a worsening and 23% had no change. Half of them were satisfied with outcome and the remaining had their curvature corrected surgically.

Guidelines recommendations on non-operative treatment for Peyronie's disease	**LE**	**GR**
Conservative treatment for Peyronie's disease is primarily aimed at treating patients in the early stage of disease. It is an option in patients not fit for surgery or when surgery is not acceptable to the patient.	3	C
Oral treatment with potassium para-aminobenzoate may result in a significant reduction in penile plaque size and penile pain as well as penile curvature stabilisation.	1b	B
Intralesional treatment with verapamil may induce a significant reduction in penile curvature and plaque volume.	1b	C
Intralesional treatment with clostridial collagenase showed significant decreases in the deviation angle, plaque width and plaque length.	2b	C
Intralesional treatment with interferon may improve penile curvature, plaque size and density, and pain.	1b	B
Topical verapamil gel 15% may improve penile curvature and plaque size.	1b	B
Iontophoresis with verapamil 5 mg and dexamethasone 8 mg may improve penile curvature and plaque size.	1b	B
Extracorporeal shock-wave treatment fails to improve penile curvature and plaque size, and should not be used with this intent but may be beneficial for penile pain.	1b	B
Penile traction devices and vacuum devices may reduce penile deformity and increase penile length.	3	C
Recommendations AGAINST		
Intralesional treatment with steroids is not associated with significant reduction in penile curvature, plaque size or penile pain. Therefore intralesional treatment with steroids cannot be recommended.	1b	B
Oral treatment with vitamin E and tamoxifen are not associated with significant reduction in penile curvature, plaque size or penile pain thus should not be used with this intent.	2b	B
Other oral treatments (acetyl esters of carnitine, pentoxifylline) are not recommended.	3	C

4.4 Surgical treatment

Although conservative treatment for Peyronie's disease should resolve painful erections in most men, only a small percentage will experience any significant straightening of the penis. The aim of surgery is to correct curvature and allow satisfactory intercourse (102). Surgery is indicated only in patients with stable disease for at least 3 months, although a 6-12 month period has also been suggested (103).

During informed consent, the potential aims and risks of surgery should be discussed. Specific issues that should be mentioned during consent are the risks of penile shortening, erectile dysfunction, penile numbness, the risk of recurrent curvature, the potential for palpation of knots and stitches underneath the skin, and the potential need for circumcision at the time of surgery (32).

Two major types of repair may be considered for both congenital penile curvature and Peyronie's disease: penile shortening and penile lengthening procedures (104). Penile shortening procedures include the Nesbit wedge resection and the plication techniques performed on the convex side of the penis. Penile lengthening procedures are performed on the concave side of the penis and require the use of a graft. They aim to minimise penile shortening caused by Nesbit or plication of the tunica albuginea or correct complex deformities. Penile degloving with associated circumcision (as a means of preventing post-operative phimosis) is considered the standard approach for all types of procedures (104). However, recent data suggests that circumcision is not always necessary. In cases where the foreskin is normal pre-operatively, circumcision is unnecessary (105). Finally, in patients with Peyronie's disease and erectile dysfunction not responding to medical treatments, the surgical correction of the curvature with concomitant penile prosthesis implantation should be considered (106).

Choosing the most appropriate surgical intervention is based on penile length assessment, curvature severity and on the erectile function status, including response to pharmacotherapy in cases of erectile dysfunction (32). Patient expectations from surgery must also be included in the pre-operative assessment. There are no standardised questionnaires for the evaluation of surgical outcomes (102). Data from well-designed prospective studies are scarce, with a low level of evidence. Most data are mainly based on retrospective studies, typically non-comparative and non-randomised, or on expert opinion (32,107).

*4.4.1 **Penile shortening procedures***

In 1965, Nesbit was the first to describe the removal of tunical ellipses opposite a non-elastic corporal segment to treat congenital penile curvature (11). Fourteen years later, this technique became a successful treatment option, also for Peyronie's disease (108). This operation is based on a 5-10 mm transverse elliptical excision of the tunica albuginea or approximately 1 mm for each 10º of curvature (104). The overall short- and long-term results of the Nesbit operation are excellent. Complete penile straightening is achieved in more than 80% of patients (109). Recurrence of the curvature and penile hypoesthesia are uncommon (about 10%) and the risk of post-operative erectile dysfunction is minimal (104,110). Penile shortening is the most commonly reported outcome of the Nesbit procedure (110). However, shortening of only 1-1.5 cm has been reported for about 85% of patients, which is rarely the cause for post-operative sexual dysfunction (108,111). Patients often perceive the loss of length as greater than it actually is (109,110). It is therefore advisable to measure and document the penile length peri-operatively, both before and after the straightening procedure, whatever the technique used. Only one modification of the Nesbit procedure has been described (partial thickness shaving instead of conventional excision of a wedge of tunica albuginea) (112).

Plication procedures actually share the same principle as the Nesbit operation but are simpler to perform. Many of them have been described as Nesbit modifications in the older literature. They are based on single or multiple longitudinal incisions on the convex side of the penis closed in a horizontal way, applying the Heineke-Miculicz principle, or plication is performed without making an incision ((113-118). Another modification has been described as the '16 dot' technique with minimal tension under local anaesthesia (119). The use of non-absorbable sutures reduced recurrence of the curvature. Results and satisfaction rates are similar to the Nesbit procedure (104). However, a lot of different modifications have been described and the level of evidence is not sufficient to recommend one method over the other.

*4.4.2 **Penile lengthening procedures***

Tunical lengthening procedures entail an incision in the short (concave) side of the tunica to increase the length of this side, creating a tunical defect, which is covered by a graft. However, plaque removal may be associated with high rates of post-operative erectile dysfunction due to venous leak (120).

Devine and Horton introduced dermal grafting in 1974 (121). Since then, a variety of grafting materials and

techniques have been reported (Table 2) (122-136). Unfortunately, the ideal material for grafting has yet to be identified. In addition, grafting procedures are associated with erectile dysfunction rates as high as 25%. Despite excellent initial surgical results, graft contracture and long-term failures resulted in a 17% re-operation rate (137). Vein grafts have the theoretical advantage of endothelial-to-endothelial contact when grafted to underlying cavernosal tissue. Saphenous vein is the most common vein draft used, followed by dorsal penile vein (104). In the latter case, a secondary incision for graft harvesting is avoided. Post-operative curvature (20%), penile shortening (17%) and graft herniation (5%) have been reported after vein graft surgery (122-124). Tunica vaginalis is relatively avascular, easy to harvest and has little tendency to contract due to its low metabolic requirements (126). Dermal grafts are commonly associated with contracture resulting in recurrent penile curvature (35%), progressive shortening (40%), and a 17% re-operation rate at 10 years (138). Cadaveric pericardium (Tutoplast®) offers good results by coupling excellent tensile strength and multi-directional elasticity/expansion by 30% (129). In a retrospective telephone interview, 44% of patients with pericardium grafting reported recurrent curvature, although most of them continued to have successful intercourse and were pleased with their outcomes ((129,138). Small intestinal submucosa (SIS, a collagen-based xenogenic graft derived from the submucosal layer of the porcine small intestine) has been shown to promote tissue-specific regeneration, and supports the growth of endothelial cells. Small intestinal submucosa acts as a scaffold to promote angiogenesis, host cell migration and differentiation, resulting in tissue structurally and functionally similar to the original. It has been used successfully to repair severe chordee and Peyronie's disease, without significant contraction or histological alterations, but data are limited (133).

Tunical preferably incision with grafting offers an excellent surgical option for men with curvatures over 60º as well as patients with an hourglass deformity and good erectile function that are willing to risk a higher rate of post-operative erectile dysfunction (139). The presence of pre-operative erectile dysfunction, the use of larger grafts, age more than 60 years, and ventral curvature are considered poor prognostic factors for functional outcome after grafting surgery (106). Although the risk for penile shortening is significantly less compared to the Nesbit or plication procedures, it is still an issue and patients must be informed accordingly (104). The use of a penile extender device on an 8- to 12-hour daily regimen has been advocated as an effective and safe way to the loss of penile length in patients operated on for Peyronie's disease (140).

Table 2: Types of grafts used in Peyronie's disease surgery

Autologous grafts
Dermis
Vein grafts
Tunica albuginea
Tunica vaginalis
Temporalis fascia

*4.4.3 **Penile prosthesis***

Penile prosthesis implantation is typically reserved for the treatment of Peyronie's disease in patients with erectile dysfunction, especially when they are not responders to phosphodiesterase type 5 inhibitor (PDE5i)

(104). Although all types of penile prosthesis can be used, the implantation of inflatable penile prosthesis seems to be most effective in these patients (141).

Most patients with mild-to-moderate curvature can expect an excellent outcome simply by cylinder insertion. In cases of severe deformity, intra-operative 'modelling' of the penis over the inflated cylinders (manually bent on the opposite side of the curvature for 90 seconds, often accompanied by an audible crack) has been introduced as an effective treatment (142,143). If there is a residual curvature of less than 30°, no further treatment is recommended, as the prosthesis will act as a tissue expander and will result in complete correction of curvature in a few months (142). While this technique is effective in most patients, a Nesbit/plication procedure or plaque excision/incision and grafting may be required in order to achieve adequate straightening (144-146).

The risk of complications (infection, malformation, etc.) is not increased compared to the general population. However, a small risk of urethral perforation (3%) has been reported in patients with 'modelling' over the inflated prosthesis (143).

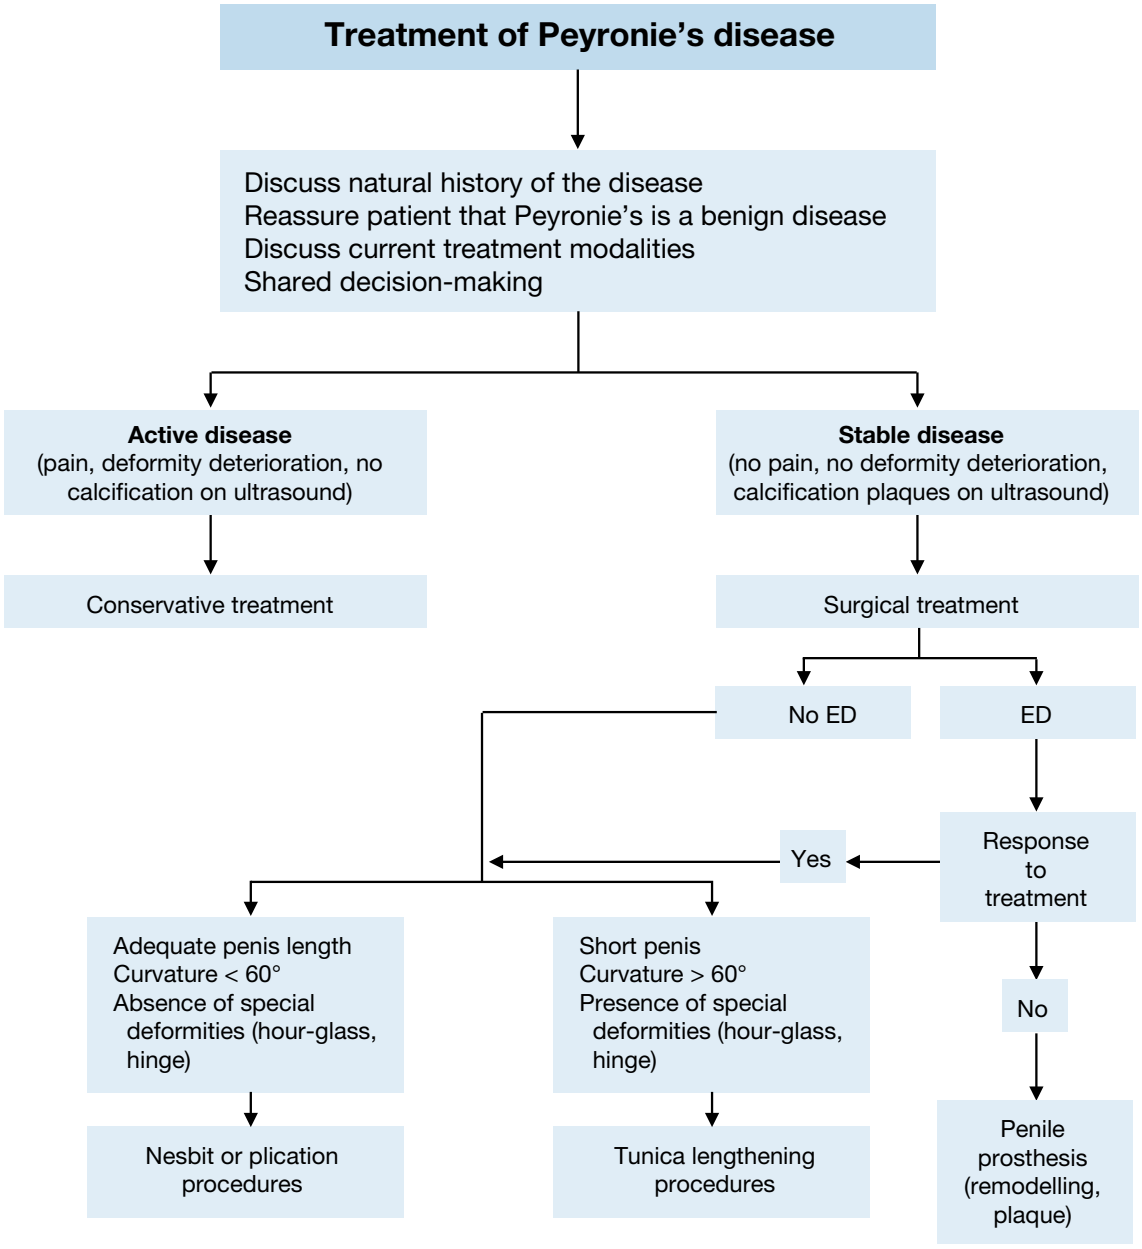
Table 3: Results of surgical treatments for Peyronie's disease (data from different, non-comparable studies) (108,110-136,138,139)

	Tunical shortening procedures		**Tunical lengthening procedures**
	Nesbit	**Plication**	**Grafts**
Penile shortening	4.7-30.8%	41-90%	0-40%
Penile straightening	79-100%	58-100%	74-100%
Persistent or recurrent curvature	4-26.9%	7.7-10.6%	0-16.7%
Post-operative erectile dysfunction	0-13%	0-22.9%	0-15%
Penile hypoesthesia	2-21%	0-21.4%	0-16.7%
Technical modifications	1	At least 3	Many types of grafts and techniques used

*4.4.4 **Treatment algorithm***

The decision on the most appropriate surgical procedure to correct penile curvature is based on pre-operative assessment of penile length, the degree of the curvature and erectile function status. If the degree of curvature is less than 60°, penile shortening is acceptable and the Nesbit or plication procedures are usually the method of choice. This is typically the case for congenital penile curvature. If the degree of curvature is over 60° or is a complex curvature, or if the penis is significantly shortened in patients with a good erectile function (with or without pharmacological treatment), then a grafting procedure is feasible. If there is erectile dysfunction, which is not responding to pharmacological treatment, the best option is the implantation of an inflatable penile prosthesis, with or without an associated procedure over the penis (modelling, plication or even grafting plus the prosthesis). The treatment algorithm is presented in Figure 1.

Figure 1: Treatment algorithm for Peyronie's disease



ED = erectile dysfunction.

The results of the different surgical approaches are presented in Table 3. It must be emphasised that there are no randomised controlled trials available addressing surgery in Peyronie's disease. The risk of erectile dysfunction seems to be greater for penile lengthening procedures (32,104). Recurrent curvature implies either failure to wait until the disease has stabilised, a reactivation of the condition following the development of stable disease, or the use of re-absorbable sutures that lose their strength before fibrosis has resulted in acceptable strength of the repair (104). Accordingly, it is recommended that only non-absorbable sutures or slowly reabsorbed absorbable sutures be used. Although with non-absorbable sutures, the knot should be buried to avoid troublesome irritation of the penile skin, this issue seems to be alleviated by the use of slowly re-absorbed absorbable sutures (110). Penile numbness is a potential risk of any surgical procedure involving mobilisation of the dorsal neurovascular bundle. This will usually be a neuropraxia, due to bruising of the dorsal sensory nerves. Given that the usual deformity is a dorsal deformity, the procedure most likely to induce this complication is a lengthening (grafting) procedure for a dorsal deformity (104).

Guidelines recommendations on surgical treatment for penile curvature	LE	GR
Surgery is indicated when Peyronie's disease is stable for at least 3 months (without pain or deformity deterioration), which is usually the case after 12 months from the onset of symptoms and intercourse is compromised due to deformity.	3	C
Penile length, curvature severity, erectile function (including response to pharmacotherapy in case of erectile dysfunction) and patient expectations must be assessed prior to surgery.	3	C
Tunical shortening procedures, especially plication techniques are the first treatment options for congenital penile curvature and for Peyronie's disease with adequate penile length, curvature < 60º and absence of special deformities (hour-glass, hinge).	2b	B
Grafting techniques are the preferred treatment option for patients with Peyronie's disease with no adequate penile length, curvature > 60º and presence of special deformities (hour-glass, hinge).	2b	B
Penile prosthesis implantation, with or without any additional procedure (modelling, plication or grafting), is recommended in Peyronie's disease patients with erectile dysfunction not responding to pharmacotherapy.	2b	B
